Introduction. Ventilator-associated brain injury (VABI) may contribute to delirium during mechanical ventilation, but the relationship between ventilatory settings and delirium risk has not been established (1, 2).
Objectives. To establish whether ventilator settings, including tidal volume, inspiratory pressure, respiratory rate, and mode of mechanical ventilation ("controlled" versus "assisted", defined by the presence or absence of patient-triggered breaths), are associated with the rate of delirium during mechanical ventilation.
Methods. We analyzed data from a prospective longitudinal cohort study, the Toronto Intensive Care Observational Registry, which included all patients receiving mechanical ventilation for at least 4 h across 9 intensive care units in the Greater Toronto Area between April 2014 and February 2023. As part of routine clinical practice in these ICUs, nurses use the Confusion Assessment Method-ICU or the Intensive Care Delirium Screening Checklist to assess patients for delirium. Patients with delirium at baseline (time 0) were excluded, and an administrative censoring time of 30 days was used. The association between daily ventilator settings and the development of delirium was evaluated using cause-specific Cox proportional hazards models adjusting for confounders including organ dysfunction and sedation depth. The landmarking approach was used to handle daily updated time-dependent covariates. Death and discharge were considered as competing events. Separate models were constructed for each primary exposure of tidal volume, inspiratory pressure, and respiratory rate, with an interaction term for ventilation mode (assisted versus controlled).
Results. A total of 1935 patients were available for analysis (20,847 patient-days of mechanical ventilation) (**Table**). Higher tidal volume during controlled ventilation was independently associated with a higher hazard of developing delirium (adjusted hazard ratio [aHR] 1.24 per 142 mL increase, 95% confidence interval CI, 1.10–1.41). This association was significantly attenuated during assisted ventilation (adjusted HR 1.08, 95% CI 1.01–1.16, p = 0.04 for interaction) (**Figure**). Conversely, even after including sedation level as covariate, higher respiratory rate during controlled ventilation was associated with a lower hazard of developing delirium (adjusted HR 0.78 per 7 breath per minute increase, 95% CI 0.69–0.89) and this was significantly attenuated during assisted ventilation (adjusted HR 0.99, 95% CI 0.92–1.06, p < 0.001 for interaction). Higher inspiratory pressure during controlled ventilation was associated with a higher hazard of death (aHR 1.22 per 7 cm H2O increase, 95% CI 1.07–1.40) and a lower hazard of delirium (aHR 0.84, 95% CI 0.75–0.94).TABLE.
Conclusions. Higher tidal volume and lower respiratory rate during controlled mechanical ventilation are associated with a higher hazard of developing delirium over time, possibly reflecting VABI. Maintaining respiratory muscle effort during mechanical ventilation may mitigate VABI and reduce the risk of delirium.

Adjusted associations between ventilator settings and the cause-specific hazards of of delirium, death, or discharge, according to whether the patient was undergoing controlled ventilation (no patient-triggered breaths) or assisted ventilation (patient-triggered breaths).

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000622***.

Introduction. In patients with critical illnesses, sleep and circadian rhythms are significantly disrupted, and these disturbances have been linked to deleterious outcomes, including increased mortality. Factors inherent to the intensive care unit (ICU) environment, such as exposure to suboptimal light and noise levels during daytime and nighttime hours, or inflexible schedules of daily care activities, have been identified as playing a pivotal role in sleep disturbances. The present study hypothesizes that a multicomponent intervention is a viable strategy for implementation in the ICU, with the potential to enhance sleep quality in critically ill patients.

Objectives. To evaluate the feasibility of implementing a multi-component intervention of the environment in an intensive care Unit (ICU) to promote sleep in critically ill patients and to determine the impact of the intervention on the quantity assessed by polysomnography and other semi-quantitative methods compared to standard care. In addition, we will compare the effect of both strategies on delirium and circadian rhythm biomarkers.

Methods. Prospective, two parallel groups, unblinded pilot randomized controlled trial. Adult patients with at least 48 h of invasive mechanical ventilation and no sedation or superficial sedation during the last 24 h were recruited between October 2022 and December 2024. Participants were randomized to receive a multi-component ICU environmental control intervention (dynamic light therapy, auditory masking, and rationalization of ICU nocturnal patient care activities) or to standard care. A responsible family member of each participant consented to participate in the study. The setting was an intensive care unit in a tertiary care teaching hospital in Santiago, Chile. The primary outcomes were the feasibility of enrolling and retaining participants and fidelity to the intervention, which was recorded daily until seven days of follow-up or until ICU discharge. Secondary outcomes were sleep quantity and quality, the prevalence of delirium at day three post-randomization, and neuropsychological impairment at six months post-ICU discharge.

Results. After screening, 17 patients were randomized (See Fig. 1), and sixteen participants were included in the final analysis. Table 1 shows the participants' main demographic and clinical characteristics by group. Concerning the primary outcomes, 17 patients were randomized to the intervention group (n = 9) and the control group (n = 8). Of the randomized patients, 78% (n = 7) and 100% (n = 8) were in the ICU until the night of day three of the study, respectively. One patient did not receive the intervention due to death during the first 3 days of the intervention. Regarding the intervention fidelity, the enrollment rate was 94%, with only one family member refusing the participation of their loved one in the study.

Our primary outcomes were time in slow wave sleep-N3 and time in Rapid eye movement-REM assessed by PSG. While no statistically significant differences were found between groups in total sleep time or REM/N3 sleep on day 3, the within-group analysis showed an increase in slow-wave sleep (N3) in the intervention group. Notably, the melatonin peak was higher among those receiving the intervention, supporting its role in circadian rhythm regulation. There were no significant differences between both groups regarding other interest outcomes, such as sleep quality assessed by the questioner, the oscillation of plasma concentrations of cortisol, and the incidence of delirium.

Conclusions. The study demonstrated the feasibility and acceptability of sleep-promoting interventions in high-acuity ICU settings, with high patient satisfaction and good protocol adherence. However, challenges in evaluating sleep using polysomnography and the limited sample size suggest the need for more scalable, cost-effective measurement tools in future studies.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000623***.

Introduction. Numerous biomarkers have been proposed for sepsis management due to their associations with inflammatory processes. While many studies have confirmed their associations with patient outcomes, few have explored their temporal dynamics or investigated how changes in these biomarkers over time relate to outcomes.
Objectives. This study employed a statistical framework known as joint modeling, which integrates the analysis of longitudinal biomarker trajectories with survival outcomes, aiming to investigate the associations between biomarker dynamics and sepsis outcomes.
Methods. We retrospectively reviewed patients diagnosed with sepsis between January 2019 and July 2024 at Zhongshan Hospital, affiliated with Fudan University in Shanghai, China. Biomarkers, including white blood cell count (WBC), neutrophils, lymphocytes, C-reactive protein (CRP), procalcitonin (PCT), interleukin-6 (IL-6), interleukin-8 (IL-8), interleukin-10 (IL-10), interleukin-2 receptor (IL-2R), interleukin-1β (IL-1β), and tumor necrosis factor (TNF), measured within the first 7 ICU days were included for analyses. Baseline characteristics were compared between survivors and non-survivors. To assess the associations between biomarker trajectories and survival, both proportional hazards models and joint modeling framework were applied. The analyses considered both the absolute values and the rates of change (slopes) of these biomarkers in relation to survival outcomes.
Results. The study included 664 sepsis patients (200 female; mean age 66.6 ± 14.7 years), with 227 in-hospital deaths. Abdomen and lung were the two main infections. Surgery was associated with lower in-hospital mortality (HR = 0.60, P = 0.010), while higher SOFA scores (HR = 1.09, P < 0.001) and AKI with shock (HR = 1.77, P = 0.015) were associated with increased mortality. No significant associations were found between the absolute values of biomarkers measured during the first 7 ICU days and in-hospital mortality. However, significant associations were observed between in-hospital mortality and the trajectories (slopes) of IL-6 (HR = 1.0023; 95% CI: 1.0006–1.0040; P = 0.007), IL-1β (HR = 0.9947; 95% CI: 0.9911–0.9994; P = 0.030), and IL-2R (HR = 1.0009; 95% CI: 1.0001–1.0017; P = 0.015). The trajectories of cytokines are presented in Fig. 1.
Conclusions. This study underscores the added prognostic value of cytokine dynamics in sepsis. While traditional biomarkers such as WBC, CRP, and PCT showed no significant association with in-hospital mortality when evaluated over time, the slopes of specific cytokines, e.g., IL-6, IL-1β, and IL-2R, were significantly associated with patient

outcomes. These results suggest that dynamic changes in cytokines provide superior prognostic insight compared to conventional markers and may serve as more reliable indicators for risk stratification and clinical management in sepsis.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000624***.

Introduction. Diaphragm dysfunction and dyspnea are common in patients undergoing invasive or non-invasive ventilatory support. This study aimed to evaluate whether diaphragm dysfunction and dyspnea, assessed 1) within the 24 h following the weaning from ventilatory support and 2) at the time of intensive care unit (ICU) discharge, are associated with adverse outcomes during a 90-day follow-up after inclusion.
Methods. This is a prospective, observational study currently conducted in a medical ICU. Eligible patients were [md1] adults weaned from ventilatory support (invasive mechanical ventilation or non-invasive ventilation/high-flow nasal cannula therapy during ≥ 48 h). Diaphragm dysfunction was[md2] assessed by ultrasound (diaphragm thickening fraction < 20% and/or diaphragm excursion < 1 cm [md3]), and dyspnea was assessed using a visual analog scale (VAS), within the 24 h after weaning from ventilatory support and at ICU discharge. The primary outcome was a composite endpoint including mortality, readmission (hospital or ICU) or need for ventilatory support or respiratory complications (pneumonia and/or atelectasis) during a 90-day follow-up after inclusion.
Results. Herein, we report preliminary findings from the first patients enrolled in the study. As of today, 23 patients with complete follow-up have been included after a median (interquartile range [IQR 25–75]) duration of 6 [4–8] days of ventilatory support. Within the 24 h following the weaning from ventilatory support, diaphragm dysfunction was present in 43% of the patients and dyspnea (VAS > 3) in 35%. At ICU discharge, these proportions were 40% and 15%, respectively. Thirteen patients met the composite outcome during a 90-day follow-up after inclusion. After weaning from ventilatory support, dyspnea-VAS was significantly higher in patients who met the composite outcome whereas the diaphragm excursion was not (Fig. 1C).
Multivariate logistic regression found that dyspnea VAS within the 24 h following weaning from ventilatory support was associated with the composite endpoint (OR 1.1–2.8, 95% CI 0.07–1), independently of the presence of diaphragm dysfunction. Conversely, diaphragm dysfunction at weaning showed no independent association after adjusting for dyspnea.
Conclusions. These preliminary results suggest that dyspnea at the time of weaning from ventilatory support is associated with adverse outcomes. Diaphragm dysfunction, at weaning or at ICU discharge, was not associated with outcomes. A larger sample of patients is needed to confirm these preliminary results.

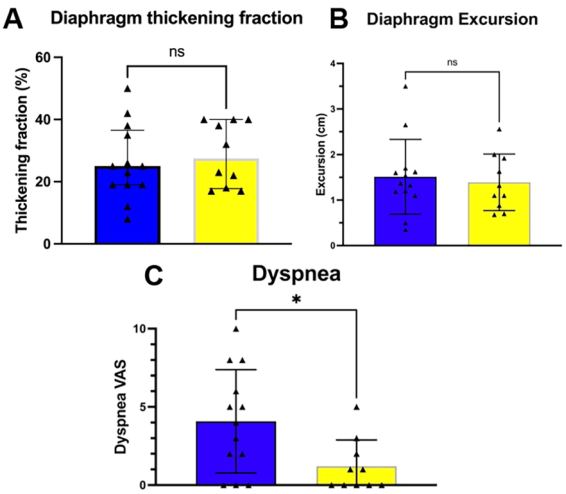

Fig 1 (abstract 000624) Diaphragm thickening fraction (A), diaphragm excursion (B) and dyspnea visual analogical scale (C) within the 24 h following the weaning between patients who met (blue bars) and who did no met (yellow bars) the primary endpoint (mortality, readmission, need for ventilatory support or respiratory complication) at day 90

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000625***.

Introduction. The amount of time spent on invasive mechanical ventilation is a major prognostic factor, and it is essential to initiate the weaning process as early as possible.
Objectives. The objective of our study was to identify the factors associated with the absence of a separation attempt in patients who met predefined weaning eligibility criteria.
Methods. The international observational study WEAN SAFE (WorldwidE AssessmeNt of Separation of pAtients From ventilator assistancE) assessed the weaning process in a large "real life" cohort of patients who received invasive mechanical ventilation for at least two calendar days [1]. The weaning eligibility criteria for a separation attempt (WEC) were as follows: FiO_2 < 50%, PEEP < 10 cmH_2O, and no use of neuromuscular blocking agents or high-dose vasopressors. A separation attempt was defined (1) in intubated patients as a spontaneous breathing trial (SBT) or a direct extubation without SBT and (2) in tracheostomized patients as a low respiratory support trial or a T-tube trial.
Each day that WEC were met but no separation attempt was performed, clinicians were asked to report the reason(s) why on a dedicated daily form and to specify whether they considered the patient to be in the weaning phase.
To better understand the barriers to weaning in patients undergoing intermediate or prolonged weaning [1] who met eligibility criteria for a separation attempt, we analyzed the prevalence of reported reasons for not performing a separation attempt and its evolution over time.
Results. Among the 1800 patients included (60% male; age 66.5 ± 16 years; 70% admitted for medical reasons), a median of 5 [2–11] daily reports per patient were available. Days patients met WEC but did not have a separation attempt accounted for 56% of the total duration of ventilation. The weaning failure rate at day 90 was 55% (n = 990), and ICU mortality was 48% (n = 870).
Seven main reasons were reported (Figure), with multiple reasons cited for 40% of the reporting days. Their evolution over the course of ventilation is shown in the Figure.
On the first day patients fulfilled WEC (regardless of ventilation duration) and no performed separation attempt, the main reasons cited were altered consciousness (35%, n = 887), unresolved respiratory failure (20%, n = 506), and muscle weakness (12%, n = 319).
On the last day without a separation attempt, altered consciousness remained the most frequent reason (29%, n = 700), but the proportion of muscle weakness increased (19%, n = 440). For 18% (n = 417) of patients, no reason was documented on the last day they met WEC and did not have a separation attempt.
Patients were considered to be in the weaning phase by clinicians in only 42% of daily occurrences on which WEC were present.
Conclusions. Altered consciousness and unresolved respiratory failure are the main reasons for not performing a separation attempt on the first day when weaning eligibility criteria are met. Later on, muscle weakness becomes the primary reported reason. Potential eligibility for weaning may be largely underestimated.

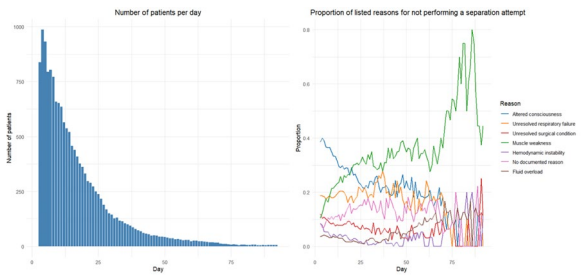

Fig 1 (abstract 000625) Evolution over time of the proportion of reasons for not performing a separation attempt in patients with CESA from initiation of invasive mechanical ventilation.
Day 0 is the day on which invasive mechanical ventilation was started.

A review of adult critical care calls to the out-of-hours resident pharmacist service: a retrospective single centre observation study

J. Wang[1]; J. Waghorn[1]; S. Khoo[2]; H. Patel[2]; C. Remmington.[2]
[1]Institute of Pharmaceutical Science, School of Cancer & Pharmaceutical Sciences, King's College London, London, United Kingdom; [2]Pharmacy and Critical Care, Guy's and St Thomas' NHS Foundation Trust, London, United Kingdom.
Correspondence: S. Khoo.
Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000628***.

Introduction. Pharmacy departments provide out-of-hours (OOHs) services to ensure timely access to critical medicines and advice internationally [1–3]. OOHs services are particularly important for adult critical care areas given the acuity and complexity of this patient cohort [4]. CC patients are complex due to pharmacokinetic-pharmacodynamic changes in critical illness, the need for dynamic dose optimisations in organ dysfunction and extracorporeal support (renal replacement therapy and extracorporeal membrane oxygenation), and frequent route of administration changes to medicines [5].There is good evidence describing general on-call pharmacy services internationally, however limited evidence exists reporting the characteristics of out-of-hours calls from adult critical care units.
Objectives. To evaluate the characteristics of out-of-hours calls from adult critical care units to the on-call Resident Pharmacists, to inform service provision to this high-risk speciality.
Methods. Retrospective review of all adult critical care out-of-hours calls received by Resident Pharmacists from August 2023 to July 2024 at a large tertiary centre. Data collected included ward location, query type, name and category of drug, route of administration, day of the week, date and time of call received and time to resolution of call.
Results. We identified 5085 out-of-hours calls from adult critical care area, representing 15.3% of all calls received by the Resident Pharmacist. Most calls related to male patients 2364 (46.5%), with a mean ± SD of 56.6 ± 17.5 years. The greatest proportion of calls was received on a Thursday 806 (15.9%), and January 2024 was the busiest month 528 (17.6%). Most calls were for medication supply 4885 (96.1%), and fewer calls for medicine advice 200 (3.9%). We report 5915 medication requests, with total parenteral nutrition the most requested medicine 255 (4.3%), followed by anidulafungin 175 (3.0%). Anti-infectives was the most requested category of medicine 921 (18.1%).
Conclusions. Calls from adult critical care units represented a large proportion of calls received by the Resident Pharmacist out-of-hours. The provision of out-of-hours pharmacy services to adult critical care is essential in supplying time critical medications and medications advice to optimise patient care. Further work should explore impact of calls on avoidable patient harm, effect of CC pharmacist support and the number medications requests that were not actioned due to inappropriateness of request.

Introduction. Sepsis is one of the most common causes of hospital admission and a leading cause of in-hospital mortality. Source control of the infection is considered essential in the management of these patients, but the optimal timing remains unclear.
Objectives. To evaluate the impact of source control performed at different time points (early: 6 and 12 h; late: 18 and 24 h) on hemodynamics, bacterial load, systemic and pulmonary inflammatory response, and mortality using a rat model of sepsis induced by cecal ligation and puncture (CLP).
Methods. An abdominal sepsis model was performed in all animals using CLP, followed by surgical source control at different times: 6 h, 12 h, 18 h, and 24 h (n = 15 rats per group). A sham control group and a CLP group without source control were also included. All rats received fluid resuscitation and broad-spectrum antibiotics starting at 0 h after CLP and every 12 h until killing at 72 h. We analyzed weight loss, mean arterial pressure (MAP), plasma lactate, bacterial load (CFU/µL), cultures, and inflammatory cytokines in plasma and bronchoalveolar lavage (BAL), as well as lung histology at 72 h. Survival rate was assessed at 72 h in all groups.
Results. Animals that underwent early source control showed significantly less weight loss (– 23 g vs – 43 g; p = 0.012) compared to late source control. MAP (69.33 mmHg vs 51.00 mmHg; p = 0.03) and lactate levels (2.15 mmol/L vs 2.82 mmol/L; p = 0.03) improved significantly in the early source control group. Cultures (blood, peritoneal) showed growth of gram-negative bacteria (Escherichia coli, Proteus mirabilis, Bacteroides fragilis). Bacterial load, total protein count, and pro-inflammatory markers (TNF-α and IL-6) in plasma were significantly reduced in the early control group. Additionally, early source control significantly reduced pulmonary inflammation (TNF-α, IL-1β, IFN-γ, and others) and especially pulmonary bacterial load compared to the late group. The early source control group showed a non-significant trend toward higher survival compared to the late control group (70% vs 53%).
Conclusions. Delayed source control in an animal model of abdominal sepsis is associated with increased bacterial load, poorer hemodynamic recovery, and greater systemic and pulmonary inflammation. Moreover, earlier source control shows a trend toward higher survival.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000633***.

Introduction. Fluid overload (FO) is associated with increased morbidity and mortality in critically ill paediatric patients. The Renal Angina Index (RAI) has emerged as a validated tool for predicting acute kidney injury (AKI), a condition associated with significant morbidity and mortality.
Objectives. This study investigates the relationship between FO, renal dysfunction, and mortality in the paediatric intensive care unit (PICU), focusing on fluid input versus output contributions. Additionally, we assess the role of early FO, fluid creep, and the Renal Angina Index (RAI) in predicting adverse outcomes.
Methods. This retrospective cohort study included critically ill children (1 month–18 years) admitted to an academic PICU for ≥ 96 h between 2020 and 2024. Patients with chronic kidney disease or congenital heart disease were excluded. Fluid balance, renal function (RAI, creatinine clearance), and illness severity scores were analyzed. FO was defined as cumulative fluid balance > 5% or > 10% of body weight. The primary outcome was PICU mortality; secondary outcomes included AKI incidence, mechanical ventilation duration, and PICU length of stay.

Results. Among 217 patients, total fluid balance was more than twice as high in non-survivors (2125 ± 2157 ml vs. 791 ± 629 ml, p = 0.001), along with significantly greater total FO% (10.8 ± 9.8% vs. 5.6 ± 8.8%, p = 0.014) and a higher proportion of patients with FO > 5% or > 10%. Fluid creep on day 1 correlated with RAI (r = 0.29, p < 0.001) and was an independent mortality predictor (OR 1.01, 95% CI 1.0–1.02, p = 0.02). Reduced fluid output contributed more significantly to FO than increased intake. ROC analysis indicated that cumulative fluid balance (AUC 0.72, 95% CI 0.59–0.85, p = 0.001), cumulative FO% (AUC 0.68, 95% CI 0.55–0.80, p = 0.006), and RAI (AUC 0.69, 95% CI 0.58–0.80, p = 0.001) demonstrated similar predictive accuracy for mortality.
Conclusions. FO, particularly fluid creep and reduced output, is a key determinant of mortality in critically ill children. RAI may aid in early risk stratification, guiding fluid management strategies to improve outcomes.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000634***.

Introduction. Upper extremity deep-vein thrombosis (DVT) is often under-recognized and perceived as having less clinical significance than lower extremity DVT. Our objective was to evaluate the risk factors and outcomes of critically ill patients with upper extremity vein thrombosis**.**
Methods. We evaluated patients in the intensive care unit of King Abdulaziz Medical City, a tertiary-care hospital with > 1000 beds in Riyadh, Saudi Arabia, who had Doppler ultrasound for suspected upper extremity vein thrombosis between January 2022 and December 2023. We compared patients who had upper extremity DVT to those who did not and examined their outcomes including the incidence of pulmonary embolism and hospital mortality.
Results. Among the 421 patients included in this study, Doppler ultrasound was performed a median of 13 days after hospital admission, targeting the right upper extremity in 48.7% of patients, the left in 37.3% and bilaterally in 14.0%. A total of 216 patients (51.3%) had either upper extremity DVT and/or superficial vein thrombosis (SVT). DVT was found in 128 patients (30.4%) and occurred on the right in 63.3%, left in 32.8% and bilaterally in 3.9%. The most affected veins were the internal jugular (53.9%), brachial (29.7%) and subclavian (26.6%). Patients with and without DVT had similar baseline comorbidities except for cancer, which was more common in patients with DVT (24.2% versus 16.4%, p = 0.06). On multivariable logistic regression analysis, the predictors of DVT were the presence of central venous catheters in the internal jugular or subclavian vein (odds ratio 2.14, 95% confidence interval 1.33–3.43) and peripherally inserted central lines (odds ratio 1.74, 95% confidence interval 1.08–2.80). SVT was diagnosed in 147 patients (40.1% had concomitant upper extremity DVT). The affected veins were the cephalic (61.2%) and basilic (45.6%). Pulmonary embolism occurred in 53 patients (12.6%) with a similar incidence in patients with or without upper extremity DVT (14.1% and 11.9%, respectively, p = 0.55%) and in patients with and without SVT (12.2% and 12.8%, respectively, p = 0.88). Patients with DVT had higher hospital mortality (46.9% versus 30.7% for patients without DVT; p = 0.001), while SVT was not associated with increased mortality (37.4% versus 34.7% for patients without SVT; p = 0.58).
Conclusions. Almost one in two patients who had upper extremity ultrasound for suspected vein thrombosis had either DVT or SVT. The presence of a central venous catheter was a predictor of DVT. Patients with SVT or DVT had similar rates of pulmonary embolism compared to other patients. Upper extremity DVT, but not SVT, was associated with higher hospital mortality.

Introduction. Early autonomic dysfunction (eAD) is a recognized critical but understudied component of secondary injury in severe traumatic brain injury (TBI). Using high-resolution physiologic waveform data obtained from multi-modal monitoring in the BOOST-3 trial, we analyzed measures of autonomic nervous system function over the first five days post-injury.
Methods. We performed a retrospective analysis of cardiac waveform data collected via Moberg analytics from 42 patients enrolled in BOOST-3 with available data. BOOST-3 is a randomized clinical trial to determine the comparative effectiveness of two strategies for monitoring and treating patients with TBI in the intensive care unit setting. eAD metrics were derived from continuous arterial blood pressure (ABP) and electrocardiogram (ECG) waveforms. The primary analysis focused on changes in key AD indices, including time-domain (root mean square of successive differences [RMSSD], standard deviation of NN intervals [SDNN], percentage of successive normal-to-normal intervals differing by more than 50 ms [pNN50] and baroreflex sensitivity), frequency-domain metrics (low to high-frequency ratio [LF/HF]), and signal entropy over the first 5 days following injury. We analyzed beat-to-beat measurements averaged over one hour epochs.
Results. Preliminary analysis of the first 42 patients revealed significant variation in eAD parameters within the first 24 h (Fig. 1). Specifically, RMSSD decreased from a median of 26 ms on day 1 to 21 ms by day 5. Similarly, SDNN decreased from 31 ms on day 1 to 27 ms by day 5. The LF/HF ratio decreased from 1.3 on day 1 to 1.1 by day 5. Baroreflex sensitivity (BRS) showed a rise and fall, with median values peaking to 8.7 ms/mmHg and decreasing to 5.2 ms/mmHg by day 5.
Conclusions. eAD is prevalent in severe TBI and evolves over time, with significant changes in key metrics such as RMSSD, SDNN, pNN50, LF/HF, and BRS, indicating reduced parasympathetic and increased sympathetic activity. This study leverages high-resolution physiologic monitoring to characterize these changes, providing insights into potential prognostic and therapeutic implications. Further analysis of the full dataset will refine our understanding of eAD in severe TBI.

Metrics	Day 1	Day 2	Day 3	Day 4	Day 5
LF to HF ratio	1.28	1.18	1.15	1.04	1.07
pNN50	1.50	2.53	1.68	2.08	1.22
RMSSD	26.16	26.00	23.53	23.83	21.16
SDNN	31.38	33.26	29.26	30.86	26.96
HR	77.17	73.65	74.77	73.76	79.37
ICP	12.84	13.55	13.02	11.82	11.61
MAP	86.14	87.79	85.62	88.79	88.58
Sample entropy	1.40	1.44	1.41	1.41	1.42
BRS	5.13	8.72	7.44	6.88	5.23

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000638***.

Introduction. Cancer patients increasingly require intensive care due to complications related to malignancy or its treatment. Yet, their representation in randomized controlled trials (RCTs) that shape critical care guidelines remains unclear. This systematic review aimed to evaluate how oncology patients are included, excluded, and analyzed in critical care setting RCTs focused on mortality outcomes.
Objectives. To assess the inclusion or exclusion of oncology patients in intensive care units (ICU) RCTs and analyze the mortality outcomes specifically within this subgroup.
Methods. We performed a systematic search of PubMed, Embase, and the Cochrane Library for multicenter RCTs published between January 2010 and January 2025. Eligible studies enrolled adult ICU patients and reported mortality as a primary or co-primary endpoint. We excluded trials focused exclusively on trauma, cardiac surgery, or COVID-19. We used Pubmed's core clinical journals filter as inclusion criteria. Two independent reviewers extracted data on oncologic exclusion criteria, the proportion of cancer patients enrolled, and whether subgroup analyses involving malignancy were conducted.
Results. A total of 63 RCTs met inclusion criteria encompassing 110,908 patients. Among these, 34 trials (54%) did not specify the inclusion or exclusion of oncology patients, and 11 trials (17.4%) explicitly excluded them. Only 18 articles (28.5%) allowed the inclusion of patients with cancer. Among these, 17 articles reported the number of cancer patients enrolled, with proportions ranging from 0.5% to 33%, with most of them (n = 13) reporting a prevalence less than 20%. None of the trials performed dedicated subgroup analyses assessing mortality outcomes specifically in oncology patients. No RCT was designed specifically to assess outcomes in critically ill oncology populations.
Conclusions. Critically ill cancer patients are substantially underrepresented in large ICU RCTs, with the majority of trials either excluding them or failing to report their inclusion status. Even when included, subgroup analyses are infrequent and often inadequately powered to inform oncologic subpopulations. This limits the generalizability of ICU trial data to cancer patients and undermines evidence-based decision-making in this growing and high-risk population. Future studies should prioritize transparent reporting, inclusive eligibility criteria, and oncologic stratification to improve the applicability of critical care research to patients with cancer.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000639***.

Introduction. Sepsis is a heterogeneous syndrome that can present with a wide variety of signs and symptoms.
Objectives. To describe the diversity of variables that trigger an artificial intelligence (AI) tool for early sepsis detection, depending on the hospital department responsible for the patients.
Methods. We developed an AI tool for early sepsis detection by retrospectively analyzing a database that included both patients identified as having sepsis by the sepsis team and others without sepsis. The database comprised all patients over 14 years old admitted to our hospital between 2014 and 2018. We then studied structured variables that triggered the alert in departments with at least 90 septic patients.
Results. Records from 203,755 patients were used to develop the final model. An ensemble approach combining machine learning models and a Sepsis-2-based model was selected for its superior performance (ROC AUC = 0.95). A total of 61 structured variables were found to be significant. Departments included in the analysis were Emergency (ED), Intensive Care Unit (ICU), Surgery (SUR), Gastroenterology (GE), Internal Medicine (IM), Infectious Diseases (ID), Pulmonology (PN), Oncology (ONC), and Urology (URO). The number of significant variables per department is shown in Table 1.

Table 1. (abstract 000639) Number of significant variables per department

Department	Number of significant variables	%
ED	58/61	95,08%
SUR	56/61	91,80%
URO	53/61	88,33%
ONC	52/61	85,24%
PN	49/61	80,32%
IM	40/61	65,57%
ID	26/61	42,62%
GE	25/61	40,98%
ICU	23/61	37,70%

The significant variables for sepsis detection varied across departments. Table 2 presents the most relevant variables. Interestingly, some variables included in the SOFA score were not significant in the overall model.

Table 2.(abstract 000639) Significant (1) and non-significant (0) variables across departments. MAP: mean arterial pressure, CRP: C-reactive-protein, PT: prothrombin time.

Variable	SUR	GE	IM	ID	PN	ONC	ED	URO	ICU	Overall
Age	1	0	0	0	0	0	1	0	0	1
Heart rate	1	1	1	0	0	0	1	1	0	1
Resp rate	1	0	0	1	1	0	1	0	0	1
FiO2	1	1	1	1	1	1	0	1	1	1
SpO2	1	1	0	0	0	0	1	0	0	1
MAP	0	0	1	1	1	1	1	0	0	0
Temp	1	1	1	1	1	1	1	1	1	1
Lactate	1	1	1	1	1	1	1	1	1	1
Procalcitonin	1	0	1	1	1	1	1	0	1	1
CRP	1	0	1	0	0	1	1	1	0	1
Creatinine	1	0	0	0	0	1	1	1	1	1
Bilirubin	1	0	0	0	0	1	1	1	1	1
Leukocyte	1	1	1	0	0	0	1	1	0	1
Platelets	1	0	0	0	1	1	1	1	1	0
PT	1	0	1	0	1	1	1	1	1	1

Conclusions. An AI-based tool was able to detect different patterns in structured variables for patients with sepsis across various departments. Some variables included in current sepsis criteria were not relevant in our model, while others not typically considered proved useful.

Topic: Sepsis

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000641***.

Introduction. Pelvic fractures represent a potentially life-threatening source of hemorrhage in trauma patients. Due to the complex anatomy and the risk of massive bleeding, rapid and coordinated intervention is essential. Current management relies on multimodal strategies aimed at achieving hemodynamic stability and controlling the source of bleeding. Among the most widely used therapies are preperitoneal packing, selective arterial embolization, and external fixation. The choice and sequence of these interventions depend on the patient's clinical status and the resources available. This clinical challenge provides an opportunity to evaluate and compare which of these strategies offers the best outcomes for hemorrhage control and patient survival in our center.
Objectives. To evaluate the effectiveness and safety of preperitoneal packing (PPP), arterial embolization (AE), their combination, and external fixation in polytrauma patients with pelvic fractures and active bleeding treated at Parc Taulí University Hospital (2006–2024).
Methods. A retrospective study of 87 patients classified into four groups according to the intervention received: PPP (Group 1), AE (Group 2), combination of PPP and AE (Group 3), and external fixation (Group 4). Clinical, demographic, and intervention-related data were collected, including mortality, complications, and effectiveness. Statistical tests were used to identify significant differences between groups.
Results. The mean age was 48.3 years, with a male predominance (72.4%). The most common traumas were traffic accidents (34.5%) and falls (33.3%). AE was performed in 78.2% of patients, with an effectiveness of 85.3%. PPP was used in 32.2% (Groups 1 and 3). In Group 3, 60.7% of those treated with PPP required AE due to persistent bleeding. External fixation was used in 9.2% (Group 4).Overall mortality was 32.2%, highest in Group 1 (45.5%), followed by Group 3 (41.2%) and Group 2 (31.4%), with no deaths in Group 4. Although mortality was higher in Group 1 compared to Group 3, the difference was not statistically significant (p = 0.273).Group 3 showed worse indicators:

higher ISS (48.8 ± 13.8; p = 0.016), ABC score (3.0 vs. 2.0 in Group 1, 1.0 in Groups 2 and 4; p < 0.001), shock index (1.5 vs. 1.3 in Group 1, 1.1 in Group 2, and 1.0 in Group 4; p < 0.001), and more pre-intervention transfusions (4.6 vs. 2.0 in Group 1; p = 0.013). Acute mortality (< 48 h) was higher in Groups 1 and 3 (29.4% and 27.3%, respectively; p = 0.317), mainly caused by hemorrhagic shock, affecting 13.8%. Late mortality (4.6%) was linked to multiorgan failure due to sepsis, predominantly in Group 1 (18.2%) and Group 3 (11.8%). Packing removal time was longer in Group 1 (52.5 h) compared to Group 3 (48.0 h; p < 0.001).

Conclusions. In our study, arterial embolization (AE) was effective (85.3%) in controlling hemorrhage. However, 60.7% of patients initially treated with preperitoneal packing (PPP) required AE, suggesting that combined strategies may be useful in more severe cases. Higher mortality in Groups 1 and 3 may reflect greater injury severity. Acute deaths were mainly due to hemorrhagic shock, while late mortality was associated with multiorgan failure.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000643***.

Introduction. The role of albumin administration in patients with acute brain injury (ABI) remains controversial. While previous studies have focused on mortality, data on neurological outcome and adverse events are limited. We therefore aimed to explore the association of albumin exposure and neurological outcome in ABI patients.

Methods. We conducted a post hoc analysis of the TRAIN study, a randomized controlled trial evaluating two different transfusion strategies in ABI patients. Patients were analyzed according to whether they received albumin during their ICU stay. The primary outcome was unfavorable neurological status at 180 days (e.g. Glasgow Outcome Scale Extended ≤ 4). Secondary outcomes included mortality, ICU and hospital length of stay and serious adverse events. Multivariable logistic regressions were performed to identify predictors of different outcomes.

Results. A total of 820 patients were included (albumin group: n = 109; non-albumin group: n = 711).

Baseline characteristics were overall balanced, although the albumin group was older and had a higher prevalence of diabetes, cancer and subarachnoid hemorrhage, as initial reason of admission. No significant difference was found in the occurrence of the primary outcome (72.0% vs. 67.1%; relative risk 1.07, 95% CI 0.94–1.22, p = 0.32) between groups and albumin administration was not an independent predictor of unfavorable neurological outcome in the multivariate analysis (OR 1.08, 95% CI 0.77–1.51, p = 0.65). Similarly, the cumulative dose of albumin was not independently associated with neurological outcome (OR 0.998, 95% CI 0.9992 – 1.0004, p = 0.43). Notably, albumin use was associated with a significant reduction in cerebral ischemia (5.5% vs. 12.1%, RR 0.46, p = 0.04), although this association was no more significant in the multivariate analysis (OR 0.52, 95% CI 0.26–1.06, p = 0.07). Conversely, albumin administration was associated with an increased risk of acute respiratory distress syndrome and sepsis (adjusted OR 2.00, 95% CI 1.16–3.43, p = 0.012 and OR 1.65, 95% CI 1.07–2.53, p = 0.022, respectively).

Conclusions. In this post hoc analysis of a prospective trial, albumin administration was not associated with unfavorable neurological outcome or mortality in a heterogeneous population of ABI patients. While albumin exposure was associated with a reduction in the occurrence of cerebral ischemia, a higher incidence of ARDS and sepsis was observed in patients receiving albumin.

Introduction. Unplanned interruption of continuous renal replacement therapy (CRRT) is common in critically ill patients with acute kidney injury and may lead to undertreatment and blood loss. Studies on systemic heparinization to prolong CRRT filter lifespan have shown mixed results. We evaluated whether using an intravenous heparin infusion protocol during CRRT increased filter lifespan in patients in a medical intensive care unit (ICU).

Methods. This clinical audit was a part of a quality improvement project to improve CRRT in the medical ICU of the Intensive Care Department of King Abdulaziz Medical City, a large tertiary care hospital in Riyadh, Saudi Arabia. In 2017, the department implemented a quality improvement project to prolong CRRT filter lifespan that included optimization of CRRT prescription, and an intravenous heparin infusion protocol based on bleeding risk assessment. The protocol targeted low therapeutic partial thromboplastin times for patients receiving CRRT and having a low bleeding risk. In this audit, we evaluated patients in the ICU who needed CRRT between February 2023 and March 2024. We prospectively collected data on the start and end times of CRRT filters, reason for CRRT termination, and heparin protocol use. The primary outcome in this study was CRRT filter lifespan.

Results. During the study period, 86 patients had CRRT requiring 314 filters (range: 1 to 15; 310 filters had data on lifespan). The median filter lifespan was 20 h (interquartile range: 10–41; mean: 27 ± 22 h). The most common reasons for CRRT termination included filter clotting (n = 78, 25.2%), high transmembrane pressure (n = 77, 24.8%), procedures outside the ICU (n = 33, 10.6%), and completion of the entire 72-h use period (n = 32, 10.3%). Intravenous heparin infusion protocol was used in 76 of 310 filters (24.5%). The median filter lifespan was 23 h (interquartile range: 10–57; mean: 33 ± 25 h) with the heparin protocol versus 19 h (interquartile range: 9–36; mean: 25 ± 21 h) without the protocol (P = 0.01). Excluding CRRT sessions terminated for performing procedures, the median filter lifespan was 23 h (interquartile range: 10–63, mean: 34 ± 26 h) with heparin versus 19 h (interquartile range: 9–36; mean: 25 ± 21 h) without (P = 0.01). Filter clotting was reported in 22 of 76 filters (28.9%) with the heparin protocol and 56 of 234 filters (23.9%) without the heparin protocol (P = 0.38). High transmembrane pressures were reported in 12 of 76 filters (15.8%) with heparin and 65 of 234 filters (27.8%) without (P = 0.04).

Conclusions. Intravenous heparin infusion targeting low therapeutic partial thromboplastin times was used in only a quarter of ICU patients who needed CRRT and was associated with approximately 30% increase in filter lifespan.

Introduction. Vasodilatory shock is frequently associated with dysregulation of the renin–angiotensin system (RAS) classical pathway, marked by reduced angiotensin II (Ang II) and elevated plasma renin concentrations (PRC) [1]. In a secondary analysis of a randomized trial [2], higher PRC were associated with a greater response to exogenous Ang II [3]. However, emerging evidence indicates that elevated PRC independently predicts adverse clinical outcomes in the broader critically ill population [4].
Objectives. To evaluate PRC kinetics in refractory shock patients and its potential correlation with hemodynamic response to a second-line vasopressor therapy.
Methods. Adult (> 18 years) patients admitted to the ICU between 05/2024 and 04/2025 with refractory shock and included in an ongoing prospective registry were eligible for a second-line treatment with vasopressin (AVP) or Ang II, according to the treating physician. We analyzed collected blood samples to evaluate PRC before the start of the second vasopressor infusion and at 24 h post-administration (T0 and T24). We considered 172.7 pg/mL as the upper threshold of PRC, as indicated in the literature for patients with refractory shock [3]. Also, patients were considered "responders" if any relative decrease in PRC was observed from baseline value.
Results. At T0, plasma renin samples were available from 34 patients, of whom 26 had high and 8 normal levels. Main characteristics were comparable between the two groups. However, the high-renin group showed significantly higher median norepinephrine (NE) doses (1.05 [IQR 0.79–1.75] vs. 0.77 [0.71–0.83] mcg/Kg*min, p = 0.02) and vasoactive-inotropic scores (VIS) (111 [80.5–179] vs. 79.5 [70.8–84.3], p = 0.02) at T0. Of 27 patients with PRC samples at T0 and T24, 11 (40.7%) were classified as responders (median relative decrease -61.2 [from -76.4 to -18.0] %). Comorbidities were similar between responders and non-responders, except for a lower prevalence of hypertension (36.4% vs. 87.5%, p = 0.01), and less angiotensin-converting enzyme inhibitors exposure in responders (9.1% vs. 50%, p = 0.04). Responders had significantly lower median PRC at T0 (200.0 [96.8–879.0] vs. 1513.0 [420.0–4642.0] pg/mL, p = 0.04), despite similar severity scores. Responders had higher mean arterial pressure at T0, required lower NE over time and had reduced VIS at T24, despite similar fluid balance. No significant differences in the responders rate was observed between the two drugs.
Conclusions. In our mixed cohort of refractory shock patients, higher baseline PRC were associated with increased NE requirements and higher VIS. A 24-h decline in PRC was associated with improved hemodynamic profile, regardless of the fluid administration.

Introduction. Given that platelets support the integrity of the alveolar-capillary membrane (1), it is conceivable that thrombocytopenia may be associated with development of acute respiratory distress syndrome (ARDS). Yet, clinical studies confirming such an association are limited.

Objectives. We endeavoured to examine whether thrombocytopenia is independently associated with development of ARDS in critically ill patients.
Methods. First, we performed a systematic review and meta-analysis of observational studies reporting the number of patients at risk for ARDS with, versus without thrombocytopenia who eventually developed ARDS. Next, we performed a secondary analysis using individual patient-level data from three large randomized controlled trials conducted in North America by the Prevention and Early Treatment of Acute Lung Injury (PETAL) Network [namely, VIOLET, CLOVERS and ASTER](2–4) to estimate whether thrombocytopenia (defined as < 100,000 platelets/μL) was independently associated with development of ARDS.
Results. In the meta-analysis, six observational studies (seven cohorts) involving 3647 critically ill patients were included. Patients with versus without thrombocytopenia were more likely to develop ARDS [43.0% versus 32.0%; relative risk 1.46, 95% confidence intervals (CI) 1.19–1.80; $p < 0.001$]. In the secondary analysis, data from 2927 critically ill patients were analyzed. After adjustment for confounders, such as sex, age, extrapulmonary sepsis as a primary risk factor for ARDS and hematologic malignancy, thrombocytopenia was independently associated with development of ARDS (2884 patients, 102 events; odds ratio 1.86, 95% CI 1.13–3.06; $p = 0.015$).
Conclusions. Both the meta-analysis of observational studies and the secondary analysis of randomized controlled trials suggest that thrombocytopenia may be associated with development of ARDS. These findings may further elucidate the role of platelets in ARDS.

Introduction. Microvascular blood flow oscillations correlate with various physiological processes based on their frequency range [1]:
·[0.6–2.0 Hz]: cardiac activity.
·[0.145–0.6 Hz]: respiratory activity.
·[0.052–0.145 Hz] (I3): myogenic activity.
·[0.021–0.052 Hz] (I2, low frequency or LF): neurogenic (sympathetic) activity.
·[0.0095–0.021 Hz] (I1, very low frequency or VLF): endothelial activity mediated by nitric oxide (NO).
While laser Doppler flowmetry (LDF) and photoplethysmography (PPG) are useful for studying superficial tissues like the skin, they do not provide insights into deeper tissues. In a previous study in healthy volunteers, we demonstrated that microvascular blood flow oscillations can be monitored on the skeletal muscle using a hybrid time-domain near-infrared spectroscopy (TD-NIRS) and diffuse correlation spectroscopy (DCS) device [2].
Objectives. To assess the ability of TD-NIRS/DCS derived microvascular blood flow oscillations to detect differences between healthy volunteers and septic patients admitted in the ICU.
Methods. A hybrid TD-NIRS/DCS device was used to measure healthy volunteers and septic patients admitted to the ICU. The technology enables simultaneous measurement of oxy- and deoxy-hemoglobin concentrations and microvascular blood flow. Hemoglobin concentrations are used to derive tissue oxygen saturation (StO2), while diffuse laser speckles influenced by red blood cell motion are used to derive the microvascular blood flow index (BFI). StO2 and BFi were monitored on the thenar eminence during a 900-s period. Power spectral density (PSD) of BFi was computed for each frequency using the Welch algorithm, employing Hamming windows of 300 s with a 50% overlap. Mann–Whitney U-test was used for performing comparisons between healthy subjects and septic patients.
Results. Fourteen healthy volunteers and ten ICU septic patients were included in the analysis. Healthy volunteers were younger than septic patients (27 ± 3 vs 64 ± 8 years). All septic patients were stable, under mechanical ventilation, with normalized mean arterial pressure (MAP) values (79 ± 14 mmHg). Eight patients were receiving norepinephrine (0.5 ± 0.6 mcg/kg/min). Baseline microcirculatory status was similar in terms of tissue oxygenation (StO2 60 ± 6 vs 58 ± 11%, p ns) and microvascular blood flow (BFi 18·10–9 ± 9·10–9 vs 20·10–9 ± 16·10–9 cm2/sec, p ns). The PSD of BFI was significantly higher in healthy subjects in all the low frequency ranges: 37.1 ± 25.3 vs 7.9 ± 8.2 a.u. ($p = 0.001$) for LF (I2); and 35.9 ± 32.5 vs 4.1 ± 3.3 a.u. ($p < 0.001$) for VLF (I1) (Fig. 1).
Conclusions. Non-invasive diffuse optics technology can detect distinct patterns of microvascular blood flow oscillations in healthy individuals and septic patients. Sepsis-related changes in endothelial activity within the NO-dependent range can be effectively monitored at the bedside using TD-NIRS/DCS on skeletal muscle. These findings warrant further investigation to elucidate their clinical relevance.

Panel A: (abstract 000648) comparison of the PSD of BFI measured on healthy volunteers and ICU patients, on the thenar eminence (solid lines represent the mean PSD values, while shaded regions indicate the standard error). Panel B: absolute area of PSD BFI of healthy subjects and ICU septic patients

Association between humoral immunity proteins and mortality in sepsis: a systematic review and meta-analysis

A. Villa[1]; M. Singer[1]; N. Arulkumaran.[1]
[1]Bloomsbury Institute of Intensive Care Medicine, University College London, London, United Kingdom.
Correspondence: A. Villa.
Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000649***.

Introduction. Humoral immune proteins, including immunoglobulins, complement proteins, and antimicrobial peptides, play critical antimicrobial and immunomodulatory roles. We hypothesised that circulating levels of these proteins are lower in sepsis non-survivors than in survivors.
Objectives. To evaluate the relationship between circulating levels of humoral immunity proteins, specifically immunoglobulins, complement and antimicrobial peptides, and mortality among critically ill septic patients.
Methods. A systematic review and meta-analysis were conducted using PubMed and Embase databases up to January 2025. Inclusion criteria were papers describing adult ICU patients with sepsis that reported plasma levels of immunoglobulins, complement proteins or antimicrobial peptides, comparing survivors and non-survivors. Complementary data were sourced from the MIMIC-IV database and three proteomic studies. Random-effects meta-analyses provided standardized mean differences (SMD) with 95% confidence intervals (CI).
Results. Thirty-six studies with 6,330 patients were included. Thirteen studies reported data on immunoglobulin levels, 17 on complement proteins, and 7 on antimicrobial peptides. The MIMIC-IV database provided data on an additional 2452 patients on immunoglobulins and complement proteins. Higher levels of C3 (0.53 [0.12 to 0.94]) and C4 (0.42 [0.14 to 0.71]), and lower levels of IgA (-0.21 [-0.36 to -0.06]) and C4a (-1.17 [-1.77 to -0.56]) on ICU admission were significantly associated with survival. C3a levels were lower in survivors but the difference was not statistically significant (Figs. 1 & 2). Levels of IgG, IgM, other complement proteins, and heparin binding protein were similar between survivors and non-survivors. Proteomic data confirmed a

rapid depletion of complement proteins within 72 h in non-survivors. In the longitudinal analysis of MIMIC-IV data, survivors exhibited relative stability in IgG, IgA, IgM and complement proteins C3 and C4 between days 0–1 and 2–5, whereas non-survivors showed significant declines over the same period.

Conclusions. Lower levels of complement proteins are associated with mortality in sepsis. These findings highlight the potential of targeting complement pathways as a therapeutic strategy in sepsis.

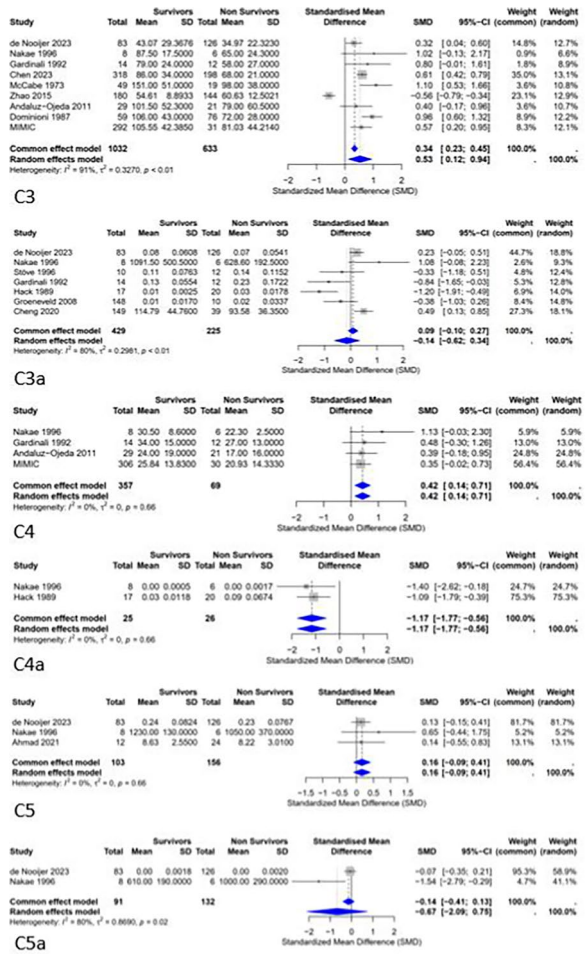

Fig 1 (abstract 000649) Meta-analysis of complement proteins in septic shock patients. Forest plots comparing the levels of different complement proteins between survivors and non-survivors in the ICU. Each individual study is represented by a square, with its size proportional to the study's weight in the meta-analysis. Horizontal bars indicate 95% confidence intervals. The blue diamond represents the pooled effect estimate from the random-effects model. Heterogeneity values (I^2) *are provided for each analysis.*

Introduction. Bloodstream infections (BSIs) are frequent ICU acquired infections in intensive care units (ICUs) in Greece and are often caused by multidrug resistant (MDR) pathogens which impacts length of stay, costs and mortality. Previous publications involve predominantly single center studies and data on a national level is scarce.
Objectives. The Section of Infection Prevention and Management of the Hellenic Society of Intensive Care Medicine designed the BACT.GR 2024 study to ascertain the prevalence and microbial etiology of BSI episodes in Greek ICUs on a national scale.
Methods. A prospective, observational two-month point prevalence study was performed between November and December 2024. All ICU-acquired BSIs in patients with a central venous catheter were included. Definitions and methodology were according to CDC-NHSN and ECDC guidelines. Demographic, clinical and microbiological data were collected anonymously using Redcap software. Pathogen identification and antimicrobial sensitivity was determined according to EUCAST criteria (applied currently by Greek Microbiology Departments).
Results. 295 patients with BSI were reported from 43 adult ICUs. In total, 392 isolates were recovered in 338 BSI episodes. 227(58%) isolates were Gram negative, 88 (22.4%) Gram positive and 77(19.6%) fungi. The most common Gram negative pathogens were *Acinetobacter baumannii* (30.4%) and *Klebsiella pneumoniae* (29.96%). Detailed information on pathogens and antibiotic susceptibility is presented in the following Table.

Isolates		**Percent (%) susceptible to**				
Gram negative	**N (%)**	**Meropenem**	**Colistin**	**Ceftazidime Avibactam**	**Imipenem Relebactam**	**Meropenem Vaborbactam**
A. baumannii	69 (30.4)	2	36	-	-	-
K. pneumoniae	68 (29.96)	5	42	36	30	31
P. aeruginosa	45 (19.82)	25	90	45	37	-
Other Gram(-)	45 (19.82)					
Total Gram negatives 227						
Gram positive	N (%)	Gentamycin	Vancomycin			
Enterococcus sp.	46 (52.27)	42	57			
S. aureus	1 (1.14)		100			
Coagulase negative Staphylococcus spp.	29 (32.95)		100			
Other Gram(+)	12 (13.64)					
Total Gram positives 88						
Fungi	N (%)	Fluconazole	Anidulafungin	Micafungin	Caspofungin	Ampho. B
Candida auris	39 (50.65)	3	95	81	75	70
C. parapsilosis	16 (20.78)	46	100	100	72	100
C. albicans	14 (18.18)	100	90	90	92	100
Other fungi	8 (10.39)					
Total fungi 77						

Conclusions. Gram-negative pathogens predominate in the etiology of BSIs in Greek ICUs, mainly multidrug resistant *A. baumannii and K. pneumoniae*. High resistance rates of *K. pneumoniae* to newer BL/BLI's is an alarming issue. Among Gram-positive bacteria, *c* exhibits 43% non-susceptibility to vancomycin. Half of fungemias is due to *Candida auris.* Our results raise concerns for empirical and targeted antimicrobial regimens, as well as, for infection prevention and control issues in Greek ICUs.

Effectiveness of protocolised early rehabilitation in adult ICU patients compared to standard care: a systematic review

MI. Sepulveda[1]; P. Correa[1]; S. Secoli[1]; V. De Araújo-Püschel.[1]
[1]Escola Enfermagem, Universidade Sao Paulo, Sao Paulo, Brazil.
Correspondence: M.I. Sepulveda.
Intensive Care Medicine Experimental*, *2025*;13(1)**: ***000652.

Introduction. Intensive Care Unit–Acquired Weakness (ICU-AW) is a syndrome characterised by diffuse, symmetrical, and generalised muscle weakness that prolongs the duration of invasive mechanical ventilation (IMV) and ICU stay, and affects short- and long-term functionality. It includes polyneuropathy, myopathy, and neuromyopathy, conditions that may persist for months or years after hospital discharge, significantly reducing quality of life. Immobility is a key risk factor for the development of ICU-AW; therefore, early rehabilitation (ER) has been proposed as a preventive strategy. ER in the ICU (ER-ICU) includes physiotherapy, occupational therapy, and other interventions, initiated once physiological stability is achieved and maintained throughout the ICU stay, ideally within 1–2 days of IMV initiation. Studies have reported mixed findings regarding its impact on IMV duration, ICU-AW incidence, and mortality. This systematic review assesses the effectiveness of protocolised ER-ICU compared with standard care in reducing ICU-AW and improving short- and long-term functionality.
Objectives. To determine the effectiveness of protocolised ER-ICU compared to standard care in reducing ICU-AW incidence and functional decline.
Methods. A systematic search was conducted in PubMed, Scielo, Scopus, EMBASE, Web of Science, Cochrane Central Register, JBI, and CINAHL, with no restrictions on date or language. Two independent reviewers selected studies and assessed methodological quality using JBI checklists. A narrative synthesis and meta-analysis were performed. PROSPERO Registration: CRD42023388385.
Results. A total of 1,974 articles were identified. After screening, 151 full texts were reviewed and 31 studies were included. Meta-analysis showed no significant differences in ICU mortality or mobilisation-related adverse events. ICU length of stay was reduced by 2.22 days in the ER-ICU group [95% CI: -3.51; -0.93], and hospital stay by 2.68 days [95% CI: -5.01; -0.34]. The reduction in ICU-AW incidence was not statistically significant [-0.12; 95% CI: -0.33; -0.07].
Conclusions. Protocolised ER-ICU was associated with shorter IMV duration and ICU stay, with no significant difference in ICU-AW incidence or increase in adverse events. Additionally, patients experienced less functional decline at hospital discharge.

Dynamic assessment of recirculation and non-shunted pulmonary blood flow in V-V ECMO using oxygen-flow relationship analysis

SC. Frei[1]; G. Loosen[1]; P. Werner-Moller[2]; D. Berger[1]; KF. Bachmann.[1]
[1]Intensive Care Unit, Department of Acute Medicine, University Hospital Basel, Basel, Switzerland; [2]Department of Anaesthesia, SV Hospital Group, Institute of Clinical Sciences at the Sahlgrenska, University of Gothenburg, Gothenburg, Sweden.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000655***.

Introduction. Veno-venous extracorporeal membrane oxygenation (V-V ECMO) is a life-support modality for severe respiratory failure. Recirculation of oxygenated blood and the relationship between extracorporeal and pulmonary blood flow significantly impact treatment efficacy. Determination of pulmonary blood flow using gas exchange analysis and adapted thermodilution have been hypothesised for ECMO [1, 2], but current monitoring techniques lack reliability and validation during V-V ECMO [3].
Objectives. To develop a method for assessing recirculation and pulmonary blood flow during V-V ECMO using dynamic oxygenation-to-flow relationships.
Methods. We hypothesised that the relationship between ECMO blood flow (QECMO) and membrane oxygen transfer (VO_2ECMO) in relationship to total oxygen transfer (lung and membrane; VO2Total) would allow determination of recirculation and pulmonary blood flow; 1) at low recirculation fractions the ratio of VO_2Total to maximum blood flow (Qmax) equals the slope of VO_2ECMO versus QECMO ($\Delta VO_2/\Delta Q$), which would allow calculation of non-shunted pulmonary blood flow; 2) the extent of increased recirculation at higher QECMO could be estimated from the deviation from the initially established $\Delta VO_2/\Delta Q$.
The hypothesis was tested using a simulation model of V-V ECMO [4] with changing QECMO (0.5–5.0 L/min) and the following variables: cardiac output (5 L/min), recirculation fraction (0–30%), fraction of inspired oxygen (60% for ventilator and membrane), 0% shunt, and a fixed VO_2Total. Simulation of progressive recirculation started at 0% for ECMO flows up to 1/3 of cardiac output and then increased linearly with ECMO flow.
Results. Modelling analysis confirmed a linear relationship between VO2ECMO and QECMO (with constant recirculation fractions), representing the oxygen-carrying capacity per unit of blood (Fig. 1A). The maximum theoretical QECMO, where the linear relationship intersected with VO_2Total, equalled non-shunted pulmonary blood flow (Fig. 1A) and could be calculated as:
Qmax = (VO_2Total*ΔQECMO)/ΔVO_2ECMO.
Recirculation caused a proportional decrease in VO2ECMO and underestimation of Qmax (Fig. 1A).
In cases of progressive recirculation with increasing blood flow, simulated VO_2ECMO would deviate from projected values determined at low QECMO where recirculation is assumed to be constant (Fig. 1B). This deviation for a target blood flow is proportional to the recirculation fraction (RF), quantified as:
RF = 1—measured VO_2/projected VO_2.
Conclusions. This novel approach estimated recirculation and non-shunted pulmonary blood flow during V-V ECMO by determination of total gas exchange before and after a stepwise change in QECMO. By analysing the dynamic relationship between ECMO flow and oxygen transfer, clinicians may better guide real-time ECMO therapy towards maximum oxygen delivery. If cardiac output is estimated using other methods [5, 6], the proposed approach may provide a tool to estimate pulmonary shunt fraction.

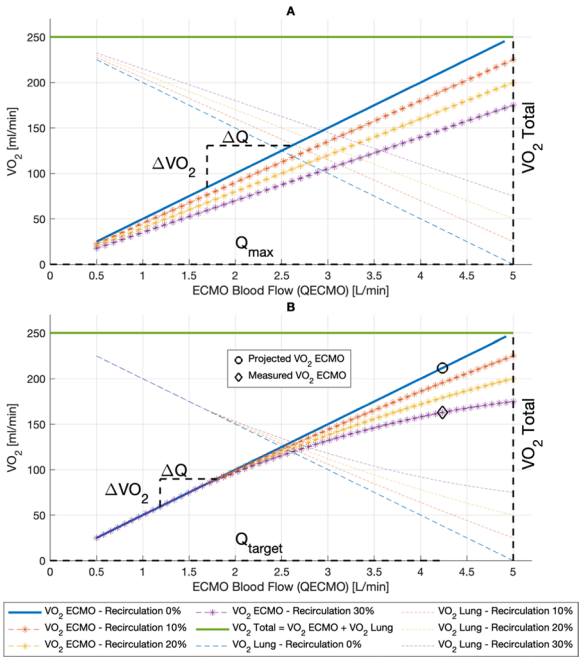

Fig 1 (abstract 000655) Relationship between ECMO blood flow and oxygen transfer during V-V ECMO. (A) Oxygen transfer over the membrane lung (VO_2ECMO) increased linearly with ECMO blood flow (QECMO) at low flow. The slope of this linear portion ($\Delta VO_2/\Delta Q$) and measurement of VO_2Total (which equals VO_2Lung + VO_2ECMO), allowed determination of the theoretical maximum oxygenation capacity (Qmax), where ECMO delivers total oxygenation. **(B)** At higher recirculation fractions, the measured VO_2ECMO (diamond marker) for a targeted blood flow (Qtarget) deviated from the projected linear relationship (circle marker). The magnitude of this deviation is inversely proportional to the recirculation fraction, allowing its calculation as 1 – measured VO_2/projected VO_2. Colours represent varying recirculation fractions.

Intensive Care Medicine Experimental, 2025;13(1): ***000658***.

Introduction. Excessive activation of macrophages in sepsis can result in certain patients displaying characteristics akin to those observed in macrophage activation-like syndrome (MALS).
Objectives. To identify and characterize the differences between patients meeting MALS criteria and the rest of the cohort.
Methods. A retrospective cohort study was conducted including patients with septic shock and severe sepsis activated under the Sepsis Code of our center between April 2018 and November 2024. Inclusion criteria: severe sepsis or septic shock (Sepsis-2 definitions), determination of ferritin levels. Exclusion criteria: none. MALS criteria were defined by a ferritin level > 4400 ng/mL obtained within the first 12 h of sepsis/septic shock development.
Demographic, comorbidity, infection-related, and sepsis-evolution variables were studied. A descriptive analysis was performed using median and interquartile range for quantitative variables and frequency and percentage for categorical variables. An exploratory univariate analysis was then performed using the Chi-square test for categorical variables and the Mann–Whitney U test for continuous variables. Statistical significance was defined as $p < 0.05$. Statistical analysis was performed using StataBE 18.5 (StataCorp 2023). The study was approved by the ethics committee under registration number PR(AG)336/2016.
Results. A total of 375 patients were included. The majority were males (236, 62.9%) with a median age of 61.5 years (51–71), and 164 (43.7%) presented some form of immunosuppression. The most common septic foci were respiratory (126, 33.9%) and abdominal (85, 22.8%).
Fifty patients (13.3%) met MALS criteria. These patients were generally younger than the rest of the cohort (58.5 years [47–64] vs. 62 [52–72] years, $p = 0.031$), more frequently immunosuppressed (60% vs 41.2%, $p = 0.04$), and exhibited worse outcomes (ICU mortality 72.9% vs. 28.2%, $p < 0.001$). Other differences in comorbidity and organ support can be found in Table 1.
Conclusions. Ferritin levels > 4400 ng/mL identified a subgroup of septic patients with more organ dysfunction and worse outcomes.

Table 1 Univariate analysis of differences between patients meeting MALS criteria and those who do not

Variable	Without MALS Criteria (n=325)	With MALS Criteria (n=50)	p-value
Sex (male)	205 (63.1%)	31 (62.0%)	0.310
Age (years)	62 (52–72)	58.5 (47–64)	0.031

adult intensive care unit survivors and financial toxicity: a scoping review

MI. Sepulveda[1]; D. Pinto[2]; V. Rojas[3]; V. Gatica[4]; T. Regueira[5]; V. De Araújo-Püschel[1]; S. Secoli.[1]
[1]Escola Enfermagem, Universidade Sao Paulo, Sao Paulo, Brazil; [2]I + D + i, SIGMA SA, Santiago, Chile; [3]I + D + i, SIGMA, Santiago, Chile; [4]I + D, SIGMA S.A., Ñuñoa, Chile; [5]Unidad de Paciente Crítico, Clínica Santa María, Providencia, Chile.
Correspondence: M.I. Sepulveda.
Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000660***.

Introduction. Financial toxicity is an emerging issue among intensive care unit (ICU) survivors, defined as the economic burden resulting from medical expenses and loss of income. While this phenomenon has been widely studied in oncology patients, its impact on survivors of critical illness remains poorly understood. This scoping review examines the available evidence on financial toxicity in this population, as well as its effects on return to work and income loss.
Objectives. To systematically describe the scope and nature of the available evidence on financial toxicity in adult ICU survivors, identifying its impact on individual and family finances, return to employment, and long-term financial stability.
Methods. A scoping review was conducted following the Joanna Briggs Institute (JBI) methodology. Searches were carried out in databases such as MEDLINE, EMBASE, CINAHL, Web of Science, LILACS, and the Cochrane Library, as well as grey literature. Studies assessing financial toxicity in adult ICU survivors (≥ 18 years) were included without geographical or cultural restrictions. Article selection was performed

by two independent reviewers, and a descriptive analysis was applied to the extracted data.
Register OSF: Sepulveda, M. I., Pinto-Galleguillos, D., Rojas, V., Regueira, T., Secoli, S., & de Araujo, V. A. (2024, July 29). Adult Intensive Care Unit survivors and financial toxicity: a scoping review. Retrieved from osf.io/7jdc2.
Results. Sixteen studies were included, comprising prospective cohort designs, secondary analyses, and qualitative studies(1–16). Findings indicated that financial toxicity is common among ICU survivors, manifesting as high medical bills, reduced income, and reliance on external financial support. In studies from the USA and Europe, between 33 and 67% of patients were reported to experience significant financial hardship following ICU discharge (14,16).
Return to work was limited: 44% of patients with ARDS in the USA did not return to employment after 12 months (7), while 42% of critical illness survivors in the USA, UK, and Australia experienced employment changes due to post-ICU disability(3,11). The estimated income loss over a five-year follow-up period reached USD $200,000 per patient (12).
Conclusions. Financial toxicity severely affects survivors of critical illness, limiting their access to healthcare and worsening their quality of life. Financial support strategies and employment rehabilitation programmes are needed to mitigate its effects. Future research should focus on identifying populations at risk and evaluating policies aimed at reducing the economic impact of critical illness.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000661***.

Introduction. In liver transplantation, human albumin is administered as maintenance fluid during surgery. Postoperatively, it is used to compensate for drain losses, ensure circulatory stability, and maintain a plasma albumin level of 25 g/L. However, evidence supporting this practice is limited. In a previous study conducted by our group, we observed net albumin leakage (NAL) in patients undergoing stable, uncomplicated liver transplantation, with significant albumin losses continuing until postoperative day 3 (POD3) (1).
Objectives. To assess NAL during and after surgery through postoperative day 7 (POD7) (primary aim) and continuing until hospital discharge or POD21 (PODlast) in adults undergoing liver transplantation at Karolinska University Hospital, Huddinge, Sweden. To investigate clinical factors associated with NAL.
Methods. Over a two-year period, a total of 131 adult patients were studied during and after liver transplantation, with 87 remaining hospitalized for more than seven days. NAL was assessed using mass balance calculations, *i.e.* comparing hemoglobin and albumin dilutions when all losses and gains of the two compounds are considered. A greater albumin dilution is interpreted as net albumin lost from the intravascular space. Data are presented as mean with 95% confidence intervals. T-tests were used to assess whether data differed from zero. NAL was correlated to albumin gains minus losses (ΔAlb) in 4 time intervals: from start of surgery until end of surgery (EOS), from EOS until POD3, from POD3 until POD7, and from POD7 until PODlast (GraphPad Prism 10).
Results. NAL at POD7 was 42 g (31–52, $p < 0.001$). NAL for the 4 time intervals was 23 g (19–28, $p < 0.001$), 0 g (–7–7, $p = 0.91$), 18 g (11–25, $p < 0.001$), and 22 g (10–33, $p < 0.001$), respectively. ΔAlb at the same time intervals was 42 g (37–46, $p < 0.001$), 7 g (–1–14, $p = 0.073$), 8 g (1–16, $p = 0.027$), and 25 g (12–37, $p < 0.001$), respectively. There was a positive correlation between NAL and ΔAlb for all time intervals that increased gradually over time from $r2 = 0.281$ for the first interval to $r2 = 0.835$ at the last.
Conclusions. NAL persisted throughout the surgery and continued until POD7 and PODlast. The correlation between NAL and ΔAlb increased over time towards a strong association. We suggest that over-substitution of albumin is a major contributor to NAL, especially in the postoperative period, after liver transplantation.

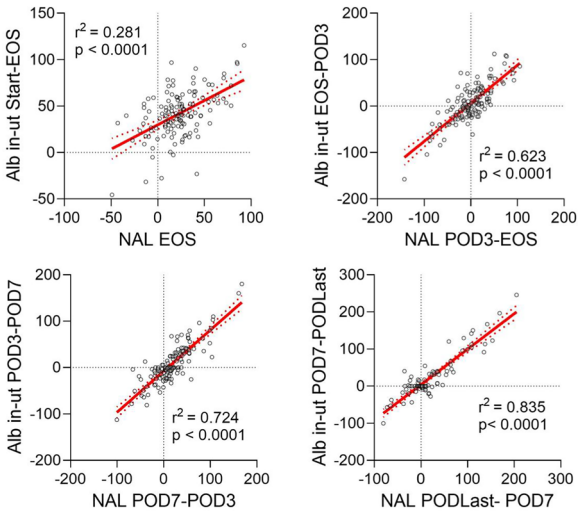

Fig 1 (abstract 000661) Net albumin leakage (NAL) vs albumin gains minus losses (Alb in–out) in four time intervals during and after liver transplantation. EOS = end of surgery, POD = post-operative day

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000662***.

Introduction. Post-intensive care syndrome (PICS) describes the physical, cognitive and psychological sequelae that persist after an ICU stay. Chronic pain is a common manifestation, significantly affecting quality of life. This persistence of pain is often intertwined with sleep disturbances, creating a vicious cycle that hinders the patient's recovery and well-being. Understanding this relationship is crucial to comprehensively address PICS.
Objectives. To analyze the quality and characteristics of sleep disturbances suffered by patients and their influence on the subjective perception of pain after ICU stay.
Methods. Descriptive, observational and analytical retrospective study on a prospective database. We included critically ill patients who were consecutively admitted to an intensive care unit (ICU) of a tertiary level university hospital between November 2020 and August 2024, for more than 72 h, requiring some type of organic support and patients with a history of anxiety or depression. Variables related to sleep habits, time, quality, need for drugs to fall asleep and frequency of pain were analyzed. Quantitative variables are expressed as mean ± standard deviation or median (interquartile range), and qualitative variables as absolute and relative frequency. Comparison between dichotomous qualitative variables was performed using Pearson's χ^2.
Results. We analyzed 71 patients, with a mean age of 58.7 ± 13.7 years, of whom 43(60.6%) were male, with a mean BMI of 27.8 ± 6.9. The median ICU stay was 19 days (9.30). Of the 71 patients interviewed about their sleep characteristics, 34 patients (47.8%) reported taking more than 30 min to fall asleep as a significant problem,56 (78.8%) had frequent awakenings during the night, 46 (64.7%) needed to get up to go to the toilet, and 34 (47.8%) required two or more drugs to fall asleep. Of the patients who presented these sleep disturbances, a higher percentage of the patients who required a long time to fall asleep reported frequent or very frequent pain (51.7%vs. 45%, $p = 0.581$), a higher percentage of those who had nocturnal awakenings(100% vs. 82.5%, $p = 0.019$), a higher percentage of those who needed to get up to go to the toilet (82.8% vs. 70%, $p = 0.225$) and a higher percentage of those who required 2 or more drugs to fall asleep (55.2% vs. 35%, $p = 0.095$).
Conclusions. Patients who were admitted to the ICU and met criteria for requiring post-ICU consultation with sleep disturbances presented a higher frequency of subjective perception of pain, being statistically significant in those who presented nocturnal awakenings.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000663***.

Introduction. Therapeutic drug monitoring (TDM) of antibiotics is an important tool for precision medicine, particularly in critically ill patients with variable pharmacokinetics (PK) and pharmacodynamics (PD).
Objectives. To investigate PK/PD target attainment of β-lactam antibiotics in critically ill patients and to identify predictors for suboptimal exposure.
Methods. A retrospective study on TDM of β-lactam antibiotics was conducted at AZ Sint-Jan Hospital, Bruges in 2023. All adults admitted to the intensive care unit (ICU) and receiving β-lactam antibiotics for > 24 h were included. The primary endpoint was PK/PD target attainment, defined as a steady-state concentration (Css) that was at least 4 times the minimum inhibitory concentration (MIC), epidemiological cut-off (ECOFF), or breakpoint (BP), and did not exceed 10 times the worst-case breakpoint (BP). (4xMIC/ECOFF/BP < Css > 10 × Worst-case BP). Predictors of non-attainment were analysed using binary logistic regression.
Results. In 63 patients, 91 TDM assessments were conducted. Most patients were male (61.9%), with a mean age of 68 years. Target attainment was achieved in 50.5% of patients, with 84.6% meeting the efficacy target (100% *f*T > 4xMIC). Lower target attainment was observed in augmented renal clearance (ARC) and obesity (BMI > 30 kg/m^2). Renal insufficiency (OR 0.11; 95% CI [0.026 – 0.479]) and obesity (OR 0.31; 95% CI [0.100 – 0.944]) were significant predictors of reaching the efficacy target, while ARC was a relevant predictor for non-target attainment (OR 1.60; 95% CI [0.523 – 4.891]). Overexposure (100% *f*T > 10xMIC) occurred in 40.3% of TDMs, particularly in patients with renal insufficiency and extracorporeal circuits. Obesity (OR 0.083; 95% CI [0.008 – 0.471]) was a significant predictor for reduced likelihood of overexposure, while extracorporeal circuits (OR 1.12; 95% CI [0.581 – 2.15]) and renal insufficiency (OR 0.80; 95% CI [0.316 – 2.027]) showed trends of increased and decreased odds, respectively.
Conclusions. Achieving adequate β-lactam exposure in critically ill patients is challenging due to variable PK and difficult-to-treat infections, and toxicity risks. We observed a high efficacy target attainment, with lower rates in patients with ARC and obesity. Overexposure was seen with extracorporeal circuits and renal insufficiency. Our study shows that TDM of β-lactam should be considered in these patients groups.

Toxic encounters: acute intoxication in a Portuguese intensive care unit

A. Sousa Lopes[1]; JP. Vinhal,[1]; E. Sousa,[1]; J. Alves,[1]; R. Pinho,[1]
[1]Medicina Intensiva, Unidade Local de Saúde de Entre Douro e Vouga (CHEDV), Santa Maria da Feira, Portugal.
Correspondence: A. Sousa Lopes.
Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000668***.

Introduction. Acute intoxication, whether it is intentional or unintentional, constitutes an important cause for admission in the emergency department. While clinical severity may vary, life-threatening presentations prompt haste in the diagnosis and treatment followed

by intensive care admission (ICU). ICU mortality can range between 0 to 6%.

Objectives. The present study characterizes the admissions due to acute intoxication in a Portuguese ICU and examines its incidence, epidemiological characteristics, morbidity and mortality.

Methods. A retrospective study was conducted in a 12-bed Portuguese ICU from January 2023 to January 2024. The center manages around 650 admissions annually. All patients admitted to the ICU with a diagnosis of intoxication, regardless of intentionality, were included. Data sources included hospital and ICU databases, with analysis focusing on demographic variables, diagnosis, scoring systems, treatments required, and outcomes. GraphPad Prism software was used to statistical analysis. Parametric and non-parametric data were appropriately handled, and correlations were examined with significance set at $p < 0.05$.

Results. Out of all ICU admissions, 30 patients were included (14 in 2023 and 16 in 2024), representing 2.3% of total ICU admissions. There was a clear preponderance of female admissions (73.3%). The mean patient age was 54 years (IQR 19 – 87). In general, male intoxicated patients were older than the female ones with medians of 59 and 49 years, respectively. Most patients were brought to the emergency department by non-differentiated pre-hospital teams. The vast majority of admitted intoxications were due to intentional poisoning with suicidal intent, accounting for 93.3% of admissions. This data is in line with the finding that 76.6% of the patients presented with major depressive disorder.

Almost two-thirds of the patients present mixed drug intoxication (= 18, 60%). The most common intoxication drugs were benzodiazepines (= 20, 66.7%), antidepressants (= 12, 40%) and antipsychotics (= 9, 30%). Analgesics, herbicides and anticonvulsants were the other drugs used (representing 13.3%, 13.3% and 10%). Single cases were reported with methamphetamines, carbon dioxide and caustic intoxication.

The median ICU stay was three days, with no readmissions within 48 h post-discharge. Mechanical ventilation was required in 76.7% of cases due to neurologic impairment with a median Glasgow Coma Scale of seven points. Notably, one patient needed renal replacement therapy due to severe metabolic acidemia related to herbicide intoxication.

No deaths were reported during the study.

Conclusions. In the present study, the high rate of pre-existing psychiatric illness and the predominantly suicidal-related intent brings forth the need for multidisciplinary therapeutic management. Prompt referral to specialized psychiatric consultation and continued follow-up are deemed necessary to prevent recurrence and the potentially life-threatening consequences in need of ICU care.

Prognosis of cancer patients in the intensive care unit of a regional hospital

A. Alonso[1]; M. Salgado[1]; A. Alvarez[1]; J. Garcia[1]; J. Gómez[1]; A. Ubeda.[1]
[1]Intensive care unit, Hospital Punta de Europa, Algeciras, Spain.
Correspondence: A. Ubeda.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000670***.

Introduction. Cancer, considered globally, represents the first cause of death in men and the second cause of death in women, with an annual mortality rate of 204 deaths/100,000 inhabitants. Advances in early diagnosis and the development of new therapies have managed to prolong the survival of these patients and, as a consequence, the number of cancer patients admitted to intensive care units (ICU) for the management of complications related to cancer treatment, due to side effects or because they present a condition independent of cancer that is considered an indication for admission to the ICU is increasing.

Objectives. To analyze the clinical characteristics and prognosis of patients with a history of cancer (CH) admitted to the Intensive Care Unit of Punta de Europa University Hospital, as well as factors associated with mortality.

Methods. A retrospective descriptive analysis of a prospective cohort conducted in a 12-bed ICU between 2019 and 2024. Demographic variables, comorbidities, severity scores, treatment received, mechanical ventilation (MV), risk factors, ICU infections, antibiotic therapy, ICU and hospital stay were included. Statistical analysis: categorical variables (frequencies and percentages) and quantitative variables (mean and standard deviation or median and interquartile range). Comparisons: χ test (percentages), Student's t test (means), and Mann–Whitney U test (medians). Multivariate logistic regression. Statistical significance at $p < 0.05$.

Results. 2303 patients were included. CH (n = 333) vs. non-CH (n = 1970). Age (68 [58; 76] vs. 64 [53; 75], $p < 0.001$). APACHE II (13 [8; 18] vs. 9 [5; 15], $p = 0.001$), SAPS II (35 [23; 47] vs. 27 [18; 40], $p = 0.001$). Risk factors: ATB 48 h prior (38.7% vs. 17.7%, $p < 0.001$), TPN (28.8% vs. 10.5%, $p < 0.001$), neutropenia (5.1% vs. 1.4%, $p < 0.001$), CVC (81.7% vs. 47.2%, $p < 0.001$), MV (51% vs. 33.2%, $p < 0.001$), UC (88.3% vs. 60.3%, $p < 0.001$). MV time 1 [0; 3] vs. 0 [0; 1], $p < 0.001$. Length of stay: ICU (4 [2; 7.2] vs. 3 [2; 6]), hospital (13 [7; 24] vs. 8 [4; 15]); $p < 0.001$. In-hospital mortality: 105 (31.5) vs. 437 (22.2), $p < 0.001$.

Mortality analysis (CH patient): alive (n = 228) vs. dead (n = 105). APACHE II (12 [7; 16] vs. 16 [11; 21], $p < 0.001$). SAPS II (31 [21; 44] vs. 45 [32; 56], $p < 0.001$). GCS (15 [15; 15] vs. 15 [12; 15], $p < 0.001$). Comorbidity: immunosuppression 5.7% vs. 21.9%, $p < 0.001$. Risk factors: ATB 48 h prior (34.6% vs. 47.6%, $p = 0.033$), neutropenia (1.7% vs. 12.4%, $p < 0.001$), RRT (2.6% vs. 3.8%, $p < 0.001$), MV (41.7% vs. 71.4%, $p < 0.001$), UC (84.2% vs. 97.1%, $p < 0.001$), CVC (76.7% vs. 92.4%, $p = 0.001$). Vasopressin 1.3% vs. 9.5%, $p < 0.001$. Intra-ICU infection 9.6% vs. 24.8%, $p < 0.001$. MV time 0 [0; 1] vs. 2 [1; 7.5], $p < 0.001$. Hospital stay 14 [8; 25] vs. 11 [4; 23], $p = 0.009$.

Multivariate logistic regression: RRT (OR 5.99 [2.21–18.27], $p < 0.001$), SAPS II (OR 1.04 [1.02–1.05]), immunosuppression (OR 3.13 [1.33–7.57], $p = 0.009$), MV time (OR 1.06 [1.02–1.10], $p = 0.001$), surgical patient (OR 0.48 [0.26–0.87], $p = 0.017$).

Conclusions. Patients with CH admitted to the ICU have greater severity of illness, infectious risk factors, comorbidities, greater resource use, and a higher incidence of infections.

The use of extrarenal purification techniques, SAPS II at admission, immunosuppression, MV time and post-surgery admission behaved as predictors of mortality.

Introduction. regional citrate anticoagulation (RCA) is the standard of care for CRRT anticoagulation. However, evidence on its use in CRRT circuits during extracorporeal membrane oxygenation (ECMO) is limited. In ECMO patients, CRRT circuit patency is usually preserved with systemic anticoagulation using unfractionated heparin (UFH). RCA may enhance CRRT circuit lifespan by reducing clotting, consumption coagulopathy, and associated complications.
Objectives. To evaluate whether the addition of RCA to CRRT circuits in patients on systemic UFH for venovenous (V-V) ECMO reduces circuit clotting. Secondary endpoints included the impact of CRRT anticoagulation regimen on platelet count, D-dimers, fibrinogen, and adverse events.
Methods. We conducted a prospective, randomized crossover study in ICU patients undergoing V-V ECMO and CRRT at IRCCS San Gerardo Hospital (Monza, Italy). Patients were randomized to start with either RCA + UFH or UFH alone, following the sequence in Fig. 1. CRRT circuit was integrated into the ECMO circuit, with the inlet line placed post-oxygenator and the outlet line between the centrifugal pump and the oxygenator. CRRT was performed using multiFiltratePRO (Fresenius). RCA was obtained with 4% sodium citrate to target a postfilter ionized calcium of 0.25–0.34 mmol/L. Circuits were electively replaced every 72 h as per manufacturer recommendations. Coagulation and blood gas analysis were assessed every 8 h; CRRT circuit pressures and settings were monitored every 2 h. Anticoagulation effect of RCA + UFH versus UFH was evaluated with thromboelastography (TEG). The study was registered at clinicaltrials.gov NCT 5148026.
Results. Fifteen patients were included, for a total of 61 circuits (31 RCA + UFH; 30 UFH). No clotting events were reported in the RCA + UFH group, compared to 6 (20%) in the UFH group. When censoring for non-clotting circuit replacements, log-rank analysis showed significantly longer circuit survival with RCA + UFH ($p = 0.009$, **Fig. 2**). Platelet counts showed an upward trend from baseline—defined as the value at new circuit start—during RCA + UFH, but declined with UFH alone. D-dimer trend significantly increased in the UFH group, while fibrinogen remained comparable (**Fig. 3**). Systemic anticoagulation remained comparable between RCA + UFH and UFH (aPTT ratio: median 1.28 [1.11–1.44] vs. 1.29 [1.18–1.45], $p = 0.134$; anti-Xa: median 0.25 [0.18–0.33] vs. 0.24 [0.17–0.32], $p = 0.985$). RCA + UFH significantly prolonged the circuit TEG R-time compared to UFH alone (median 90 [90–90]vs 30.1 [15.1–50.8] minutes, $p = 0.021$). No citrate-related complications were observed.
Conclusions. The addition of regional citrate anticoagulation significantly reduced CRRT circuit clotting rates in patients receiving systemic UFH during V-V ECMO. It was also associated with a favorable effect on platelet count and D-dimer levels. TEG analysis confirmed a stronger anticoagulant effect with RCA + UFH compared to UFH alone. The technique was feasible, safe, and did not increase the incidence of adverse events.

Correspondence: Y.H. Liew.
Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000675***.

Introduction. Trauma severity scoring systems are widely used to guide clinical decision-making and monitor trauma patient outcomes. Despite their widespread use, identifying the most accurate scoring system remains challenging, with varying performance across different populations. To our best knowledge, no study has compared the predictive accuracy of these trauma scoring systems in Singapore.
Objectives. This study evaluates the performance of the Trauma and Injury Severity Score (TRISS), Injury Severity Score (ISS), and Revised Trauma Score (RTS) in predicting mortality among trauma patients at Singapore General Hospital (SGH) from 2015 to 2018, assessing their applicability in the local population.
Methods. A retrospective analysis was conducted on 1555 trauma patients with a median age of 67 years (IQR 41.0–79.0). Blunt trauma was the predominant mechanism (94.6%). Mortality prediction was assessed through sensitivity, specificity, and AUROC. ROC curve analysis was used to determine the ability of each score to distinguish survivors from non-survivors.
Results. The study found that TRISS demonstrated the highest predictive accuracy with an AUROC of 0.76 (95% CI: 0.69–0.83), combining moderate sensitivity (51.6%) and high specificity (92.5%), making it the most reliable tool overall. ISS showed moderate predictive performance, with an AUROC of 0.60 (95% CI: 0.59–0.72), with high specificity (90.0%) but low sensitivity (33.9%), indicating a propensity for under-triage. RTS, with a sensitivity of 99% and an AUROC of 0.28 (95% CI: 0.22–0.35), had extremely low specificity (3.5%), leading to significant over-triage.
Conclusions. Among the three scoring systems, TRISS showed the best overall predictive accuracy in the Singaporean cohort, with high specificity but moderate sensitivity. However, it missed nearly 50% of deaths, limiting its effectiveness as a standalone tool for high-stakes mortality prediction. While RTS effectively minimised missed deaths with its high sensitivity, its low specificity and poor discriminative power (AUROC) restrict its practical utility. The ISS showed limited predictive capability, with significant under-triage due to low sensitivity. These findings underscore the need for refined or locally tailored trauma scoring systems to improve mortality prediction and resource allocation in Singapore's trauma population.

Intensive Care Medicine Experimental*, *2025*;13(1)**: ***000676.

Introduction. Patients with critical illnesses have diverse etiologies and acute life-threatening conditions, and their pathologies are extremely heterogeneous. Conventional uniform treatment based on clinical diagnosis fails to adequately capture this diversity of pathophysiology and has limited therapeutic efficacy. In recent years, molecular-level analysis has proposed novel subgroups that transcend conventional classifications, increasing the need for personalized medicine according to the pathophysiology.
Objectives. The purpose of this study is to classify critical illnesses into novel molecular subgroups and extract molecular signatures that can be used as therapeutic targets through new classifications based on transcriptome analysis of whole blood.
Methods. This was a prospective multicenter study of patients with critical illnesses admitted to the ICU of tertiary care hospitals in Japan for at least one day. The study population was divided 2:1, with one cohort as the derivation cohort and the other as the validation cohort. Peripheral blood was collected at admission and whole blood RNA-seq was performed. Latent class analysis was applied to the expression data to identify endotypes. Differential gene expression analysis, pathway analysis, and upstream regulator analysis were used to evaluate the molecular characteristics of each endotype.
Results. Analysis was performed on 199 cases in the derivation cohort and 99 in the validation cohort, and three endotypes were identified. Endotype 1 was mainly infections with the highest severity and mortality in the elderly, endotype 2 was mainly trauma with the lowest severity and mortality, and endotype 3 was middle-aged patients with a variety of disease backgrounds. Endotype 1 showed activation of inflammatory responses as well as immunosuppression and suppression of metabolic functions including nucleic acid synthesis and mitochondrial function. Endotype 2 was characterized by activation of metabolic functions including lipid and steroid metabolism and leukocyte differentiation, in addition to activation of inflammatory and immune responses. Endotype 3 was characterized by a relatively low inflammatory response, immunosuppression including T-cell responses and antigen-presenting pathways, and suppression of metabolic functions including ribosome-related and RNA transcription. These analyses were generally replicated in the validation cohort, confirming consistent molecular pathogenetic features of each endotype.
Conclusions. Critical illnesses was classified into three endotypes based on molecular signatures across diseases based on gene expression profiles. Endotype 1 showed a high inflammation, low metabolism, and immunosuppressive pattern; endotype 2 showed a high inflammation, high metabolism, and immunoactive pattern; and endotype 3 showed a low inflammation, low metabolism, and immunosuppressive pattern.

Local validation of the STS risk score in adult rheumatic heart disease patients undergoing valve surgery at a tertiary hospital in the Philippines.

RB. Mendoza.[1]
[1]adult cardiology-critical care medicine, Philippine Heart Center, Quezon City, Philippines.
Correspondence: R.B. Mendoza.
Intensive Care Medicine Experimental*, *2025*;13(1)**: ***000677.

Introduction. The Society of Thoracic Surgeons (STS) risk model is widely used to estimate surgical outcomes in cardiac procedures. However, its applicability in populations with rheumatic heart disease (RHD), particularly in low- and middle-income countries (LMICs), remains unvalidated.
Objectives. To evaluate the predictive performance of the STS score for postoperative outcomes in adult RHD patients undergoing valvular surgery at a tertiary hospital in the Philippines.
Methods. A total of 245 adult RHD patients who had valve surgery between 2017 and 2023 were included in this retrospective cohort

analysis. In-hospital mortality, surgical morbidity, prolonged ventilation, acute renal failure, reoperation, stroke, and prolonged hospital stay were among the outcomes that were examined. Multivariable associations, calibration (Hosmer–Lemeshow test, O:E ratios), and discrimination (AUC) were used to evaluate predictive ability.
Results. In-hospital mortality was 11.02%, whereas morbidity was 66.12%. STS scores correlated significantly with adverse outcomes, yet showed poor discriminative ability (AUC < 0.70) and suboptimal calibration. Complex procedures (e.g., MVR + AVR) and comorbidities such as liver disease and renal failure were significant predictors of poor outcomes.
Conclusions. The STS score demonstrates limited predictive utility in RHD patients in LMIC settings. A recalibrated or novel, locally adapted risk model is recommended to improve surgical planning and patient counseling.

Clinical characteristics and prognostic implications of respiratory comorbidities in OHCA patients: a nationwide study

S. Kim[1]; TJ. An.[1]
[1]Division of Pulmonary, Allergy and Critical Care Medicine, Department of Internal Medicine, Yeouido St. Mary's Hospital, Seoul, Republic of Korea.
Correspondence: S. Kim.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000678***.

Introduction. Respiratory diseases are known risk factors for cardiovascular comorbidities, but their impact on outcomes after out-of-hospital cardiac arrest (OHCA) remains underexplored. Understanding the clinical characteristics and prognoses of OHCA patients with pre-existing respiratory diseases is crucial for improving post-arrest care and survival.
Objectives. To investigate differences in clinical features and post-resuscitation outcomes between OHCA patients with and without underlying respiratory diseases.
Methods. This retrospective cohort study used data from the Out-of-Hospital Cardiac Arrest Surveillance registry (2008–2023), provided by the Korea Disease Control and Prevention Agency. A total of 446,075 adult OHCA patients were included and categorized based on the presence (n = 22,407) or absence (n = 423,668) of pre-existing respiratory disease, which included asthma, COPD, tuberculosis, interstitial lung disease, and bronchiectasis. Baseline characteristics and clinical outcomes were compared between the groups. Cox proportional hazards models were applied to evaluate and compare predictors for 3-day and 1-year mortality according to the presence of respiratory disease, adjusting for age, sex, comorbidities, arrest characteristics, and in-hospital interventions. Subgroup analyses were performed among patients who survived to hospital admission (n = 66,500).
Results. Patients with respiratory disease were older (77 vs. 69 years; Table 1), had more comorbidities including hypertension, diabetes, heart disease, and renal disease, and experienced more witnessed arrests (53.3% vs. 45.1%). However, they presented with lower rates of initial shockable rhythm (6.8% vs. 13.0%) and received less AED use (11.9% vs. 18.6%). Respiratory causes of OHCA were significantly more prevalent in this group (9.1% vs. 0.3%). Despite slightly lower 1-day (81.8% vs. 85.0%) and 7-day mortality (88.0% vs. 89.2%), 1-year mortality was slightly higher in patients with respiratory disease (91.7% vs. 91.1%, p = 0.003). Kaplan–Meier curves showed the higher 7-day survival in patients with respiratory disease; however, this group exhibited lower survival rates at 90-days and 1-year (all log-rank p < 0.001; Fig. 1). In patients without pre-existing respiratory disease, older age, witnessed arrest, bystander CPR by EMS, non-shockable rhythm, and non-public arrest location were significant predictors of both 3-day and 1-year mortality in the overall cohort as well as in those who survived to admission (Table 2). Among patients with respiratory disease, these factors were also significantly associated with 3-day and 1-year mortality, except that non-shockable rhythm did not significantly affect mortality in those who survived to admission. Interventions such as CAG/PCI and TTM significantly reduced mortality in both groups, although their protective effects were attenuated in patients with respiratory disease.
Conclusions. OHCA patients with respiratory comorbidities had distinct clinical features. They demonstrated better short-term survival but slightly poorer long-term outcomes. Personalized post-resuscitation strategies are needed for this high-risk group, with particular attention to early identification of respiratory causes and targeted interventions.

***Intensive Care Medicine Experimental*, *2025*;13(1): *000679*.**

Introduction. Medication errors (ME) significantly impact patient safety and healthcare costs globally. Technologies such as Computerized Physician Order Entry (CPOE), Smart Pumps, Barcode Medication Administration (BCMA), and electronic Medication Administration Records (eMAR) have emerged to address this issue. This systematic review evaluates the cost-effectiveness of these technologies in reducing adverse drug events (ADE) and improving patient outcomes.
Methods. Following PRISMA guidelines, we included primary economic evaluations of CPOE, Smart Pumps, BCMA, and eMAR in hospitalized patients. Databases searched included PubMed, CINAHL, and Web of Science. Studies assessing cost-effectiveness, cost-utility, and cost–benefit analyses were reviewed. Data extraction focused on costs, effectiveness, and incremental cost-effectiveness ratios (ICER), analyzed through the JBI Dominance Ranking Matrix.

Results. Nine studies were included, predominantly from high-income countries. CPOE and Smart Pumps demonstrated cost-effectiveness in reducing ADE, with CPOE intercepting up to 96% of prescription errors and Smart Pumps preventing 86% of dose-related ADE. Cost savings ranged from €3.54 per ADE avoided with CPOE to €172,279 saved with Smart Pumps. Sensitivity analyses supported robust cost-effectiveness findings despite methodological heterogeneity.
Conclusions. CPOE and Smart Pumps are effective and economically viable in reducing ADE and improving safety outcomes in hospitals. Future research should address methodological gaps, including long-term patient and societal costs, to inform broader implementation strategies.

Outcomes of adult patients treated with extra-corporeal membrane oxygenation following major cardiac surgeries

JY. Kim[1]; K. Pil-Je.[1]
[1]Department of Thoracic and Cardiovascular Surgery, ASAN Medical Center, Seoul, Republic of Korea.
Correspondence: J.Y. Kim.
Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000683***.

Introduction. Postcardiotomy cardiogenic shock (PCS) occurs in 0.2% to 6% of patients undergoing cardiac surgery, with approximately 0.5% requiring venoarterial extracorporeal membrane oxygenation (VA-ECMO) support. Survival rates remain low, ranging from 25 to 44%.
Objectives. This study aimed to evaluate risk factors influencing early mortality in PCS patients requiring VA-ECMO following major cardiac surgery.
Methods. We conducted a retrospective analysis of 300 consecutive patients (mean age: 62.9 ± 13.4 years; 133 females) who underwent VA-ECMO for PCS between 2005 and 2021. The primary outcome was early mortality. Univariate logistic regression analyses were performed to identify factors associated with early mortality.
Results. Advanced age (RR: 1.03; 95% CI: 1.01–1.05; P < 0.001), higher BMI (OR: 1.08; 95% CI: 1.01–1.15; P = 0.016), postoperative continuous renal replacement therapy (CRRT) (OR: 5.24; 95% CI: 3.12–8.78; P < 0.001), bleeding control (OR, 1.45; 95% CI, 1.01–2.07; P = 0.416) and RBC transfusion (OR: 1.13; 95% CI: 1.07–1.19; P < 0.001) were significantly associated with increased early mortality. ECMO-related complications included mediastinal bleeding in 172 patients (57.3%), reoperation for bleeding in 131 patients (43.7%), lower limb ischemia in 33 patients (11.0%), and cannulation-related complications in 36 patients (12.0%).
Conclusions. This study identifies advanced age, higher BMI, postoperative CRRT, inadequate bleeding control, and RBC transfusion as significant risk factors for early mortality in PCS patients requiring VA-ECMO. Effective management of these high-risk patients should prioritize meticulous bleeding control during surgery and timely intervention for postoperative bleeding, which could help minimize RBC transfusion and improve clinical outcomes.

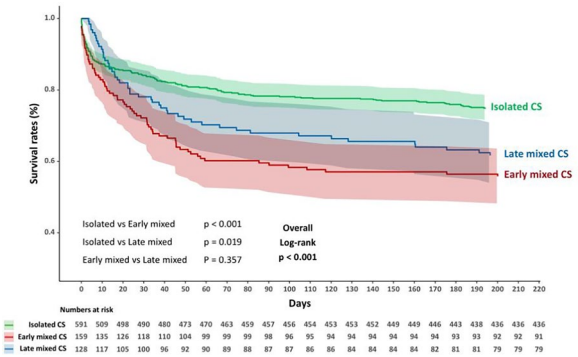
Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000684***.

Introduction. Mixed cardiogenic shock (CS) is defined as CS with at least one additional contributing cause to the shock. A considerable proportion of patients admitted to cardiac intensive care units (CICUs) present with mixed CS. [1,2] Infections are common predisposing factors for mixed CS due to their contribution to systemic vasodilation, however, data on the prognosis of mixed CS complicated by infection remain limited. This study compared the clinical picture and outcomes of isolated CS and mixed CS, stratified by the timing of infection.
Methods. We analyzed 878 adult CS patients admitted to a cardiac intensive care unit (CICU) providing level 1 critical care services

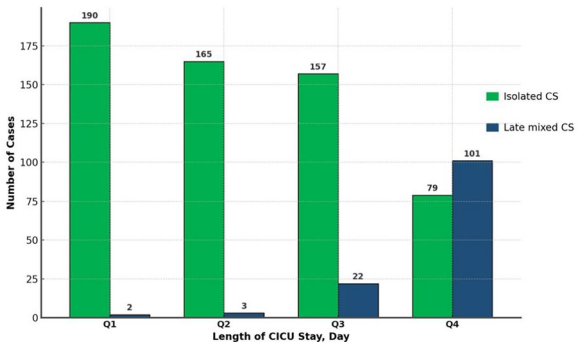
between 2012 and 2020. Patients were classified as isolated CS (non-infected), early mixed CS (infection identified within 48 h of CICU admission), and late mixed CS (infection identified after 48 h of CICU admission). The primary outcome was in-hospital mortality.

Results. Of 878 patients, 591 (67.3%) had isolated CS, while 287 (32.7%) had mixed CS (early: 18.1%; late: 14.6%). Demographics including etiology of CS were comparable across all groups. Pneumonia was the most common infection in mixed CS. Mixed CS patients experienced prolonged mechanical ventilation (isolated: 2.2 vs. early: 4.7 vs. late: 9.5 days; $p < 0.001$), and indwelling catheterization (2.0 vs. 7.0 vs. 25.2 days; $p < 0.001$). In late mixed CS patients, an increasing trend of nosocomial infection was observed with increasing of total catheterization day and CICU length of stay. In-hospital mortalities in both mixed CS groups were higher than in isolated CS (both $p < 0.001$), with no significant difference between early and late mixed CS. Survival rates were also a similar pattern during the follow-up. (In the tables below, groups with different letters are significantly different ($p < 0.05$)).



Conclusions. Mixed CS complicated by infection showed worse clinical outcomes than isolated CS, irrespective of the infection timing. Further research is needed to develop targeted treatment strategies tailored to this condition.

Cardiac intensive care unit management



Variable	Isolated CS (n = 591)	Early mixed CS (n = 159)	Late mixed CS (n = 128)	P-value

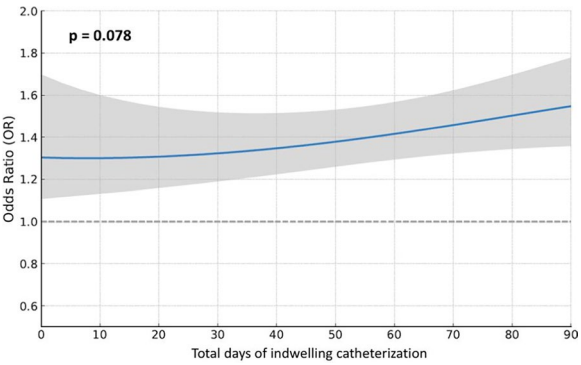
Length of support, day	2.2 (1.0–4.8)a	4.7 (2.0–14.4)c	9.5 (4.8–15.6)b	< 0.001
CRRT				< 0.001
Known ESRD	22 (3.7)a	11 (6.9)a, b	11 (8.6)b	
Newly started	106 (17.9)a	67 (42.1)b	48 (37.5)b	

Clinical event and outcomes during CICU stay

Variable	Isolated CS (n = 591)	Early mixed CS (n = 159)	Late mixed CS (n = 128)	P-value
CICU mortality	90 (15.2)a	52 (32.7)b	39 (30.5)b	< 0.001
CICU length of stay, day	3.1 (1.9–6.0)a	6.2 (3.0–13.9)c	15.9 (9.9–23.5)b	< 0.001
CICU readmission	116 (19.6)a	48 (30.2)b	31 (24.2)a, b	< 0.001
In-hospital mortality	114 (19.3)a	59 (37.1)	44 (34.4)b	< 0.001
Hospital length of stay, day	12.7 (6.5–28.0)a	26.3 (12.0–61.0)c	41.7 (17.5–73.5)b	< 0.001



Kaplan–Meier curves illustrate the differences in survival rates among the three groups. Isolated CS exhibited better survival rates compared to both mixed CS groups. While the overall log-rank test yielded a statistically significant p-value, post hoc analysis revealed no statistically significant difference in survival rates between the late and early mixed CS groups.

When the total CICU stay duration was divided into quartiles, the late mixed CS cases first emerged in the third quartile, with a reversal in the proportions of late mixed CS and isolated CS observed in the fourth quartile

.

A spline curve presenting the relationship between total indwelling catheterization duration and hospital mortality in patients with late mixed cardiogenic shock. The curve shows an increasing trend of odds ratio observed across the duration spectrum, however, there was no

statistically significant association between total catheterization duration and mortality risk (p = 0.078)

Introduction. Sepsis, defined as life-threatening organ dysfunction due to a dysregulated host response to infection [1], affects over 19 million patients annually with mortality rates of 25–45% [2]. Early assessment using tools like APACHE II [3] and SOFA [1] is critical but limited by complexity and reliance on lab results [4]. Simplified systems (qSOFA, NEWS, MEWS) enable rapid bedside evaluation [5], yet their prognostic accuracy and consensus on clinical use remain debated [6]. Current tools focus on organ function but neglect infection-specific factors, necessitating integration of personalized infection characteristics for tailored interventions [7].
This study aims to develop a machine learning-based prognostic tool using a Chinese sepsis database, validated externally via MIMIC-IV and eICU-CRD, to enhance early risk stratification. Additionally, combining risk assessment with antibiotic selection, patients are stratified by mortality risk, enabling comparative evaluation of antibiotic regimens within homogeneous risk groups. This approach addresses empirical antibiotic challenges, balancing efficacy against resistance risks, particularly for moderate/high-risk patients.
Objectives. Developing a new accurate severity and prognostic model is crucial for early intervention and improved septic patient management.
Methods. A nation-wide Chinese Single-Disease Database of Sepsis (internal cohort) was retrospectively studied. Septic Risk Stratified (SRS) system was developed from the internal training cohort. The risk factors of SRS were selected by machine learning. Validation was performed in the internal, the Medical Information Mart for Intensive Care (MIMIC-IV) and eICU Collaborative Research Database (eICU-CRD) cohort. Evaluation metrics included discrimination (area under the ROC curve [AUROC]) and calibration. Three risk strata were identified and validated in all cohorts. We further investigated antibiotic usage across different RSR strata to understand the effectiveness of various antibiotic regimens in patients with respiratory infection in different sepsis risk levels.
Results. The study analyzed 116,852, 18,407, and 9,816 sepsis patients in the internal, MIMIC-IV, and eICU-CRD cohorts, respectively, with in-hospital mortality rates of 36.1%, 18.2%, and 17.1%. Initial lactate level, infection foci, PaO2/FiO2, age, Creatinine, Temperature, Norepinephrine, Glasgow coma scale (GCS), urinary infection foci, heart rate (HR), respiratory rate (RR), body mass index (BMI), Platelet, and white blood cell count (WBC) were included in RSR in the descending order of impacts. In the internal holdout validation cohort, the AUROC of RSR is 0.80 (95% CI 0.79 to 0.80). External validation showed that the RSR significantly outperformed the SOFA (internal validation: 0.80 vs. 0.67, p < 0.001; MIMIC-IV: 0.68 vs. 0.67, p = 0.01; eICU-CRD 0.73 vs. 0.70, p < 0.001) and APACHE II (internal validation: 0.80 vs. 0.66, p < 0.001; MIMIC-IV: 0.68 vs. 0.63, p = 0.002, eICU-CRD: 0.73 vs. 0.70, p < 0.001). In addition, our findings suggest tailored antibiotic strategies that could improve patient outcomes. Respiratory sepsis with Moderate Risk showed that Beta-lactam combined with quinolones had a protective effect compared to beta-lactam inhibitors alone. Carbapenems and glycopeptides were less effective compared to beta-lactam inhibitors alone.
Conclusions. The RSR system is a rapid and accurate severity and prognostic tool for early assessing in-hospital mortality risk in sepsis patients. The extended analysis of antibiotic usage in RSR-stratified patients underscores the importance of tailored antibiotic therapies for the Moderate Risk with respiratory sepsis.

Effect of positive pressure in airways on inspiratory thoracic cage excursion force: study on healthy volunteers

V. Vicka[1]; M. Aukstuolyte[1]; G. Balciunaite[1]; D. Trybe[1]; E. Strumiliene[2]; J. Bubulytė-Gavrilovė[3]; J. Sipylaite.[1]
[1]Clinic of Anaesthesiology and Intensive Care, Institute of Clinical Medicine, Faculty of Medicine, Vilnius University, Vilnius, Lithuania; [2]Clinic of Infectious Diseases and Dermatovenerology, Institute of Clinical Medicine, Faculty of Medicine, Vilnius university, Vilnius, Lithuania; [3]Vilnius university Hospital Santaros Clinics, Vilnius university, Vilniius, Lithuania.
Correspondence: V. Vicka.
***Intensive Care Medicine Experimental*, *2025*;13(1): *000687*.**

Introduction. Increased effort of breathing (EOB) in spontaneously breathing patients can be deleterious and lead to worse clinical consequences. Inspiratory thoracic cage excursion force (iTCEF) is a potential marker of EOB. Non-invasive ventilation (NIV) has been proved to decrease EOB.
Objectives. Aim of this study is to determine how iTCEF changes with positive pressure in the airways.
Methods. Study on healthy volunteers with no prior medical conditions was planned. EOB was measured with force sensitive respiration belt (Go Direct® Respiration Belt, Vernier, USA), iTCEF was registered as maximum (newtons), mean (newtons) and inspiratory time product (newtons sq/sec). NIV was generated with face mask and 5 cm water of PEEP and 7 cm of PS, FiO2 21%. iTCEF was registered in normal and NIV conditions. Statistical analysis was carried out with IBM SPSS statistics v23.
Results. Study on 30 healthy volunteers was conducted, data analysed of 28 of them due to fault in data gathering (age 23.89 ± 3.13, men 21.4%). No changes in spirometry evaluation were detected in any of the subjects prior the test. Three consecutive breaths were recorded with NIV and no NIV. Increase in all iTCEF parameters was noted with NIV: mean value (2.18 ± 1.02 vs 6.61 ± 4.67 $p < 0.001$, + 230%), maximum value (5.06 ± 2.40 vs 15.19 ± 12.53 $p < 0.001$, + 216%), newton time product (4.41 ± 3.51 vs 15.00 ± 17.11 $p = 0.001$, + 304%).
Conclusions. Increase in iTCEF is evident when NIV is applied. This is a likely finding if positive pressure is added and transferred to inspiration mechanics. Unfortunately, it is not possible to differentiate patient own efforts and machine pressure comparing mean, maximum and time product of inspiratory newtons.

ICU Outcomes in sepsis and septic shock: insights from a retrospective cohort study

M. Neves[1]; J. Abreu[1]; R. Rato[1]; D. Silva[1]; P. Costa[1]; N. Lourenço[1]; J. Gabriel.[1]
[1]Intensive Care Department, Hospital Amato Lusitano, Castelo Branco, Portugal.
Correspondence: M. Neves.
***Intensive Care Medicine Experimental*, *2025*;13(1)**: ***000688*.**

Introduction. Sepsis and septic shock remain major causes of ICU admission and are associated with substantial mortality and resource utilization. Despite standardized management protocols, outcomes—particularly in septic shock—continue to be unsatisfactory.
Objectives. To describe the clinical characteristics, therapeutic interventions and outcomes of ICU patients with sepsis or septic shock, and to identify factors associated with ICU mortality.
Methods. This retrospective unicenter cohort study analyzed adult patients admitted to the ICU of a secondary hospital in Portugal, from July 2023 to December 2024 with a diagnosis of sepsis or septic shock, based on Sepsis-3 definitions. Data collected included demographics, infection source, APACHE II scores, antimicrobial timing, use of organ support (vasopressors, mechanical ventilation, renal replacement therapy), and ICU outcomes. The primary outcome was ICU mortality; secondary outcomes included ICU length of stay and requirement for organ support. Statistical analyses were performed using SPSS software,
Results. A total of 186 patients were included: 102 with sepsis and 84 with septic shock. Median age was 64 years (IQR 54–75); 58% were male. Predominant infection sites were respiratory (42%), intra-abdominal (25%), and urinary tract (14%). The septic shock group had a higher median APACHE II score (23 vs. 9, $p < 0.001$). Broad-spectrum antibiotics were initiated within 1 h in 70% of cases. As implied in the definition, all septic shock patients received vasopressors. Mechanical ventilation was used in 63% of cases; 22% received renal replacement therapy. Overall ICU mortality was 34%, significantly higher in the septic shock group (45%) versus the sepsis group (18%, $p < 0.001$).
Conclusions. Mortality and organ support requirements remain high in patients with septic shock. Timely antimicrobial therapy and early hemodynamic resuscitation are critical. These findings support the importance of early sepsis recognition and adherence to established ICU protocols to improve outcomes.

Early prediction of sepsis using multimodal clinical data and AI-driven analysis: a step towards reducing antimicrobial overuse

I. Zorzos[1]; A. Kari[1]; S. Liliopoulos[1]; S. Vlachos[2]; V. Dimakopoulos[1]; I. Gkouzionis.[1]
[1]Research & Development Dept., Aisthesis Medical Ltd, London, United Kingdom; [2]Critical Care, King's College Hospital, London, United Kingdom.
Correspondence: S. Liliopoulos.
***Intensive Care Medicine Experimental*, *2025*;13(1)**: ***000690*.**

Introduction. Sepsis remains a leading cause of morbidity and mortality in hospitalized patients worldwide. While timely antimicrobial therapy is critical to improving patient outcomes, its overuse contributes to the growing threat of antimicrobial resistance (AMR), ultimately undermining the effectiveness of future treatments. These competing challenges highlight the urgent need for a reliable, early detection tool to enable timely and targeted therapeutic interventions.
Objectives. The primary objective of this study was to develop and validate an artificial intelligence (AI) model capable of predicting sepsis onset substantially earlier than current clinical practices allow. By identifying at-risk patients during a clinically relevant time window, our aim is to enable precise antimicrobial stewardship while reducing the misuse of broad-spectrum agents.
Methods. Data were retrospectively analysed from the MIMIC-IV database [1]. We incorporated high-frequency vital signs recorded in hourly intervals, less frequent laboratory test results, and static patient descriptors such as demographics and comorbidities. Sepsis-3 [2] and the suspicion of infection time was used to label the sepsis onset. A 6-h observation window was used to forecast sepsis risk within the subsequent 48-h period, reflecting the practical need for early, actionable insights. Using a sliding window method, a total number of 690,051 window samples were created, with 60% of them being positively labeled. Preprocessing techniques included forward-filling for missing values, imputation methods for underrepresented laboratory measurements, normalization of continuous features, and one-hot

encoding of categorical variables. We implemented a multi-view convolutional neural network (CNN) and evaluated its performance through a fivefold cross-validation analysis.

Results. Preliminary evaluations on mixed-patient cohorts demonstrated high accuracy, achieving an area under the receiver operating characteristic curve (AUROC) of 0.94 ± 0.003. Under a more stringent leave-group-out approach intended to mimic real-world deployment, the model maintained strong predictive capability with an AUROC of 0.86 ± 0.009. These findings illustrate the system's potential as a clinical decision-support tool for timely and targeted interventions, as well as the importance of rigorous evaluation to ensure real-world applicability.

Conclusions. An AI-driven model that uses multimodal clinical data may enhance early sepsis detection, enabling earlier clinical intervention according to international guidelines like the CMS SEP-1 [3], [4], thereby supporting the targeted use of antimicrobials and reducing the risk of AMR. Ongoing work involves refining the model with additional data sources such as clinical notes and imaging reports, conducting prospective validations, and an automated alignment of the tool with site-specific stewardship protocols for optimized antimicrobial management.

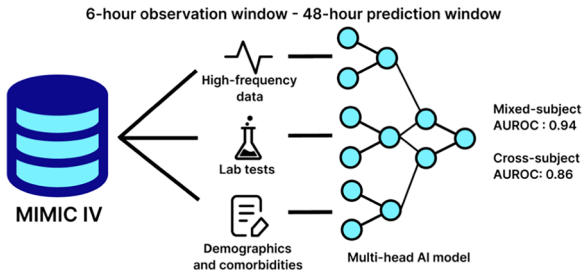

Fig 1 (abstract 000690) The proposed sepsis prediction framework. The model utilizes MIMIC-IV data to integrate high-frequency physiological signals, lab test results, and static patient descriptors (e.g., demographics and comorbidities) within a 6-h observation window to predict sepsis risk over a 48-h horizon. A multi-head AI architecture demonstrates robust performance, achieving an AUROC of 0.94 in mixed-subject evaluations and 0.86 in cross-subject evaluations, supporting its potential as a clinical decision-support tool.

Correlation of serum copeptin: c-reactive protein and procalcitonin levels with APACHE II score in sepsis

A. shami[1]; M. Thakur.[1]
[1]Medicine, VMMC & Safdarjung Hospital, New Delhi, India.
Correspondence: A. shami.

Intensive Care Medicine Experimental*, *2025*;13(1)**: ***000692.

Introduction. Sepsis affects nearly 48.9 million globally and accounts for 19.7% of deaths, with higher mortality in developing countries like India (27.6%, 33.2% Sepsis-3 positive) [1]. Rapid progression demands timely management and accurate prognostic tools. APACHE II remains a standard for sepsis assessment [2], but novel biomarkers like copeptin are gaining interest. Copeptin, derived from pre-pro-vasopressin, rises in early sepsis with hemodynamic stress [3], and unlike AVP, remains stable even in late stages [4]. It reflects AVP secretion accurately due to equimolar release [5], and is significantly elevated in septic shock (59–1572 pmol/l vs. 0.3–18 pmol/l in controls) [6]. CRP, induced by IL-6, rapidly increases in early sepsis from baseline < 8 mg/L [7]. PCT, a calcitonin precursor, normally < 0.05 ng/mL, surges to 1000 ng/mL in severe bacterial sepsis [8]. PCT aids in early detection, severity assessment, and guides antimicrobial therapy [9]. This study addresses limited Indian data on copeptin by evaluating its levels with CRP and PCT, correlating them with APACHE II scores.

Methods. This prospective observational study was conducted at Vardhman Mahavir Medical College & Safdarjung Hospital, a tertiary care level hospital in New Delhi over a period of 18 months and involved 46 patients over the age of 18 years diagnosed with sepsis according to sepsis-3 criteria [1]. Serum copeptin, CRP and PCT were measured within the first 24 h (day 1), 48 h (day 2) and 72 h (day 3). Survival at 28 days after admission was recorded.

Results. This study involved 46 patients (median age 51; 50% male/female); 63.04% died and 36.96% survived. APACHE II scores ranged widely, with most between 5 and 29. Procalcitonin, CRP, and copeptin levels were elevated throughout days 1–3, with copeptin rising from 38.02 ± 33.73 to 44.05 ± 46.43 ng/mL (Table 1). Copeptin correlated increasingly with APACHE II scores (r = 0.099 to 0.664; $p < 0.0001$) and significantly predicted mortality from day 2 onward (AUC day 3 = 1.0; 100% sensitivity/specificity at > 25.1 ng/mL) (Fig. 1). Non-survivors had significantly higher APACHE II scores and copeptin levels, especially on days 2 and 3 ($p < 0.0001$).

Table 1: (abstract 000692)—Descriptive statistics of copeptin at various time intervals

Copeptin(ng/mL)	Mean ± SD	Median (25th-75th percentile)	Range
At day 1	**38.02 ± 33.73**	**29(25.7–37)**	**8.5–200**
At day 2	**41.93 ± 42.26**	**34.75(22.275–40.375)**	**10.5–245**
At day 3	**44.05 ± 46.43**	**40.7(19–46.225)**	**8–262**

Conclusions. Our investigation revealed that copeptin levels, especially on days 2 and 3, are highly accurate predictors of mortality. The progressive improvement in predictive accuracy highlights the value of serial monitoring in critically ill patients. On day 3, copeptin levels > 25.1 ng/mL perfectly distinguished survivors from non-survivors (AUC = 1, p < 0.0001), with 100% sensitivity and specificity. On day 2, at a cutoff > 29 ng/mL, sensitivity was 93.1% and specificity was 94.12%. Day 1 showed weaker performance, with a cutoff > 43 ng/mL yielding 31.03% sensitivity but 100% specificity. These findings suggest copeptin as a useful marker for predicting sepsis-related mortality. The limitation of our study was that it was a single-center prospective observational study with a small sample size.

Introduction. The microbiome plays a crucial role in trauma recovery through interactions with host immunity. This study investigated microbiome dynamics in both drainage fluid and fecal samples during patient transition from ICU to ward settings to identify potential biomarkers associated with recovery stages.
Methods. We analyzed samples from 18 trauma patients treated at Chonnam National University Hospital Trauma Center (May 2023-June 2024), collecting 27 drainage samples from 12 surgical patients and 30 fecal samples from all 18 patients. Using 16S rDNA amplicon sequencing, we examined microbial diversity across recovery stages. Linear mixed-effects models were employed to identify significant microbes while accounting for clinical variables, with ROC analysis validating their predictive potential. Functional pathways were analyzed using PICRUSt2.
Results. Microbial compositions differed significantly between sample types (R = 0.663, p = 0.001). Alpha diversity indices in drainage samples decreased during the ward stage compared to the ICU stage for observed species and Chao1 indices. In drainage samples, nine genera and six species showed significant differences between stages, with *Enterococcus hirae* (AUC = 0.712), *Gaiella occulta*, and *Capillimicrobium parvum* decreasing in the ward stage. In fecal samples, 26 genera and 32 species differed significantly, with *Sutterella* (AUC = 0.962) and *Peptoniphilus faecalis* (AUC = 0.865) showing increased abundance during the ward stage. Functional pathway analysis revealed that L-arginine biosynthesis and menaquinol-8 biosynthesis pathways were more pronounced in the ICU stage, while S-adenosyl-L-methionine biosynthesis increased in the ward stage for both sample types.
Conclusions. This study suggests distinct microbiome signatures in drainage fluid compared to fecal samples, with specific microbial changes across recovery stages. The identified microbes show potential as candidate biomarkers for monitoring recovery status, with *E. hirae* in drainage fluid and *Sutterella* in fecal samples demonstrating promising predictive capability. While our findings provide initial insights into site-specific microbiome dynamics during trauma recovery, validation in larger, independent cohorts is necessary before clinical application.

Microbiome Dynamics in Drainage Fluid and Fecal Samples During Trauma Recovery

Introduction. Clustering algorithms have identified four distinct metabolic phenotypes in critically ill patients with vitamin D deficiency. This study aimed to predict these metabolic phenotypes using a machine learning classifier model trained on clinical data in place of metabolomics data.
Objectives. To develop and evaluate a machine learning classifier model for predicting metabolic phenotypes using clinical data from the Vitamin D Deficiency in Critically Ill Patients (VITdAL-ICU) trial.
Methods. We employed a gradient boosting model with tenfold cross validation. Our objective variable was the four previously identified metabolic phenotypes. First, we developed Model 1 incorporating all

demographic and laboratory variables as predictor variables. Then, we identified variable importance and extracted key predictors. Model 2 used the top 10 relatively important variables, while Model 3 incorporated the most commonly available variables that had high relative importance. We evaluated predictivity of Models 1, 2, and 3 with accuracy and area under curve (AUC) using bootstrapping methods. Finally, we investigated the associations between the treatment effect of vitamin D supplementation and 180-day mortality in each predicted phenotype.

Results. Model 1 demonstrated high accuracy of 100% (95% CI, 0.99–1.00) for predicting metabolic phenotypes. In Model 1 we identified more relatively important demographic and laboratory variables (Fig. 1 and 2). Model 2 using the top 10 relatively important variables (Fig. 1) showed an accuracy of 88% (95% CI, 0.85–0.91) with an AUC of 0.99 (95% CI, 0.98–0.99). Model 3 using the most commonly available variables (Fig. 2) showed an accuracy of 85% (95% CI, 0.81–0.88) with an AUC of 0.97 (95% CI, 0.96–0.98). Although the treatment effects of vitamin D supplementation in predicted phenotypes via both Model 2 and 3 were similar directions to that observed in identified metabolic phenotypes, the effects of vitamin D supplementation were not significant regarding 180-day mortality (predicted phenotype A: Odds ratio (OR) 1.14 [95%CI 0.57–2.26]; predicted phenotype B: OR 0.55 [95%CI 0.27–1.12]; predicted phenotype C: 0.62 [95%CI 0.23–1.69]; predicted phenotype D: OR 0.57 [95%CI 0.25–1.32], via Model 3).

Conclusions. We developed a machine learning classifier model using demographic and laboratory data to predict the four metabolic phenotypes with high predictivity. Further validation studies are needed as a next step to utilize clinical data to identify metabolic phenotypes.

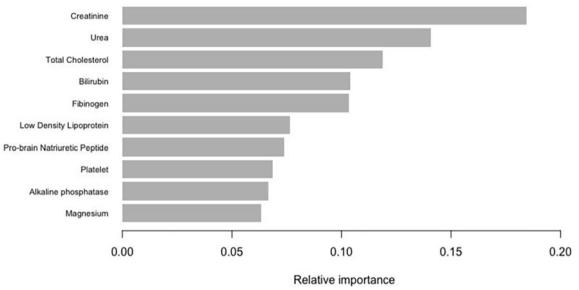

Fig 1 (abstract 000694) Top 10 relatively important demographic and laboratory variables

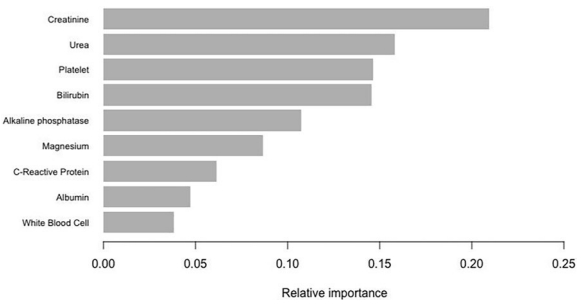

Fig 2 (abstract 000694) Most commonly available variables with high relative importance

Septic shock: analysis of mortality in an intensive care unit of a regional hospital

A. Alonso[1]; J. Garcia[1]; J. Gómez[1]; M. Salgado[1]; A. Alvarez[1]; A. Ubeda.[1]
[1]Intensive care unit, Hospital Punta de Europa, Algeciras, Spain.
Correspondence: A. Ubeda.
Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000695***.

Introduction. Sepsis is a state of multisystem dysfunction, which is caused by a dysregulated host response to infection. Several factors influence the severity, clinical manifestations and progression of sepsis.

Objectives. To analyze the factors associated with mortality in patients diagnosed with septic shock (SS) in the Intensive Care Unit of Punta de Europa University Hospital.

Methods. Retrospective descriptive analysis of a prospective cohort conducted in a 12-bed ICU between 2019 and 2024. Demographic variables, comorbidities, severity scores, treatment received, mechanical ventilation (MV), risk factors, ICU infections, antibiotic therapy, ICU and hospital stay were analyzed. Statistical analysis: categorical variables (frequencies and percentages) and quantitative variables (mean and standard deviation or median and interquartile range). Comparisons: χ test (percentages), Student's t test (means), and Mann–Whitney U test (medians). Multivariate logistic regression was used. Statistical significance at $p < 0.05$.

Results. 432 patients were included. Non-SS (n = 133) vs. SS (n = 299). SAPS II (32 [24; 49] vs. 39 [27; 53.5], p = 0.049). GCS (15 [7; 15] vs. 15 [13; 15], p = 0.028). Comorbidity: neoplasia (11.3% vs. 24.4%, p = 0.003). Infection (p < 0.001): secondary bacteremia (6% vs. 21.7%), CRB/unknown source (4.5% vs. 19.1%), abdominal infection (4.5% vs. 13%), UTI-SU (8.3% vs. 4.3%), VAP (18% vs. 7.7%).

Mortality analysis: alive (n = 152) vs. dead (n = 147). Sex: male (50.6% vs. 67.3%, p = 0.005). APACHE II (13 [9;18] vs. 15 [11; 20.5], p = 0.005). SAPS II (36 [25;50] vs. 41 [28;58], p = 0.041). Risk factors: neutropenia (3.9% vs. 10.2%, p = 0.042), RRT (9.2% vs. 31.9%, p < 0.001), MV (51.3% vs. 87.7%, p < 0.001), SU (96% vs. 100%, p = 0.029), tracheostomy (9.9% vs. 23.1%, p = 0.003). Comorbidities: DM (25% vs. 38.8%, p = 0.015). Infection (p < 0.001): secondary bacteremia (23% vs. 20.3%), CRB/unknown focus (10.5% vs. 27.9%), abdominal infection (17.1% vs. 8.8%), UC-infection (4.6% vs. 4.1%), VAP (4.6% vs. 10.9%). MV time (1 [0; 8] vs. 9 [3; 17], p < 0.001). ICU stay (7 [4; 13] vs. 12 [5; 21], p = 0.001). Multivariate logistic regression: RRT (OR 3.79 [1.87–8.07], p < 0.001), DM (OR 2.09 [1.15–3.87], p = 0.017), MV time (OR 1.21 [1.13–1.31], p < 0.001), intra-ICU infection (OR 2.55 [1.36–4.86], p = 0.004), ICU stay (OR 0.87 [0.81–0.92], p < 0.001).

Conclusions. Mortality in patients with septic shock was high (41%). RRT, diabetes, MV time, intra-ICU infection, and ICU stay were independently associated with mortality in septic shock in our patients.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000696***.

Introduction. Early Warning Scores (EWS) utilizing vital signs enable the early detection and intervention of clinical deterioration in hospitalized patients. However, vital signs recorded in electronic medical records often include outliers or missing values due to input errors or technical issues. Appropriate correction of these abnormal values is essential for accurate scoring, yet little research has been conducted on the optimal correction methods.
Objectives. To develop and evaluate an optimal algorithm for correcting outlier and missing values in vital signs used for EWS calculation, with the goal of improving the predictive performance of EWS for unexpected ICU admissions and in-hospital mortality.
Methods. We analyzed data from adult patients admitted to general wards between June 1, 2023, and February 29, 2024. Two EWS systems were assessed: the Visensia Safety Index (VSI) and the Modified Early Warning Score (MEWS). The target events were unexpected ICU admissions or death. EWS performance was evaluated by determining whether an alert was triggered within 12 h prior to an event. Sensitivity (Sn) and positive predictive value (PPV) were calculated. Two algorithms were compared for outlier and missing values correction (Fig. 1):
Method 1: The most recent set of vital signs within the specified time window (3, 6, 12, or 24 h) prior to score calculation.
Method 2: Search up to 24 h back and use a value recorded within a specified time window (3, 6, 12, or 24 h) prior to the first detected value.
Results. We analyzed data from 16,486 patients. The incidence of unexpected ICU admission was 2.1%, and in-hospital mortality was 1.9%. For VSI, Method 1 yielded a sensitivity of 40.8% and a PPV of 5.84%. Method 2 improved sensitivity to 43.7% with a PPV of 5.74%. While PPV remained similar, sensitivity increased by approximately 3%. MEWS showed a similar trend: Method 1 had a sensitivity of 30% and PPV of 15.5%, whereas Method 2 improved sensitivity to 32% and PPV was 15.6%. Thresholds of VSI = 3 and MEWS = 7 were applied. Among variations of Method 2, a 24-h look-back period and a 6-h correction window was found to be the most effective setting (Fig. 2).
Conclusions. Correcting abnormal vital sign values using a defined time-window-based algorithm improved the sensitivity of EWS compared to simply using the most recent value. Implementation of this algorithm could enhance the accuracy of clinical decision support systems in general wards.

Method 1 The most recent set of vital signs within the specified time window (3, 6, 12, or 24 h) prior to score calculation

Method 2: Search up to 24 h back and use a value recorded within a specified time window (3, 6, 12, or 24 h) prior to the first detected value
'24–none' indicates using the latest available value within the 24-h look-back period.
'24–6' refers to using the most recent value within 6 h after the latest value found by looking back 24 h.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000698***.

Introduction. Sepsis-induced coagulopathy (SIC) is a life-threatening complication of sepsis. Excessive activation of monocyte-mediated immunothrombosis is the predominant mechanism underlying SIC. While prior flow cytometry (FCM)-based investigations have implicated distinct contribution of CD14 + and CD16 + monocyte in SIC pathogenesis, the limited resolution of FCM in delineating functionally heterogeneous subpopulation promoted the employment of single-cell RNA sequencing (scRNA-seq) for deeper molecular characterization. This approach allows precise identification of monocytes subpopulations and their potential roles in SIC.
Objectives. This study aimed to characterize the monocyte atlas in SIC.
Methods. A prospective cohort study was implemented for Sepsis-3.0-diagnosed patients in 2023 at the intensive care unit of Zhongda Hospital, with retrospective analysis of mHLA-DR (HLA-DR + /CD14 +) expression in septic cases from 2016 to 2022 [1]. Sepsis patients were categorized into two groups according to the SIC diagnostic criteria:

non-SIC (NSIC) group and SIC group [2]. Peripheral blood mononuclear cells from healthy controls (HC), SIC and NSIC patients were analyzed by scRNA-seq, with subsequent dimensionality reduction, clustering, and cell type annotation. Differential gene expressions were performed to identify functional features of distinct subpopulation. Cell Chat was used to decode intercellular signaling networks. The target subpopulation was validated by peripheral blood from sepsis patients.
Results. We identified 5 major cell types and 22 subpopulations in scRNA-seq analysis of PBMC from HC, SIC and NSIC group. Monocyte-DC compartment showed a significantly higher proportion in both SIC and NSIC groups compared to HC group. Cell Chat analysis indicated enhanced communication between monocyte-DC and platelets in the SIC group relative to the NSIC group, suggesting a key role of monocyte in thrombosis. To characterize the heterogeneous subpopulations of monocyte, we performed secondary dimensional reduction found that Monocyte-DC cells were classified into 9 subpopulations. Remarkably, the proportion of LGALS2 + CD14 + monocytes in CD14 + and global monocytes were significantly lower in SIC group compared to NSIC and HC groups. Meanwhile, LGALS2 + CD14 + monocytes showed a high level of HLA-DRA. To further demonstrate the association of LGALS2 + CD14 + monocytes and SIC, we conducted retrospective analysis of HLA-DR + /CD14 + in sepsis patients and found significantly reduced HLA-DR + /CD14 + expression in SIC group. The mRNA levels of LGALS2 in blood samples from SIC group were also significantly lower than NSIC group.
Conclusions. Our study employed single-cell resolution analysis to characterize SIC. We have identified a new monocyte subpopulation LGALS2 + CD14 + monocytes associated with SIC, and the specific function of this subpopulation in SIC needs to be further verified. These findings provide a conceptual advance for elucidating the molecular mechanisms underlying SIC pathogenesis.

High levels of patient–ventilator asynchrony caused by flow insufficiency is associated with poor outcomes in patients with covid-19: application of a digital mechanical ventilation monitoring platform in intensive care unit (ICU).

X. Chen[1]; S. Yuan[1]; Y. Chi[1]; S. Liu[1]; F. Cai[2]; Y. Li[2]; L. Su[1]; Y. Long.[1]

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000701***.

Introduction. Patient-ventilator asynchrony (PVA) is common in mechanically ventilated critically ill patients, the monitoring of which is valuable and urges advanced technology. This study reported the refined monitoring platform by our group that achieved the real-time identification of eight types of PVAs, and explored the relationship between the frequency of various PVAs and the mortality of corona virus disease 2019 (COVID-19) patients.
Objectives. This study investigated the correlation between dynamic patient-ventilator asynchrony and prognosis in intensive care unit (ICU) patients with COVID-19.
Methods. This is a retrospective study based on the ventilatory monitoring data of 23 patients with COVID-19. The study ran from December 2022 to August 2023 and the research data were gathered from Peking Union Medical College Hospital (PUMCH). Gross and individual indexes of dynamic asynchrony, which included eight types of PVA (ineffective trigger, auto trigger, double trigger, reverse trigger, flow insufficiency, overshoot, premature cycle, and delayed cycle), were analyzed to find the correlation between PVA and prognosis.
Results. 23 patients were included in this study. No correlation was found between the index and ventilatory parameters, compliance, and disease severity. Patients with dynamic asynchrony index (DAI) > 10% were more likely to have fewer 28d ventilator-free days (VFD) (1.33d vs 11.4d, p = 0.027) and were demonstrated to have a higher ICU mortality (66.7% vs 18.2%, p = 0.036). Among eight types of PVA, flow insufficiency was found to be associated with prognosis (p = 0.012).
Conclusions. DAI correlated with the prognosis of COVID-19 patients. Patients with a DAI ≥ 10% were more likely to have fewer 28d VFDs and higher ICU mortality. The index of flow insufficiency was associated with prognosis, as those with a higher prevalence of flow insufficiency were prone to ICU death.

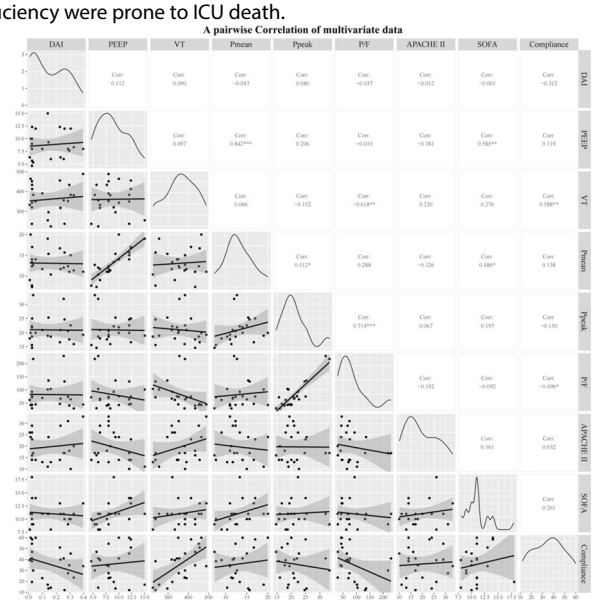

Fig 1 (abstract 000701) Pairwise correlations among DAI, ventilatory parameters, respiratory compliance, and disease severity. Each cell in the matrix displays a scatterplot and correlation coefficient (Corr), ranging from -1 to 1, indicating the strength and direction of the relationship between two variables. The diagonal of the matrix shows the distribution of each variable, including density curves and central tendency. Pmean correlated positively with PEEP (r = 0.842, p < 0.001), Ppeak (r = 0.512, p < 0.05), and SOFA (r = 0.0.486, p < 0.05). P/F correlated positively with Ppeak (r = 0.714, p < 0.001), and negatively with VT (r = -0.618, p < 0.01) and compliance (r = -0.496, p < 0.05). DAI did not correlate with other parameters. *: p < 0.05; **: p < 0.01; ***: p < 0.001.

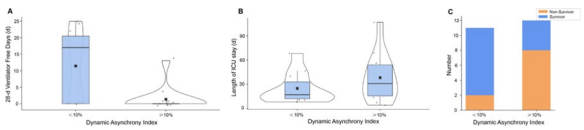

Fig 2 (abstract 000701) A. Boxplot-violin plot of 28-d ventilator-free days in two groups of patients grouped by a DAI ≥ 10% or < 10%. B. Boxplot-violin plot of length of ICU stay for two groups of patients grouped by a DAI ≥ 10% or < 10%. C. Stacked bar demonstrating the correlation between DAI and outcomes

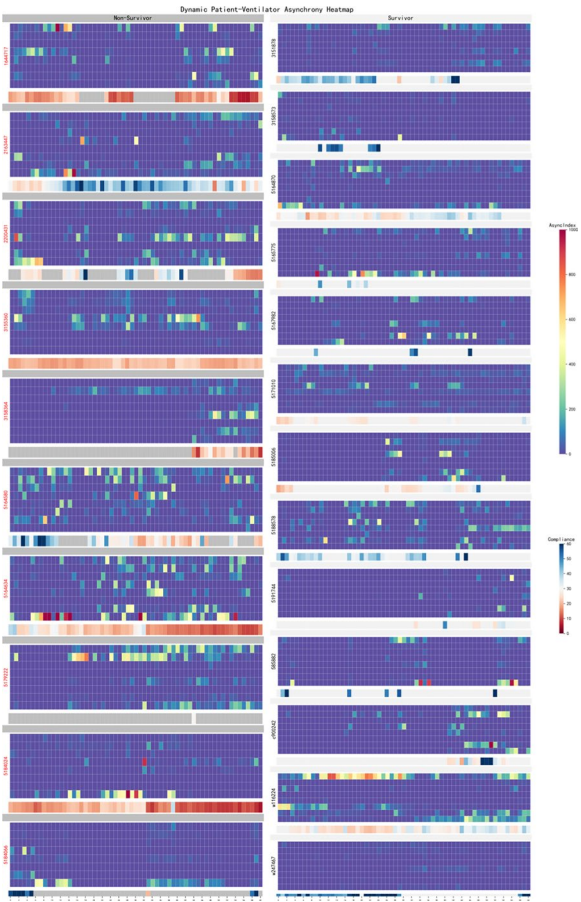

Fig 3 (abstract 000701) Heatmap of DPVA and dynamic compliance in respiratory cycles resampled by monitoring duration. The shortest time of 61 h was used as the sample size uniformly for all patients. The horizontal axis is labelled as the relative time (0–60 h), while the vertical axis in the heatmap denotes different asynchrony types: ineffective trigger, double trigger, auto trigger, reverse trigger, flow insufficiency, overshoot, premature cycle, and delayed cycle (from top to bottom). Each cell's color intensity corresponds to the total number of asynchrony events per resampled hour, with warmer hues indicating higher asynchrony frequency. Below the DPVA heatmap, a single-row heatmap represents dynamic compliance per hour, where warmer colors denote lower compliance values. Non-survivors (shown on the left) presented higher levels of asynchrony than survivors (shown on the right).

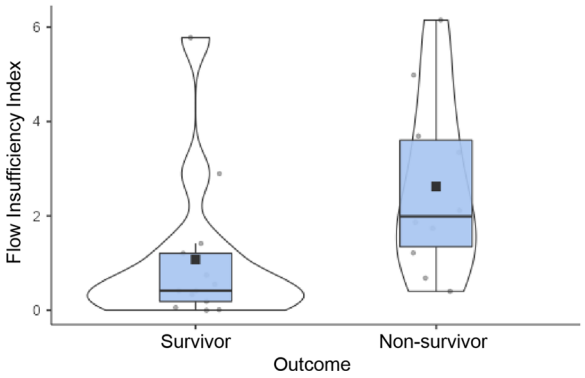

Fig 4 (abstract 000701) Boxplot-violin plot of flow insufficiency index in patients with different outcomes.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000702***.

Introduction. Acute respiratory distress syndrome (ARDS) frequently necessitates prolonged mechanical ventilation (1); despite the widespread use of tracheostomy, evidence regarding its optimal timing and impact on clinical outcomes remains inconclusive (2).
Objectives. To investigate the impact of tracheostomy on clinical outcomes in adults with ARDS who require MV.
Methods. This systematic review was conducted following the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA). Three electronic databases including PubMed, The Cochrane Library, and EMBASE to identify relevant studies on ARDS patients receiving MV were searched from inception to July 31, 2024. The reviewers assessed the risk of bias of included studies according to the Cochrane Risk of Bias 1 tool or JBI checklists, as appropriate. Two reviewers independently screened the literature and extracted the data. Outcomes among patients who underwent tracheostomy were compared and analyzed.

Results.
Twenty studies involving 4,022 patients with ARDS who required tracheostomy were included, comprising 2 randomized controlled trials, 5 prospective studies, 12 retrospective studies, and 1 case series. On average, tracheostomized patients spent 30.2 days in the ICU and 44.8 days in the hospital, with an overall mean duration of MV of 27 days. Tracheostomy-related adverse events were reported in 15 studies and local bleeding was the most common complication. Of the 1,074 patients with tracheostomy, 626 (58.3%) were successfully weaned from the ventilator. Mortality outcomes were documented in 18 studies, indicating that 883 out of 2,302 (38.4%) of these patients died during hospitalization. Twenty studies involving 4,022 patients with ARDS who required tracheostomy were included, comprising 2 randomized controlled trials, 5 prospective studies, 12 retrospective studies, and 1 case series. On average, tracheostomized patients spent 30.2 days in the ICU and 44.8 days in the hospital, with an overall mean duration of MV of 27 days. Tracheostomy-related adverse events were reported in 15 studies and local bleeding was the most common complication. Of the 1,074 patients with tracheostomy, 626 (58.3%) were successfully weaned from the ventilator. Mortality outcomes were documented in 18 studies, indicating that 883 out of 2,302 (38.4%) of these patients died during hospitalization.

Conclusions. Tracheostomy in MV patients with ARDS does not have a clearly defined impact on ICU length of stay due to variability in study findings. However, it remains a safe intervention with generally minor complications. Future research should focus on standardized weaning protocols and multidisciplinary rehabilitation strategies to potentially improve patient outcomes.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000703***.

Introduction. The arterial blood gas (ABG) test is the gold standard for acquiring patients' acid–base status. However, interpreting the ABG test sometimes is challenging for physicians due to facing physicians with six different values and time limits for the associated calculations.
Objectives. Clinical decision support systems (CDSS), developed and validated by clinical experts sound suitable for assisting physicians in such a time-consuming task.
Methods. The CDSS was developed through four stages. Firstly, the previous literature was reviewed to detect any previously developed algorithms, protocols, or guidelines. Secondly, an expert panel was formed that developed an algorithm for interpreting the ABG test as the knowledge base of the CDSS. Thirdly, the CDSS was developed through the agile methodology, and its usability was assessed after running in two Intensive Care Units (ICU). At last, the CDSS was validated by comparing the interpretations of the ABG tests presented by the CDSS with the interpretations by two attending physicians.
Results. The expert panel developed an algorithm for determining oxygenation status and an algorithm for simple analysis of ABG. The kappa coefficient for concordance rates between the interpretations of the CDSS and the expert 1 and expert 2 were 0.95 and 0.97, respectively. Out of the total 100 ABG test results analyzed by the CDSS, 96 (96%) coincided (concordance), one (1%) partially coincided (partial concordance), and three (3%) did not coincide (discordance) with the interpretations by the physicians. The ABG interpretation algorithm was modified based on the discordance and partial concordance cases.
Conclusions. The CDSS showed a high agreement with the experienced anesthesiologists. The CDSS could sensitively detect oxygenation and acid–base disorders and have also the potential to reduce errors in the associated calculations. Therefore, we expect that this CDSS, as a physician aid, will prove useful in ICU or emergency

departments by representing rapid and definite interpretations of the test results.

Recovery beyond survival: a review of the quality of rehabilitation care provided to patients following an admission to an intensive care unit

D. McWilliams[1]; A. Goodwin,[2]; D. Koomson[3]; H. Shotton.[3]
[1]Centre for care excellence, University Hospital Coventry & Warwickshire, Coventry, United Kingdom; [2]Critical Care, Royal United Hospitals Bath NHS Foundation Trust, Bath, United Kingdom; [3]Clinical Researcher, NCEPOD, London, United Kingdom.
Correspondence: D. McWilliams.
Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000704***.

Introduction. Critical care survivors are often left with significant physical and non-physical morbidity, commonly termed post-intensive care syndrome [1]. National guidance [2] in the United Kingdom highlights the need for structured rehabilitation within ICU and throughout the recovery pathway. Despite this, actual rehabilitation delivered is varied and inconsistent. The National Confidential Enquiry into Patient Outcomes and Death (NCEPOD) undertook a national review of care quality to identify potentially remediable factors in clinical and organisational provision of rehabilitation for survivors of critical illness.
Objectives. To evaluate the rehabilitation provided to critically ill adults within intensive care units, as well as throughout the recovery pathway to encompass both ward based and community care.
Methods. Data were collected for analysis using a variety of methods, including organisational questionnaires to evaluate services provided in both acute (n = 166) and community hospitals (n = 67), online anonymous surveys to gain views of both health care professional (n = 420) and patients (n = 102), and Clinical case note reviews (n = 671).
For the case note reviews, inclusion criteria were all patients aged 18 and over, who were admitted to hospital in as an emergency between 1st October 2022 to 31st December 2022 and who survived to hospital discharge, following a stay for 4 or more days on a level 3 unit. Using this criteria, clinical records for up to eight patients were selected from each hospital in England, Wales and Northern Ireland. These were then reviewed against pre-defined criteria developed a priori by a study advisory group made up of specialist multi-professional stakeholders from critical care and rehabilitation settings.
Results. Large variations in care provision were identified from all data sources and across all stages of the recovery pathway. Specific themes identified across the pathway of recovery included a failure to recognise rehabilitation needs, poor communication and handovers of care, and a lack of access to the multi-disciplinary team.
The information was used to create key areas for improvement through a consensus exercise involving the study team and specialist advisory group.
1. To improve the co-ordination and delivery of rehabilitation following critical illness at both an organisational and at a patient level.
2. A need to develop and validate a standardised rehabilitation screening tool to be used on admission to ICU.
3. To undertake and document a comprehensive, holistic assessment of the rehabilitation needs of patients admitted to ICU.
4. Ensure multidisciplinary teams are in place to deliver the required level of rehabilitation within intensive care units and across the recovery pathway in all healthcare settings.
5. Provide patients and their family/carers with clear information about their critical care stay, impact of critical illness and likely trajectory of recovery.
6. Standardise the handover of rehabilitation needs and goals for patients as they transition from the intensive care unit to the ward and ward to community.
Conclusions. This study represents the largest evaluation of critical care rehabilitation services, including ICU, ward and community settings. A number of key areas for improvement were identified with a view to improve care delivery across the entire care pathway.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000705***.

Introduction. Patients with diseases affecting the central nervous system may need to undergo surgery to treat the neurological condition or surgery unrelated to neurological disorder. It is very important to have knowledge of the underlying neurological disorder, anaesthetic techniques, drugs and monitoring modalities. The neurological disorder's perioperative course is influenced by the condition itself, medication management, the anaesthetic method, comorbidities etc. The choice of medications and perioperative management of anaesthesia may be affected by a variety of neurological conditions, including stroke, epilepsy, and Parkinson disease. Knowledge about the perioperative course of patients with pre-existing neurological diseases is important to reduce morbidity and mortality.
Objectives. The study's objective was to ascertain the postoperative outcomes of adult patients with pre-existing neurological diseases scheduled for non-neurological surgery. The patient characteristics, comorbidities, medication management, intraoperative events, postoperative events up to 30 days were noted to determine the perioperative course of these patients.
Methods. Patients of either gender aged more than 18 years scheduled to undergo surgical/diagnostic procedure under general anaesthesia were included in the study. These patients' medical history were recorded in the preoperative clinic. Complete information about neurological disorders was recorded, including medical history, comorbidities like diabetes mellitus and hypertension were identified. Preoperative medication management was recorded. According to the patient's record form, both intraoperative events and postoperative problems were recorded. Any important intraoperative occurrence, such as an arrhythmia, changes in the hemodynamic parameters, or the escalation of a neurological illness, was noted. Any new development of weakness, an exacerbation of the underlying neurological condition, or any other medical complications in the postoperative period were reported as postoperative occurrences. Patients were telephonically and physically followed up for 30 days.
Results. Fifty-five patients were included in the study, of which, 39 had history of stroke, 8 had history of epilepsy, 4 had Parkinson disease, two patients had history of both stroke and epilepsy and two patients had history of both stroke and Parkinson disease. Thus, we studied the perioperative course of 59 neurological diseases. Most of the patients were elderly with an overall mean ± SD age of 57.6 ± 17.2 years. 60.5% of stroke patients and 33.3% of patients with Parkinson disease were hypertensive. 14% of the stroke patients had a history of coronary artery disease while none of the patients with epilepsy or Parkinson disease had such history. 78% cases were done under GA and 22% cases in regional anaesthesia.
We found that 34.9% of stroke patients had residual paralysis and 37.2% patients were not taking DAPT. Among stroke patients 55.8% patients had an uneventful intraoperative period while 34.9% had hypotension and 9.3% had hypertensive episodes. Among patients having hypotension, 16.3% had post-induction hypotension and 18.6% patients were on vasopressor support. Postoperative period was uneventful for 79% while delirium was present in 9.3% patients. Out of 43, 3 patients died in the postoperative hospital stay while one died at home within 30 postoperative days.
Among the 10 patients with epilepsy, 80% patients were taking antiepileptic medication and 20% patients were not taking any medications. Intraoperative period was uneventful in 80% patients and 20% had hypotension. Postoperative period was uneventful in 70% patients while one of the patients had generalised seizures within 30 postoperative days.
Among the 6 patients with Parkinson disease, all patients were taking syndopa. Intraoperative period was uneventful in 50% patients and 50% patients had hypotension. One of the patients died during the postoperative hospital stay.
Conclusions. Patients with pre-existing neurological disease undergoing anaesthesia for non-neurological surgeries are having an unpredictable perioperative course, which may be due to the brain insult itself or may be due to associated comorbidities. Preoperative neurologist consultation will be useful for modification of the medications before surgery especially in patients with Parkinson disease. Modalities which can reduce the exposure of anaesthetic drugs can also help to improve the perioperative outcome.

Clinical characteristics of severe COVID-19: a multicenter study comparing Omicron and the original strain

R. Yu[1]
[1]Department of Critical Care Medicine, Zhongda Hospital, Southeast University, Nan Jing Shi, China
Correspondence: R. Yu
Intensive Care Medicine Experimental 2025 13(**Suppl 1**):***706***.

Introduction: Since the onset of the COVID-19 pandemic, over 700 million people have been infected with SARS-CoV-2. The Omicron variant was first identified in Africa in November 2021 and became the dominant global strain by January 2022 [1]. Although previous studies suggested that the Omicron variant has reduced virulence, primarily causing upper respiratory tract infections, it remains highly transmissible [2]. In China, after the large-scale spread of the Omicron variant, an outbreak of the Omicron variant occurred in December 2022. The number of severe COVID-19 cases subsequently increased sharply. By late December to early January, the daily increase in severe cases had approached 10,000, placing an immense burden on health care resources in a short period [3]. A large multicenter retrospective study conducted in South Africa demonstrated that compared with previous variants, the Omicron variant was associated with significantly lower hospitalization and mortality [4]. However, the number of infected patients in China has increased rapidly. This finding indicates that the population characteristics may have changed.
Objectives: Identify the population characteristics and risk factors associated with severe coronavirus disease 2019 (COVID-19) and death since the large-scale spread of the Omicron variant.
Methods: This multicenter retrospective observational study included two cohorts: the Omicron cohort, consisting of 7000 COVID-19 patients admitted to 10 national research centers in China from December 2022 to January 2023, and the Original cohort, consisting of 733 patients from Wuhan during the early outbreak in 2020. Demographic, clinical, laboratory, and treatment data were collected and analyzed. We compared the differences in patient characteristics and outcomes between the two cohorts. Multivariate logistic regression models were employed to identify risk factors for severe COVID-19 and death.
Results: A cohort of 7,000 patients admitted to 10 centers across the country was included in the Omicron cohort, among which 1,551 (22.2%) had severe cases. The original cohort consisted of 733 patients admitted to designated COVID-19 hospitals in Wuhan, all of whom had severe cases. Compared with that of the Original cohort, the median age of the Omicron cohort was notably greater (78.00 [69.00, 85.00] vs. 65.00 [56.00, 73.00], $P < 0.001$). There was a greater proportion of male patients in the severe Omicron cohort (70.0 vs. 65.2%, $P = 0.024$). Comorbidities were more prevalent in the severe Omicron cohort, such as hypertension (53.9 vs. 42.0%, $P < 0.001$), diabetes (32.1 vs. 18.8%, $P < 0.001$), coronary heart disease (20.3 vs. 12.7%, P < 0.001). Compared with that in the original cohort, mortality was slightly greater in the severe Omicron cohort (70.0 vs. 64.8%, $P < 0.001$), with shorter hospital stays (10.8 [5.0, 19.5] vs. 16.0 [9.0, 25.0] days, $P < 0.001$). Respiratory failure was slightly less common in the severe Omicron cohort (89.0 vs. 93.0%, $P = 0.002$), whereas kidney dysfunction was significantly more prevalent (23.6% vs. 11.9%, $P < 0.001$). The Sankey diagram shows the dynamic changes in organ failure among the two cohorts of severe patients within 7 days of hospitalization. On the first day, patients presented similarly, with varying levels of organ dysfunction. However, a greater number of patients infected

with Omicron died within this 7-day period (Fig. 1). After multivariate logistic regression analysis, male sex, older age, lower BMI, lack of vaccination, the use of corticosteroids before admission, the presence of underlying comorbidities, lower oxygenation, a strong inflammatory response, myocardial injury, liver injury, renal injury, and coagulation dysfunction were associated with an increased risk for severe cases (Fig. 2). Older age, the presence of malignant tumors, lower oxygenation, decreased platelet count, and elevated troponin levels were associated with an increased risk for death in severe patients (Fig. 3).

Conclusions: After the large-scale spread, the COVID-19 population was characterized by older age, male sex, and more comorbidities. Older age, male sex, unvaccinated status, preadmission glucocorticoid use, and underlying comorbidities were independent risk factors for severe COVID-19. Among severe patients, older age, underlying comorbidities, severe respiratory failure, and extrapulmonary organ injury were risk factors for death.

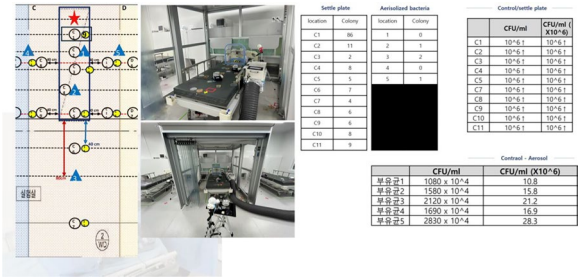
Cap-enhanced negative pressure chamber demonstrates superior aerosol containment: CFD, physical, and biological validation

JY. Hong[1]
[1]Emergency medicine, Yonsei University College of Medicine, Seoul, Republic of Korea
Correspondence: J.Y. Hong
Intensive Care Medicine Experimental 2025* 13(Suppl 1):*707



Introduction: Aerosol-generating procedures are known to carry a high risk of airborne transmission, especially in critical care settings. We've been working on a negative pressure chamber design for a while, and in this study, we tried adding a simple cap structure to improve containment. The goal was to see whether this small structural change could actually make a measurable difference.

Objectives: This study aimed to evaluate the effectiveness of a cap-enhanced negative pressure chamber in containing aerosolized particles. We validated the design through CFD simulations, physical PAO leakage testing, and biological challenge experiments using a non-pathogenic bacterial strain.

Methods: CFD simulations were conducted under three different suction configurations: directional switching (both orders) and bilateral suction. In all cases, droplet dispersion modeling showed near-zero leakage from the chamber. A physical particle leakage test was performed at Y-Medi Co., Ltd. (Incheon, Korea), using a modified HEPA filter integrity method based on ISO 14644-3.PAO particles were dispersed at 100-120 μg/L—well above standard biological concentrations—to simulate worst-case aerosol conditions. Leakage was measured using an aerosol photometer (PH-5, Tec Services Inc., USA) at nine defined positions around the hood's open side. Measurements were taken every 10 s for 90 s, at a distance of 15 cm. Three dispersion directions (toward, away from, and centered relative to the suction inlet) were tested, and each configuration was repeated five times. Simulated coughing was modeled using six bursts over 90 s. The biological test was performed in a full-scale emergency department simulation center (Paju, Korea), modeled after Seoul National University Hospital's ED.*Aerosolized Bacillus subtilis* (ATCC 6051), a nonpathogenic spore-forming organism commonly used as a biological indicator, was dispersed using a Collison nebulizer (NSF CN-311) placed at bed level. Bacteria were captured using settle plates and microbial air samplers, then quantified by serial dilution and CFU counting after incubation.
Results: CFD simulations showed complete containment with no observed particle escape in all suction configurations【1】. In the PAO leakage test, the cap-enhanced chamber showed a maximum leakage of 0.086%, with all zones dropping to 0% by 60 s【1】. In contrast, the chamber without the cap showed peak leakage of 0.567%, with ceiling leakage averaging over 0.35% at 10 s【1】. In the biological test, settle plate counts in the control group reached up to 10^6 CFU/L, although the chamber group remained below 10 CFU/L at all sites except one near the cap base (86 CFU/L). Airborne bacteria levels decreased dramatically—from 10.8 to 28.3 × 10^6 CFU/m3 in the control group to just 2 CFU/m3 with the chamber in place.
Conclusions: Adding a cap to the negative pressure chamber significantly improved containment performance across simulation, physical, and biological testing【1-2】.The improvement was especially notable during the early phase of simulated coughing, where leakage reduction was most critical.This design, which remains simple and compatible with existing suction systems, could be a realistic and scalable solution in emergency settings where full negative pressure isolation is not available【3-4,6】.The combined validation approach strengthens the reliability of this intervention for protecting healthcare workers during high-risk procedures【1-2,6】

PAO leakage during 60 s

Biological confirmation of aerosol contrainment

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***708***

Introduction: In COVID-19, overstimulated innate immunity induces adaptive immunity cells exhaustion that causes increases in viral/bacterial load and severity of the disease course. Limited number of studies have demonstrated the potential of hemoadsorption (HA) to modulate immune responses in patients with bacterial sepsis (1-3). Although several studies showed therapeutic efficacy of various HA technique in COVID-19 patients, no studies reported on post-treatment changes in adaptive immune system parameters so far (4-6). In our recent study, HA resulted in a statistically significant reduction

in proinflammatory markers and neutrophil/lymphocyte ratio, with significant benefit in 60-day survival vs. control group (7). However, no thorough analysis of immune consequences of HA for subgroups of patients has been performed. The goals of the current study are to examine whether the HA with Efferon cartridges may reverse altered immune system parameters in subgroups of severe COVID-19 patients and if the pre-treatment lymphocyte or neutrophil counts are significant for a post-treatment survival of severe COVID-19 patients.
Methods: A single-center cohort study (NCT06402279) enrolled 130 patients from October 2020 to February 2022. The main group (severe COVID-19 patients,18-75 years old, not responded to anti-cytokine/cytokine receptor antibody therapy, failed noninvasive ventilation and required invasive mechanical lung ventilation, IMLV) were treated with Efferon CT cartridges as an adjuvant to standard treatment. Control group included retrospectively acquired propensity-matched patients received no hemadsorption, standard treatment only, $n = 65$).
Results: Clinical improvements in vital parameters (increasing oxygenation index, decreasing the development of multiple organ failure and halting the septic shock) following the use of Efferon CT cartridge were accompanied with significant increase in lymphocyte count and decrease in neutrophil concentration in venous blood vs control group (Fig. 1A, B). Interestingly, that patients who not survived post-treatment exhibited significantly increased both lymphocyte and neutrophil count at day 0 and in 36 h after initiation of treatment in the main group vs control (Fig. 1C, D). Regression analysis revealed that only lymphocyte numbers not neutrophils, basophils, or eosinophils, were statistically significant for establishing link between pretreatment low lymphocyte count (< 0.71 × 109) and improved survival. Pearson correlation confirmed low lymphocyte count as an independent predicting biomarker for the life-saving effect of HA in severe COVID-19 patients.
Conclusions: Data conceptually prove an EIR with HA as a method to improve both adaptive immunity and survival in severe COVID-19 patients experiencing lymphopenia.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***709***

Introduction: Despite the potential benefits of minimally invasive cardiac surgery (MICS), cardiopulmonary bypass (CPB) during MICS can cause pulmonary complications. However, the optimal ventilation strategy for the left lung under CPB during MICS remains unclear.
Objectives: Thus, this study aimed to evaluate differences in postoperative pulmonary ventilation and complications according to ventilation strategy during MICS.
Methods: This prospective, randomized controlled trial included 60 patients who underwent MICS with one-lung ventilation. They were randomly assigned to either the nonventilation (NV) group, in which ventilation was halted during CPB, or the ventilation (V) group, in which ventilation at a tidal volume of 5 ml/kg was maintained during CPB. Electrical impedance tomography (EIT) monitoring was performed immediately after surgery to evaluate differences in regional ventilation and ventilation heterogeneity.
Results: The V group exhibited better ventilation homogeneity across the entire lung (0.5 ± 0.1 vs. 0.6 ± 0.2, $P = 0.020$) and increased ventilation in the left posterior region (1.3 ± 0.4 vs. 1.0 ± 0.3, $P = 0.003$). However, no differences were found in the clinical outcomes, including arterial blood gas analysis and postoperative respiratory complications.
Conclusions: Ventilation of the left lung during CPB in MICS showed better ventilation homogeneity and ventilation of the left posterior lung area, but did not result in differences in early complications,

including respiratory issues. Therefore, in MICS with a CPB duration of < 90 min, ventilating the left lung during CPB may not be required.

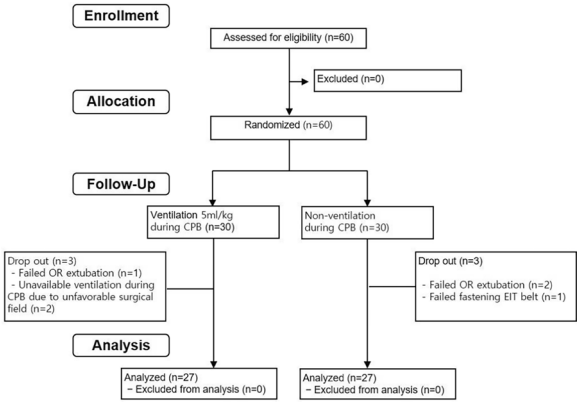

Fig. 1 (abstract 000709) Consort flow diagram. *CPB* cardiopulmonary bypass, *EIT* electrical impedance tomography, *NV* nonventilation, *OR*, operating room, *V* ventilation

Sixty patients who underwent MICS surgery requiring OLV were enrolled in this study, and 30 patients were assigned to the V or NV group using a randomization program. Finally, 54 patients in the V and NV groups were analyzed.

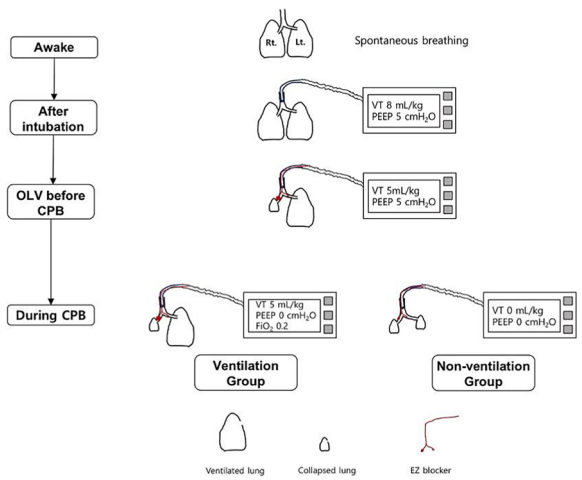

Fig. 2 (abstract 000709) Ventilation strategy. *CPB* cardiopulmonary bypass, *FiO2* fraction of inspired oxygen, *NV* nonventilation; *OLV* one-lung ventilation, *PEEP* positive end expiratory pressure, *V* ventilation

Table 1 (abstract 000709) Regional ventilation ratio, and GI index

	V group (N=27)	NV group (N=27)	P-value
Global ventilation	2471.4 ± 941.3	2479.7 ± 1403.3	0.980
Region of interest (%)			
RAA	26.3 ± 6.7	27.0 ± 6.8	0.718

Introduction: Early detection of sepsis in patients presenting to the emergency department (ED) is challenging. Organ dysfunction usually becomes apparent after the damage has been done. Therefore, tools that allow early prediction of organ dysfunction and poor outcomes are needed to improve management. Sepsis can cause immunoparalysis, Septiloop is an ex vivo test developed to diagnose sepsis and monitor the immune response during periods of immunosuppression, through a challenge test of whole blood exposed to toxins and evaluation of TNF-a release.
Objectives: To evaluate the characteristics of patients presenting to the ED with suspected infection and high risk of developing sepsis (NEWS scale $\geq$ 3) and to assess the performance of biomarkers and Septiloop in diagnosing sepsis.
Methods: We conducted a prospective observational cohort study of patients with suspected infections at high risk of developing sepsis (measured by a NEWS scale $\geq$ 3). Sepsis was defined according to the Sepsis 3 definition by two blinded investigators. Samples were collected between 0 and 4 h after admission to the emergency department. WBC, C-RP, PCT, Lactate and septiloop test was evaluated through ROC curves.
Results: We included 176 patients, of whom 139 (78%) developed sepsis within the first 24 h. Of these, 76 (43%) had respiratory infections, of which 55 had sepsis, 49 had urinary tract infections, and 51 had other sources of infection. Forty-four patients had a positive blood culture within the first 24 h. Septiloop performed at baseline and/or after 4 h showed variable accuracy depending on the focus of infection and in bacteremic disease. The best ROC AUC was for urinary tract infections (0.70 CI 95% 0.53 to 0.86) with a sensitivity of 62% and specificity of 77%. Septiloop outperformed other common markers usually used in clinical practice. The lower AUC was observed for respiratory infections. For patients with a positive blood culture, the AUC ROC was 0.67, CI 95% 0.47 to 0.86.
Conclusions: Septiloop, a new tool for sepsis diagnosis, has moderate accuracy in predicting urinary source sepsis and bacteremic sepsis.

Variable	AUC	CI 95%
WBC	0.42	0.18-0.66

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***711***

Introduction: Clinical documentation by trainees is often suboptimal. Our objective was to evaluate and enhance the quality of clinical documentation of residents of an Intensive Care Residency program using audit-based assessment and feedback.
Methods: This quality improvement project aimed to enhance trainee clinical documentation and was conducted at the Intensive Care Department of a tertiary-care hospital in Riyadh, Saudi Arabia, from October 2023 to February 2025. The Department has a five-year Adult Intensive Care Residency program. Daily progress notes are written using a standardized template in the electronic medical record (BEST-Care). One ICU consultant evaluated the quality of the written daily progress notes using a validated checklist (Northwestern University Feinberg School of Medicine responsible electronic documentation checklist). The checklist had 18 items that included critical reasoning in the Assessment/Plan section of the note and the use of copy and paste from previous notes. Each item had a two- or three-level rating scale. The score was 0 or 1 for the two-level scale items and 0, 0.5 points, or 1 for the three-level scale items. We calculated a total score as the percentage correct, ranging from 0 to 100, with the numerator being the sum of all individual item scores and the denominator the number of items, excluding those rated as not applicable. The same ICU consultant provided feedback to residents through in-person meetings, phone calls, and text messages. We performed independent and paired sample t-test analyses to compare changes in the total score.
Results: 152 progress notes were evaluated for 35 residents, with a median of 3 notes per resident (range: 2 to 8). Of these, 63 notes (41.4%) were written by PGY1 residents, 41 (27.0%) by PGY2 residents and 48 (31.6%) by PGY3 residents. The mean total score was 83 $\pm$ 13% for all residents (79 $\pm$ 17% for PGY1 residents, 85 $\pm$ 8% for PGY2 residents and 86 $\pm$ 9% for PGY3 residents; p = 0.02 for between-group difference). The mean score of the second progress notes for the 35 residents was higher than that of the first notes (83 $\pm$ 13% and 76 $\pm$ 18%, respectively; mean difference: + 7%; independent analysis p = 0.07; paired analysis p = 0.03). The mean score of the third progress notes for 30 residents was 82 $\pm$ 13 (mean difference from the first notes: + 8%; independent analysis p = 0.12; paired analysis p = 0.07). "Problems are written as diagnoses or accompanied by differentials" had a mean score of 62%. "Active problems are accompanied by clinical reasoning" had a mean score of 60%. "Problems are associated with brief, clear plans" had a mean score of 62%. "Assessment and plan are different from the previous day" had a mean score of 79%. For these items, PGY1 residents had the lowest scores (between-group differences p were 0.01, < 0.0001, < 0.0001 and 0.17, respectively). In addition, the scores of the second and third notes were higher than those of the first (between-group differences p were 0.001, 0.004, < 0.0001 and 0.002, respectively).
Conclusions: Providing feedback to ICU residents using a validated checklist significantly enhanced their clinical documentation and provided clear guidelines to facilitate medical note writing.

Risk of readmission and infection in sepsis survivors

B. van der Woude[1], O. Cremer[1], L. Derde[1], E. Sieswerda[2], HJ. De Grooth[1]

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***712***

Introduction: Approximately 40-70% of sepsis survivors are readmitted to the hospital within one year of discharge. Of these readmissions, 18-28% are related to infection. Considering the several therapies in the pipeline and growing number of sepsis survivors, there is large potential for the implementation of preventative interventions. For effective implementation, it is essential to understand risk factors for readmissions and infections in sepsis survivors.

Objectives: To identify risk factors for hospital readmission due to infection in sepsis survivors, compared to ICU survivors without sepsis.
Methods: Our project includes record linkage between a prospective research database of adjudicated infections among ICU patients in an academic hospital and national databases of mortality, hospital admission, and bacterial culture data. Uniquely, this involved full cross-linking of datasets, creating a comprehensive research infrastructure beyond mere variable exchange. This allowed us to identify all readmissions, even if they occurred in another hospital. Patients were included if they had an index ICU stay of at least 24 h and were discharged from the hospital alive. The primary outcome of interest was unplanned readmission to any hospital, stratified by readmission due to an infection vs. other reasons for readmission. In the current analysis, infection was defined using ICD-10 codes. Risk factors for unplanned readmission identifiable at index ICU discharge were evaluated using Weibull survival regression models.
Results: After linkage, 6300 ICU patients were included. One-year mortality was 13%. Cumulative incidence of unplanned readmission in the first year was 30%. Of the 2,781 patients (44%) with an infection during index ICU admission, 33% had an unplanned readmission within one year, of which 25% of those admissions were due to infection. Of the patients who never had an infection during index ICU admission, 27% had an unplanned readmission within one year, of which 18% were due to infection (Fig. 1). The most common infection codes were pneumonia, urinary tract infections, and sepsis. The adjusted hazard ratios for unplanned readmission are shown in Fig. 2. Although patients with infection during ICU stay have increased hazard for readmission, especially readmission for infection, previous hospital admission within 2 years of the index ICU admission stands out with a hazard ratio of 4.2 for readmission for infection.
Conclusions: The multivariable analysis indicates that sepsis survivors face increased risk for readmission and infection after hospital discharge. However, other characteristics, such as previous hospital admission, may be more important factors contributing to unplanned readmissions. The next steps in this ongoing work are to better identify readmission due to infection using bacterial culture data and to further stratify patients into risk groups for readmission due to infection, to ultimately identify patients at highest need for post-ICU preventative interventions.

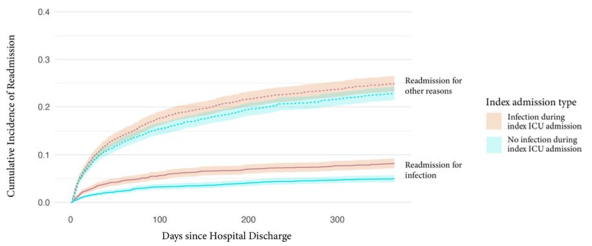

Fig. 1 (abstract 000712) Survival curves, accounting for death as a competing event, for unplanned readmission due to infection and other causes, stratified by infection status during index ICU admission

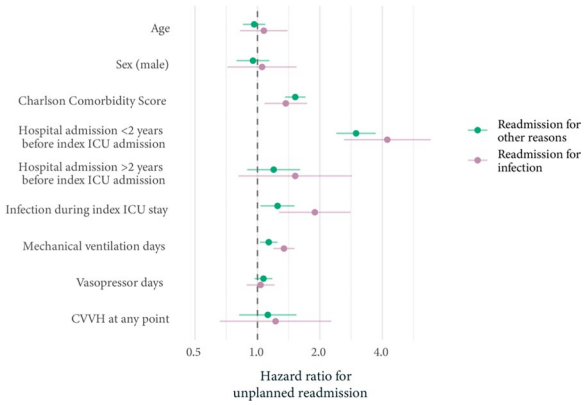

Fig. 2 (abstract 000712) Standardized coefficients from multivariable regression

Intensive Care Medicine Experimental 2025* 13(Suppl 1):*713

Introduction: Much work has been completed on developing core outcome set for use in a heterogenous ICU population (Dinglus et al., 2022). There is an identified need to include measures of physical function as part of the evaluation of ICU care (Kjaer et al., 2025). Early mobility is an intervention that is known to impact ICU length of stay, improve physical function after ICU and at hospital discharge. Adverse events are known to occur during ICU early mobility and have potential to impact on the patient experience, outcome and quality of care. Monitoring of early mobility including changes in physical function and the extent and impact of any adverse incidents would give information on the true costs and benefits of early mobility in this population.
Objectives: The aim of this study was to determine which outcome measures physiotherapy staff perform in Irish ICUs and determine how different ICU services gather information on adverse events during early mobility.
Methods: An e-survey was developed exploring the use and processes associated with physiotherapy related outcome measures in ICUs in the Republic of Ireland. The survey consisted of multiple choice

and open questions. E-surveys were distributed using national physiotherapy networks, respondents were asked to provide 1 response on behalf of the unit they worked. A second reminder was sent a month after initial distribution.
Results: There was a 60.7% response rate (17 replies; 28 ICU total listed in National Office of Clinical Audit dataset) representing hospitals across all healthcare regions in the Republic of Ireland. The most common outcome measure used in Irish ICUs was CPAx- Chelsea Critical Care Physical Assessment tool -a multi component functional score ($n = 13$). Other outcome measures sited examined impairment (peak cough flow [$n = 2$] and MRC muscle power score [$n = 2$]); mobility milestones (Manchester mobility score [$n = 4$], John Hopkins ICU highest mobility score [$n = 2$] and ICU mobility score [$n = 2$]) and baseline frailty (Clinical Frailty Score [$n = 2$]. 11 other outcome measures were mentioned by respondents, no patient reported outcome mearsures were mentioned. Although all respondents report documenting adverse events during early mobility, only one respondent graded the severity of adverse event.
Conclusions: There is a wide number and variety of outcome measures used by physiotherapists in Irish ICUs. Although all respondents recorded adverse incidents, there was very limited grading of severity, indicating a need for consensus forming for accurate recording, which would allow assessment of their impact. Measuring physical function as part of standards of critical care would ensure quality and equity of services nationally. Implementing standardised measures and recording of physical function and adverse incidents would require a national quality improvement process.

The impact of timely antibiotic administration on mortality in septic patients admitted to ICU: a re-audit

A. Tejpar1, G. Hutson[1], H. Clancy[1], H. Barnes[2], M. Zuleika[1]
[1]Intensive Care Unit, Royal Surrey County Hospital, Guildford, United Kingdom; [2]School of Medicine, University of Southampton School of Medicine, Southampton, UK, United Kingdom

Intensive Care Medicine Experimental 2025 13(**Suppl 1**):***714***.

Introduction: Septic shock is a life-threatening condition that requires timely management to reduce mortality. NICE guidelines recommend administering intravenous antibiotics within 1 h for high risk patients [1]. It has been shown that delayed antibiotic administration has been linked to increased mortality [2, 3].
Objectives: This study re-audits the relationship between antibiotic administration within 1 h from sepsis recognition and sepsis related mortality as well as other outcomes. The findings were compared to a previous audit conducted between August 2021 and March 2022.
Methods: This is a prospective re-audit of septic patients admitted to the Royal Surrey Foundation Trust Intensive Care Unit (ICU) between September 2024 and February 2025 as per sepsis 3 definition [4]. The following parameters were compared with previous audit (August 2021–March 2022): Administration of antibiotics within 1 h of sepsis recognition, vasopressor support, need for renal replacement therapy and ICU and hospital length of stay and mortality.
Following a Shapiro–Wilks test for normality, variables were described as mean and standard deviation (SD) or median and interquartile range [IQR]. Wilcoxon rank sum test was used nonparametric numerical variables and chi-squared test (or Fisher's exact) for categorical variables. Analysis was conducted on R.
Results: Comparative analysis of both audits are in Table 1.

Table 1 (abstract 000714) Further comparison of results between 2024 and 2021 audits respectively were as follows: The number of male to female patients were 28 (56%) to 41 (64%)

	Sep 2024-Feb 2025	Aug 2021-Mar 2022	*P* value
No of patients:	50	64	
Age (Years):	70 [60-80]	68 [59-75]	0.3
Antibiotics within 1 h:	38 (76%)	62 (94%)	0.002
Sepsis 6 delivered within 1 h:	27 (54%)	26 (41%)	0.25
Length of stay in ICU (Days, median [IQR])	5 [3-7]	3 [2-6]	0.007
Length of stay in hospital (Days, median [IQR])	12 [7-20]	11 [6-19]	0.57
Hospital Mortality:	13 (26%)	12 (18.75%)	0.51

Vasopressors were administered in 36 (72%) versus 48 (75%) of patients, $p = 0.48$ and renal replacement therapy was delivered to 8 (16%) versus 7 (11%) of patients, $p = 0.63$**

Conclusions: In the re-audit, only 76% of patients received antibiotics within one hour of sepsis recognition, a significant decrease from 96% in the 2021 audit ($p = 0.002$). This delay was associated with a significantly longer ICU length of stay ($p = 0.007$) and an increase in overall mortality from 18.75% to 26%, though the latter was not statistically significant—possibly due to the small sample size. The observed delay in antibiotic administration may reflect increased patient load and resource limitations during the study period, underscoring the need to prioritise timely antibiotic administration. To improve outcomes, we believe enhancing staff awareness through continued education on the urgency of timely antibiotic administration. In addition, streamlining hospital protocols to ensure faster identification and treatment initiation could be pivotal.

Combined online and in-person critical care outreach led simulation teaching scheme of noninvasive ventilation: Could ICU admissions be reduced?

A. Michie[1]; J. Brown[1]; R. Manohar[1]
[1]Intensive Care, Northern Lincolnshire and Goole NHS Foundation Trust, Scunthorpe, United Kingdom

Intensive Care Medicine Experimental 2025 13(**Suppl 1**):***717***

Introduction: Early use of Noninvasive Ventilation (NIV) is positively correlated to a reduction in patient mortality [1]. A key barrier to the early use of NIV is a lack of availability from confident, trained staff members to manage these patients [2].
Objectives: This paper sets out to increase the confidence levels of medical staff by 25%, and decrease their anxiety levels by 25%, within the context of approaching, managing, and troubleshooting patients on NIV.
Methods: A two-part teaching programme was created, aligned with British Thoracic Society and Intensive Care Society guidelines on Ventilatory Management in Acute Respiratory Failure [3]. The two-part programme was to be run in multiple sessions throughout January to April 2025, and participants included medical doctors working within the trust from the grades of Foundation Year 1 (FY1) to Senior Registrar. The first part of the programme was an online theory and physiology-based CPD session. The second part was a simulation-based workshop with the Critical Care Outreach Team (CCOT), which involved practical familiarisation with NIV machines. Data was collected using an eight-point Likert Scale and Six Point State Anxiety Scale (SAS) [4]. Participants completed the data collection before the teaching programme, after the first session, and then again two weeks after the final session to assess sustained knowledge retention and confidence.
Results: It was ascertained that 91.7% of participants had never had any formal teaching or training on NIV before. The average confidence score, out of five, before the teaching programme was 2.7. A score of five indicates the highest level of confidence. The average score then rose to 4.1 after session one, and again to 4.2 two weeks after the final session. The average level of anxiety, using the SAS, when approaching NIV in patients prior to the programme was 16, with a maximum score of twenty-four indicating the highest level of anxiety. This anxiety level then dropped to 13.6 after the first session, and again to 11.7 after the second session.
Conclusions: These results exceeded our target of reducing anxiety and improving confidence in medical staff approaching NIV. There was an increase in overall confidence by 56%, and a decreased anxiety score of 27%. It can be inferred that there is a substantial gap in medical training of doctors with regards to the use of NIV. This gap has the potential to cause harm to patients as it has already been discussed that staff members without proper training are less likely to be able to recognise the indications for NIV, and subsequently cause a delay in patients receiving the definitive care they require for respiratory failure. The introduction of a two-part teaching programme on NIV has proved to be a viable solution to this issue. The next steps involve the initiation of mandatory NIV teaching amongst foundation year doctors, increasing confidence from the early stages of their career, with the long-term aim of improved patient outcomes. Further research is to be conducted as to whether such schemes have any direct affect on number of ICU admissions due to respiratory failure.

Improved efficiency of the new mirusTM system challenged by ventilatory settings—a bench study

C. Schirra[1], K. Scheffler[1], T. Volk[1], A. Meiser[1], F. Albrecht[1]
[1]Department of Anesthesiology, Intensive Care and Pain Therapy, Saarland University Medical Center and Saarland University Faculty of Medicine, Homburg, Germany

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***718***

Introduction: The Mirus™ system [1] enables target-controlled delivery of volatile anesthetics (VA) with open-system ventilators. The interface, positioned between the Y-piece and the patient, administers anesthetic vapor during inspiration as needed although capturing and releasing VA during subsequent inspiratory phases. The system autonomously calculates the required VA amount based on self-measured parameters. The recently introduced interface Lisa-44 [2], claims improved reflection efficiency, reduced VA consumption and thereby lowered environmental impact and costs.
Objectives: This study evaluates the performance of the newly introduced Lisa-44 interface under body temperature pressure saturated (BTPS) and normocapnic conditions using a test lung.
Methods: Mirus™ and Lisa-44 were tested with isoflurane and sevoflurane. Volume-controlled ventilation was set to a tidal volume of 0.5 L, a respiratory rate of 10 bpm, and an inspiratory flow time (IF) of 2.5 s. The VA target concentration was gradually increased to 1.5 MAC

and then decreased. Real-time VA concentrations were recorded every 100 ms using an external gas monitor. End-tidal concentrations (EC), injection time and area under the curve (AUC) during injections were analyzed (Fig. 1C). VA consumption was calculated and compared to historical data [3]. Experiments were repeated with a short IF of 0.5 s to simulate spontaneous breathing conditions.

Results: There was good agreement between Mirus™ and external gas monitor readings (Fig. 1A). During vapor injections, ECs increased above the target and then decreased, with average ECs slightly exceeding the target (Fig. 1B). Each injection was analyzed individually. Based on the injection time (T.-inj) and the real-time concentration of VA, with the subsequent EC subtracted as the baseline, the AUC was calculated for each injection (Fig. 1C). Higher target concentrations required more frequent and longer injections, increasing the AUC. Compared with a historical control [3], hourly consumption was markedly decreased: To achieve 0.3 to 0.5 MAC, 1.0 to 1.7 mL isoflurane (historical control: 1.6 to 2.4 mL) or 3.8 to 6.1 mL sevoflurane (7.0 to 10.0 mL) are needed (Fig. 2). However, with short IF, VA consumption increased significantly, reaching up to 43 ml of sevoflurane due to prolonged injections extending into expiration.

Conclusions: The new device demonstrates high accuracy in EC measurements and enables demand-based administration of volatile anesthetics. Although promising for reducing anesthetic consumption in clinical practice, high target concentrations and short IF may lead to increased consumption, highlighting potential limitations.

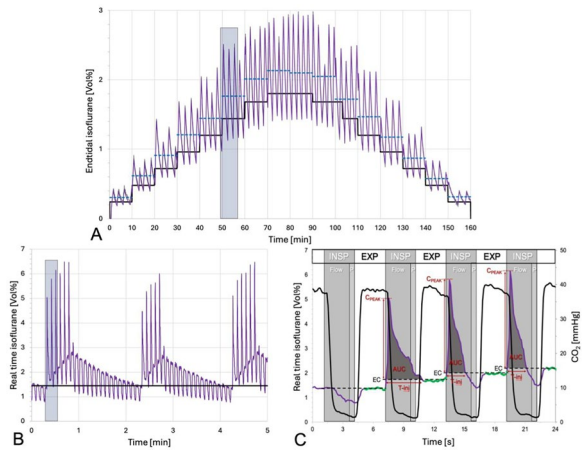

Fig. 1 (abstract 000718) **A** Overview of measurement procedure. EC measured by Mirus (purple line) and external gas monitor (grey line) compared to the target concentration (black line) and the average achieved EC (blue dashed line). **B** Zoom-in of **A**: Injection series cause the EC to rise above the target, followed by a drop below the target before a new injection series begins. **C** Zoom-in of **B** Three breath cycles with injections during inspiration (INSP), where the first injection extends into expiration (EXP), increasing the AUC. EC (green line) rises after each injection

Ventilator-associated pneumonia in trauma patients: a comparison between patients with and without traumatic brain injury

L. Kellens[1], L. De Bus[1], P. Depuydt[1], K. Vanderbiest[1]
[1]Department of Intensive Care Medicine, Ghent University Hospital, Ghent, Belgium
Correspondence: L. Kellens
Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***719***

Introduction: Trauma is a leading global cause of morbidity and mortality, with traumatic brain injury (TBI) being the main cause of death and disability among trauma patients. (1,2) Ventilator-associated pneumonia (VAP), defined as pneumonia occurring more than 48 h after intubation, results from the colonization of the upper airway and the subsequent replication of bacteria in the lower respiratory tract. (1-4) It is a common complication, particularly in TBI patients who have a unique susceptibility to VAP due to impaired airway protection, prolonged ventilatory support and possible immune dysregulation. (1,4-7) Reported VAP incidence in TBI varies widely and may impact morbidity and healthcare costs. (1-4) Understanding the incidence and risk factors of VAP in TBI and other trauma populations is crucial to improve outcomes, yet remains insufficiently explored in the literature.
Objectives: This study aimed to compare VAP incidence between TBI and non-TBI trauma patients, accounting for competing outcomes.
Methods: This retrospective cohort study included adult trauma patients who received mechanical ventilation for more than 48 h in the intensive care unit (ICU) of Ghent University Hospital in Belgium between January 2013 and December 2022. VAP incidence was compared between TBI and non-TBI patients using an incidence rate ratio

(IRR). A competing risk analysis was conducted to account for extubation and death.

Results: A total of 335 ventilated trauma patients were included in our study (Fig. 1). Median patient age was 50 years (IQR 31-63), 77.3% were male. TBI was present in 209 patients (62.4%), of whom 16.7% had an isolated TBI. VAP occurred in 67 of 209 (32.1%) TBI patients vs. 25 of 126 (19.8%) non-TBI patients ($p = 0.021$). VAP incidence rates were 33.2 and 23.3 per 1000 ventilator days in TBI and non-TBI patients, respectively (Fig. 2). IRR was 1.42 (95% CI 0.90-2.25).

Competing risk analysis showed a trend toward an increased risk of VAP in TBI patients (Subhazard Ratio (SHR) 1.82; 95% CI 0.94–3.53; $p = 0.077$). Male sex (SHR 2.65; 95% CI 1.05–6.69; $p = 0.039$) and spinal cord injury (SHR 2.01; 95% CI 1.04–3.90; p = 0.038) were significantly associated with an increased risk of VAP. No significant associations were observed for age, SOFA score at ICU admission, thoracic trauma, underlying pulmonary risk, immunocompromised status or antibiotic prophylaxis (Fig. 3).

Conclusions: TBI was associated with a trend toward increased VAP risk during ICU stay compared to non-TBI trauma patients, suggesting a potentially clinically relevant association despite lacking statistical significance. Further research is needed to confirm these findings and to clarify risk factors for VAP in both TBI and non-TBI patients. This may support earlier identification of high-risk patients and guide targeted preventive strategies.

Respiratory effects of angiotensin II and vasopressin as secondary vasopressors in ARDS patients with refractory shock

C. Dragoni[1], I. Sbaraini Zernini[1], SN. Aversente[1], C. Annicchiarico[1], E. Modica[1], F. Taccone[2], F. Annoni[3]
[1]Department of Intensive Care, Erasme hospital, University hospital of Brussels (HUB), Brussels, Belgium; [2]Soins intensif, ULB Erasme, Anderlecht, Belgium; [3]Department of Intensive Care, Erasme Hospital, Brussels, Belgium

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***721***

Introduction: Acute respiratory distress syndrome (ARDS) is frequently associated with refractory shock, requiring the introduction of a second vasopressor. The Surviving Sepsis Campaign recommends the addition of Vasopressin (AVP) [4, 5]. In the recent years, Angiotensin II (Ang-II) has been emerging as a potential alternative. Two studies suggested that Ang-II [1-3] may improve oxygenation in patients with ARDS. Nevertheless, the effects of the second vasopressor remain controversial in this population.
Objectives: To evaluate the effect of AVP and Ang-II on oxygenation and ventilatory parameters in patients with refractory shock and ARDS.
Methods: Patients aged > 18 years, admitted to the ICU between May 2024 and April 2025 with a diagnosis of ARDS and refractory shock, and enrolled in a prospective ongoing registry study, were included in the analysis. Clinical, hemodynamic, and respiratory data were recorded before the initiation of the second vasopressor infusion, and at 3, 6, and 24 h after its administration.
Results: A total of 19 ARDS patients were included: 12 received AVP and 7 Ang-II. The median age was 64 (57-72) years, 63.2% were male, with an APACHE II score of 29 (26-32). Baseline characteristics were comparable between groups (Table 1), except for a higher administration of ACE inhibitors in the Ang-II group (p = 0.04). In the 3 h before the starting of the second vasopressor, the P/F ratio declined from a median of 119 (90-189) to 103 (86-160) in the whole population. A greater improvement in the P/F ratio was observed over time in the group treated with Ang II ($p = 0.03$–Fig. 1A). In a post hoc analysis, this improvement was particularly significant at 24 h ($p = 0.01$–Fig. 1B). No significant changes in ventilatory parameters and fluid balance over the study period were observed between the two groups (Fig. 2). A significant reduction in the norepinephrine (NE) dose at 6 h was also observed in the Ang-II group ($p = 0.03$—Fig. 1D).
Conclusions: In patients with ARDS and refractory shock, the addition of Ang-II as a second vasopressor led to a significant improvement in oxygenation, compared to the AVP-treated group. This effect was observed despite unchanged ventilatory settings and fluid management strategies.

Target temperature management in neurosurgery: who survives and why?

Y.J. Lee[1], YC. Lim[1], J. Song[1]
[1]Neurosurgery, Ajou University Medical Center, Suwon, Republic of Korea
Correspondence: Y.J. Lee

Intensive Care Medicine Experimental 2025* 13(Suppl 1):*722

Introduction: Targeted temperature management (TTM) is increasingly applied in neurocritical care, yet its indications, outcomes, and risk profiles in neurosurgical patients remain unclear. Although TTM has been studied in specific brain injury types such as TBI or stroke, few studies have directly compared outcomes across multiple etiologies. Moreover, limited evidence exists regarding how TTM-related complications may influence prognosis in different injury types.
Objectives: This study aimed to identify clinical factors associated with mortality and complications among patients treated with TTM in our high-volume neurosurgical center.
Methods: We retrospectively analyzed 185 patients who received TTM who admitted in department of Neurosurgery at our institution from January 2011 to December 2024. Included patients were diagnosed with aneurysmal subarachnoid hemorrhage (SAH), intracerebral hemorrhage (ICH), traumatic brain injury (TBI), or acute cerebral infarction. Demographic and clinical factors were collected, including injury type, post-cardiopulmonary resuscitation (post-CPR) status, decompressive surgery, TTM depth and duration, and complications such as coagulopathy and pneumonia. Multivariate logistic regression was performed to identify independent predictors of mortality and coagulopathy.
Results: Among the 185 patients analyzed, the mean age was 50.6 ± 13.7 years, and 56.2% were male. The most common diagnosis was subarachnoid hemorrhage (45.4%), followed by traumatic brain injury (26.2%), infarction (15.7%), and intracerebral hemorrhage (12.4%). Decompressive surgery was performed in 73.5% of patients, and 20.5% were in a post-cardiac arrest state prior to TTM. ArcticSun was the primary cooling modality (80.5%), and long-term hypothermia (≥ 6 days) was applied in 49.2% of cases. Coagulopathy developed in 12.4%, and pneumonia in 17.3%. The overall mortality rate was 43.2%. Post-CPR state was strongly associated with increased mortality (OR = 4.079, $p = 0.003$). Long-term hypothermia (≥ 6 days) was independently associated with improved survival (OR = 0.293, $p < 0.001$). Patients who developed coagulopathy during TTM had significantly higher mortality (OR = 6.259, $p = 0.002$). Injury type showed a statistically significant association with both mortality ($p = 0.008$) and coagulopathy occurrence ($p = 0.002$), with TBI patients most frequently experiencing coagulopathy (60.9%).
Conclusions: TTM outcomes in neurosurgical patients vary significantly based on injury type, treatment duration, and complication profile. Post-CPR state and coagulopathy markedly increase mortality risk, although prolonged hypothermia may be protective. TBI patients, who had the highest coagulopathy rate, also demonstrated the highest mortality, suggesting that coagulation-related complications may play a critical role in outcome deterioration in this subgroup. Although coagulopathy in TBI has been previously acknowleged, our data uniquely suggest that coagulopathy during TTM may be a critical factor of poor outcomes in this subgroup. These findings support a tailored approach to TTM, rather than a uniform protocol, in neurocritical care settings.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***723***

Introduction: Assessment of post-traumatic stress in patients who required follow-up in the post-ICU consultation.
Methods: Descriptive, observational, and analytical retrospective study based on a prospective database. Critical patients consecutively admitted to an intensive care unit (ICU) of a tertiary university hospital between November 2020 and August 2024, for more than 72 h, requiring some type of organ support were included. Clinical, sociodemographic, and evolutionary variables were analyzed. Quantitative variables are expressed as mean ± standard deviation or median (interquartile range), and qualitative variables as absolute and relative frequency. Comparisons between qualitative variables were performed using Pearson's Chi-squared tests or Fisher's exact test. The comparison between qualitative polytomous and quantitative variables was performed by ANOVA. The comparison between quantitative variables was performed using Pearson's correlation test for variables with normal distribution and Spearman's test for those without normal distribution.
Results: The study included 21 patients, with a mean of 58.7 ± 13.7 years. Of these, 43 (60.6%) were male, with a median ICU stay of 19 days (9.30). The median PTSD score was 6.25 (3.13). 57.7% of patients did not present re-experiencing what they experienced in the ICU, 28.2% did not present avoidance behaviors of effort or activities after their stay in the ICU, being the most frequent (33.3%) the inability to remember important aspects experienced during admission. In the avoidance section, the maximum score was 30 (1.4%) and the minimum was 0 (8%), with the most frequent being the inability to fall asleep with a maximum of 3 points in 21 patients (29.6%). The presence of PTSD was not related to SAPS II ($p = 0.676$) or to the number of organic failures scored by SOFA ($p= 0.06$). We also found no relationship with regard to ICU discharge diagnosis ($p = 0.411$) although a direct relationship was observed with score attributed to sleep quality ($p = 0.017$).
Conclusions: The great part of the patients analyzed, presented low PTSD score and those who presented a higher score had worse quality in the sleep score.

The impact of advance directives on decision making for emergency surgery in elderly patients with stage IV cancer

I. Chami[1], MJ. Choi[2]

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***724***

Introduction: Advance directives are legal documents that allow patients to articulate their preferences for medical treatment in situations where they are unable to make decisions. They are particularly crucial in end-of-life care, ensuring that patients' wishes are respected even when they can no longer communicate. Despite their importance, the role of advance directives in the decision-making process for emergency surgeries in elderly patients with terminal cancer remains unclear. This study aims to evaluate whether the presence of an advance directive influences the decision to perform emergency surgery in patients aged 65 and older with stage IV cancer and to assess the subsequent clinical outcomes.
Methods: This retrospective study included patients aged 65 and older with stage IV cancer who were referred for surgical consultation from emergency department to general surgery department between 2019 and 2023. The primary outcome was decision to perform emergency surgery. Secondary outcomes included in-hospital mortality, complication rates, length of hospital stay, and hospitalization costs.
Results: The presence of advance directives did not significantly influence the decision to perform emergency surgery in elderly patients with stage IV cancer (34.5% vs. 35%, P = 0.962). Furthermore, there was no significant difference in mortality rates based on advance directive status (3.7% vs. 0%, P = 0.267). However, patients who undergone emergency surgery experienced longer hospital stays, higher complication rates and higher hospitalization costs, regardless of whether they had an advance directive.
Conclusions: For elderly patients with stage IV cancer, emergency surgery may provide immediate relief from pain, but it cannot stop the progression of the disease, often leading to complications, prolonged hospital stays, and excessive medical expenses. In particular, for patients who have advance directives—having made their own treatment decisions although they were mentally competent—these directives should be given significant consideration to prevent such worst-case scenarios.

Emergency surgery by advance directive status ($P = 0.962$)

Intensive Care Medicine Experimental 2025 13(**Suppl 1**):***725***

Introduction: Acute respiratory distress syndrome (ARDS) is a severe complication of critically ill patients with acute brain injury (ABI) associated with increased mortality. The application of positive end-expiratory pressure (PEEP) has been recognized as a key ventilation strategy in terms of alveolar recruitment and oxygenation. In the recent years, lung ultrasound (LUS) has been increasingly used to assess alveolar recruitment in critically ill patients with ARDS.
Objectives: To investigate the effect of PEEP on LUS scores and patterns in mechanically ventilated patients with ARDS and ABI.
Methods: We conducted a preliminary, interventional, prospective clinical study, including patients with ABI and ARDS. GCS on admission and LIS score were recorded. The intervention included a gradual increase in PEEP level from 5 to 8, 12 and 16 cmH2O. After each PEEP level change, we performed LUS in 6 regions in each lung and calculated the regional and global LUS score. Each part was scored based on the worst LUS pattern. We defined 4 LUS aeration patterns: Normal aeration pattern (A lines or fewer than 2 isolated B lines) = 0 point, moderate loss of aeration pattern (multiple, well-defined B lines) = 1 point, severe loss of aeration pattern (multiple, coalescent B-lines) = 2 points, and consolidation pattern (tissue pattern characterized by dynamic air bronchograms) = 3 points.
Results: A total of 18 patients were included in the study; 16 of them (88.9%) were males, with a median age of 60 years [49-69]. 8 patients (44.4%) were admitted for ICH, 6 (33.3%) for TBI and 4 (22.2%) for SAH. The median GCS score on ICU admission was 7 [4, 8] and the median LISS was 2 [1.75, 2.25]. There was a statistically significant difference in total LUS (LUStot) score regarding all PEEP pairs (p < 0.001) (Table 1).

Table 1 (abstract 000725) Comparison of LUS score between different PEEP levels

Variables	LUS	
PEEP pairs (cmH2O)	p value	95% CI
All	< 0.001	
PEEP 5/8	0.015	0.43, 1.68
PEEP 8/12	0.002	– 3.35, – 1.2
PEEP 12/16	< 0.001	1.31, 3.13
PEEP 5/12	< 0.001	– 4.56, – 2.1
PEEP 5/16	< 0.001	– 7.43, – 3.68
PEEP 8/16	< 0.001	– 6.22, – 2.78

A progressive reduction in LUStot score was also observed after PEEP augmentation from 5 to 16 cmH2O [from 22.39 (SD 5.49) to 16.83 (SD 4.71), $p < 0.001$] (Fig. 1). Considering regional LUS score, there was a significant improvement in LUS score if PEEP was raised from the minimum level of 5 cmH2O to the maximum level of 16 cmH2O, regarding anterior (LUSant) ($p < 0.001$, 95%CI 1.5, 5.5), lateral (LUSlat) ($p < 0.001$, 95%CI 1.12, 2.77) and posterior (LUSpost) ($p = 0.001$, 95%CI 1, 3) lung regions (Table 2). We also found that anterior regions were more recruitable (LUS from 4.22 to 1.5) than lateral (LUS from 7.16 to 5.61) and posterior (LUS from 11 to 9.28) regions. Considering LUStot, the percentages of normal aeration pattern were increased from 11.1% to 23.6%, while in consolidation pattern were reduced from 37% to 16.7% after PEEP augmentation from 5 to 16 cmH2O (Fig. 2).
Conclusions: LUS could be used to assess and guide alveolar recruitment in critically ill patients with ARDS and ABI. The LUS score improved significantly in all lung regions examined (anterior, lateral, posterior) after PEEP application, but the anterior regions appeared to be more recruitable.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***726***

Introduction: In Catalonia, not all hospitals have an intensive care unit (ICU), meaning that not all patients at vital risk can receive specialized care from the begining.Teleassistance tools can assist decision-making among specialists to ensure equitable care.
Objectives: To evaluate the effectiveness of a teleassistance strategy provided by ICU specialist from Althaia (universitary hospital) to a regional one (Hospital de Berga) through a 4 REMOTE connection reducing unnecessary hospital transfers and improving the care of critical patients. In addition, to assess professionals' perception of this teleassistance tool in terms of usefulness and interaction quality and reliability.
Methods: Nonrandomized interventional study with a historical control. Historical cohort: A retrospective cohort of patients transferred from *Hospital de Berga* to Althaia's ICU between April and December 2023. Prospective cohort: Patients consulted from *Hospital de Berga* to Althaia's ICU via teleassistance between April and December 2024. Patients at least 18 years old with severity criteria 1 or 2 and those hospitalized requiring therapeutic optimization due to critical deterioration were included. Demographic and clinical data, the need to transfer, length of ICU and hospitalary stay,interventions performed, and ICU mortality were recorded. A survey form was used to assess professionals' acceptance and satisfaction with the tool as well as its usefulness. Continuous variables were expressed as medians and standard deviation (*U* Mann–Whitney). Categorical variables were shown as percentages (Chi-square).
Results: From April to December 24th, 35 patients were enrolled, median age of 73 ± 1 years, 65% of whom, men with an active quality of life.
- Infectious diseases were the main reason for consultation (46.2%).
- Out of the 35 patients, 13 were transferred to the ICU (compared to 24 in the historical cohort), and 2 were transferred to a tertiary hospital.
- No significant differences were found between the teleassistance and historical cohorts in terms of median age (68.6 ± 16.6 vs. 69.2 ± 12.2), sex (65% men vs. 46.2%), or SAPS3 at admission (57.6 ± 13.5 vs. 62.5 ± 13.5).
- Statistically significantly, telemedicine increased the consultations of patients with infectious diseases (46.2% vs. 30%, p = 0.024).
- No significant differences were found between the teleassistance and historical cohorts in terms of length of stay or ICU mortality.
Although all professionals agreeded about patient accessibility, professional communication and therapeutic decision making, Althaia's doctors found the teleassistance tool easier to use than Berga ones (77% vs. 50%, p > 0,05) (see picture).
Conclusions: 65% of the discussed patients were men (median age 73) and an acceptablequality of life.
- Infectious diseases were the primary reason for consultation in both groups, and signficantly increased with teleassistance.
- The global number of transfers decreased to less than half after implementing teleassistance.
- Teleassistance was well accepted by professionals.

Prediction of in-hospital mortality among acute coronary syndrome patients using left ventricular outflow tract–velocity time integral (LVOT–VTI)

R. Torio[1], BA. Bernard[1]
[1]Division of Critical Care, Philippine Heart Center, Quezon City, Philippines
Correspondence: R. Torio
Intensive Care Medicine Experimental 2025* 13(Suppl 1):*727

Introduction: Acute coronary syndrome (ACS) requires precise cardiac function assessment for prognosis and management, with GRACE and TIMI scores commonly being used and other prognostic markers are needed. This study aimed to determine the accuracy of the echocardiographic LVOT-VTI to predict in-hospital mortality among ACS patients.
Methods: This was a single-center retrospective cohort conducted at a tertiary hospital in the Philippines between March 2023 to December 2023 which included ACS patients admitted to the Coronary Care Unit (CCU) through purposive sampling. The LVOT-VTI was determined through transthoracic echocardiogram done within 24 h of admission. Association of LVOT-VTI with in-hospital outcomes was determined by logistic regression. Diagnostic accuracy of LVOT-VTI was determined using accuracy measurements and area-under-the-receiver-operating-curve (AUC-ROC).
Results: A total of 148 patients were included in the study. The majority were male, hypertensive and ST-elevation myocardial infarction (STEMI) cases. Overall, the in-hospital mortality among ACS patients admitted at the CCU was 38.51% (57 out of 148). Age ($p = 0.030$), heart rate ($p = 0.040$), previous myocardial infarction (MI) ($p = 0.017$), and antiplatelet use ($p = 0.049$) were significantly different between survivors and expired patients. LVOT-VTI has sensitivity 16.48%, specificity 66.67%, LR(-) 1.25, LR(+) 0.49, PPV 44.12%, NPV 33.33%, overall accuracy 35.81%, and AUC-ROC of 0.6329 for predicting survival as shown in Table 1 and Fig. 1. LVOT-VTI has limited ability to accurately differentiate between survivors and nonsurvivors. LVOT-VTI is significantly associated with decreased risk of in-hospital mortality (OR 0.8941,95% CI 0.8238-0.9703, $p = 0.007$), but is not significantly associated with reinfarction, stroke, heart failure, cardiogenic shock, or prolonged CCU or hospital stay as seen in Table 2.
Conclusions: LVOT-VTI has limited accuracy in predicting in-hospital mortality among critical ACS patients. Further research is needed to explore additional echocardiographic parameters for better risk stratification and prognosis in ACS management.

Table 1 (abstract 000727) Diagnostic accuracy of LVOT-VTI in predicting patients' survival

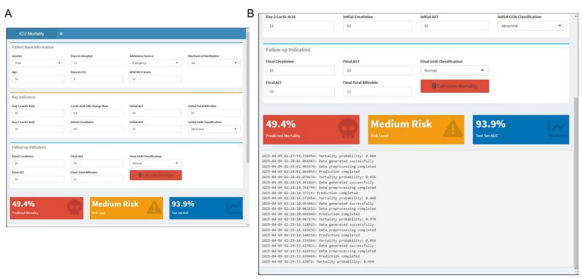
Intensive Care Medicine Experimental 2025* 13(Suppl 1):*728.



Introduction: ICU patients often present with complex and severe conditions, resulting in high mortality rates. Early use of routine laboratory tests for rapid risk stratification can support timely prognostic assessment and intervention. This study aims to develop and validate interpretable machine learning (ML) models based on early laboratory data to predict mortality risk in critically ill patients, offering clinically relevant guidance for their management.
Methods: We retrospectively analyzed clinical data from 1,465 ICU patients admitted between December 2018 and May 2019. Of these, 1,001 patients were used for model training and 465 for testing. 9 ML algorithms were employed to develop predictive models. Model performance was assessed using metrics such as the area under the receiver operating characteristic curve (AUC). SHapley Additive exPlanations (SHAP) and Explainable Feature Filtering and Selection (EFFS) were used to rank feature importance and interpret the final model.
Results: Among the 9 ML models, all except k-nearest neighbours (KNN) and decision tree (DT) demonstrated good specificity and sensitivity in the training set (Fig. 1A). Most models showed strong predictive performance, with AUC values exceeding 0.90, including ElasticNet (0.95), LightGBM (0.95), logistic regression (0.93), multilayer perceptron (MLP) (0.92), random forest (RF) (0.94), radial support vector machine (rSVM) (0.95), and XGBoost (0.95) (Fig. 1B). Further analysis indicated that the RF model had the highest stability (Fig. 1C), and its calibration curve showed strong agreement between predicted and observed mortality (Fig. 1D). SHAP analysis (Fig. 2A) and EFFS (Fig. 2B) identified key predictors, with lactate on postoperative day 2 contributing most significantly to mortality risk (Fig. 2). Based on the RF model, we developed a mortality risk calculator incorporating 22 variables, including sex, age, hospital and ICU length of stay, APACHE II score, mechanical ventilation status, lactate, creatinine, and liver enzymes. The tool enables mortality risk stratification and is available to clinicians as a plug-in, with source code accessible via GitHub (https://github.com/WenciVan/CCM/blob/main/evaluation%20death).
Conclusions: We developed and validated a visual prediction tool based on a RF model incorporating 22 readily available clinical variables to estimate mortality risk in critically ill patients. This model may assist in the early identification of high-risk individuals and support personalized treatment strategies.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):**729**

Introduction: To analyze the sleep quality of patients who have had a prolonged stay in the ICU.
Methods: A descriptive, observational and analytical retrospective study on a prospective database. We included critical patients who were admitted consecutively to an intensive care unit (ICU) of a university hospital of tertiary level between November 2020 and August 2024, for more than 72 h,requiring some type of organic support. Variables related to sleep habits, time, quality and the need for company or drugs to fall asleep were analyzed. Quantitative variables are expressed as mean ± standard deviation or median (interquartile range), and qualitative variables as absolute and relative frequency.
Results: A total of 71 patients were included in the study, with a mean age of 58.7 ± 13.7 years, of whom 43 (60.6%) were male. Mean APACHE II 17 (13.25), SOFA 8 (5.12) and median ICU stay was 19 days (9.3). 30 (45.5%) patients reported taking more than 30 min to fall asleep, 32 (48.5%) patients woke up in the early morning more than 3 or more times a week, 14 (19.7%) perceived that they did not breathe well during sleep, 28 (39.4%) snored or coughed at night and 37 (52.1%) confirmed that they suffered from nightmares at night. 30 (42.3%) patients required at least one drug to fall asleep and 38 (53.5%) reported that sleep affected their mood.
Conclusions: Most of the patients followed up by our post-ICU clinic presented sleep disturbances. The most frequent disorders were sleep onset or the use of medication to improve sleep.

000731 Not past their prime: explorative quantification of meropenem exposure in biobank samples to retrospectively determine target attainment in critically ill pediatric patients

D. Vanneste[1]
[1]Clinical pharmacology and pharmacotherapy, KU Leuven, Leuven, Belgium
Correspondence: D. Vanneste
Intensive Care Medicine Experimental 2025 13(**Suppl 1**):***731***

Introduction: Literature on antimicrobial exposure and optimal dosing in Pediatric ICU (PICU) patients remains scarce (1). Analysing biobank samples from earlier PICU trials could complement currently available data, even when these trials were not primarily designed as pharmacokinetic (PK) study, reducing the need for prospective observational PK trials. Unfortunately, quantifying antimicrobial PK target attainment directly from banked samples can be complicated as samples are taken at random timepoints. Pharmacokinetic exposure can be predicted by applying population PK (popPK) models using concentrations measured in biobank samples. In this pilot study, we confirmed predictive performance of a previously developed popPK model, and assessed target attainment for meropenem in PICU patients.
Methods: We performed a retrospective pilot study using 47 biobank samples from 10 participants, selected based on age range, in the PePANIC trial, covered by the original informed consent (2). Meropenem concentrations were quantified in serum using a validated LC–MS/MS method (3). Pharmacometric analysis was carried out in the Insight Rx Nova Bayesian dosing platform (Insight Rx, Inc, 2021) using the Rapp et al. popPK model (4). First, predictive performance of the popPK model was assessed by calculating the relative prediction error (PE%) (5). The model was informed with the patients' covariates, i.e. sex, length, actual body weight, age, serum creatinine, renal replacement therapy, dosing information and max. two previously observed meropenem trough concentrations (Cmin). A good fitting model was defined as a median PE% < 20%. Second, PK target attainment, defined as as 100%T > MIC, was calculated by predicting Cmin.
Results: In this pilot study, 47 biobank samples, collected 0.24-9.02 h after previous meropenem dose, from 10 patients were used. The predictive performance of the Rapp et al. pop PK model was found to be good, with a median [Q1-Q3] PE% of 14.8% [5.32-24.4]. Subsequently, Cmin were a posteriori predicted, with a median [Q1-Q3] Cmin exposure of 4.55 [2.13-9.25] mg/L (Table 2). According to the predictions, 72.3% and 31.9% of the Cmin reached the target of 2 and 8 mg/L, respectively.

Table 1 Meropenem quantification and prediction of target attainment

	Number of samples (n = 47)
Observed meropenem concentrations (mg/L)	9.85 [3.5-18.9] (n = 42) Below LLOQ: 5 (10.6%)
A posteriori Cmin prediction (mg/L)	4.55 [2.13-9.25]
Hourse since previous meropenem dose	6.16 [4.69-7.35]
Sub therapeutic	13 (27.7%)
100% T > MIC (2 mg/L)	34 (72.3%)
100% T > 4 × MIC (8 mg/L)	15 (31.9%)
Ongoing renal replacement therapy	11 (23.4%)

Continuous variables are given as Median [Q1-Q3], Categorical variables are given as n (%). Target attainment was defined as a Cmin above 1-4 time the MIC over a whole dosing interval (100% fT > 1-4 × MIC) considering a MIC of 2 mg/L (6). Samples below the LLOQ were considered to be sub-therapeutic. Cmin: trough concentration; LLOQ: lower limit of quantification- MIC minimal inhibitory concentration.
Conclusions: We successfully quantified meropenem exposure in biobank samples from the PePANIC trial. The previously published popPK model by Rapp et al. was found to describe meropenem exposure with acceptable accuracy in this patient population. The popPK model, informed with patient and treatment data, was used to retrospectively determine PK target attainment. This pilot study, while limited, suggetst that biobank samples could provide much needed PK data for antimicrobial agents. In the near future, PK target attainment will be determined for all patients in the PePANIC trial who had been treated with meropenem, followed by simulation of optimized dosing.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***732***.

Introduction: Lung transplantation offers a well-established therapeutic option for patients with advanced lung diseases who have exhausted other treatment alternatives. Its complexity requires careful candidate selection, highly specialized surgery, and intensive immediate postoperative monitoring. Over the years, advances in surgical techniques, immunosuppression, and complication management have significantly improved outcomes, although relevant clinical challenges still persist, particularly in intensive care units where these patients require multidisciplinary care. In this context, the University Hospital of Gran Canaria Dr. Negrín launched its lung transplantation program in July 2023, marking a milestone in the island's specialized care. This work provides a detailed description of the clinical characteristics, most frequent complications, and outcomes of the first bilateral lung transplant patients, with the aim of reflecting on the experience accumulated during the inaugural year and contributing to the continuous improvement of the care process.
Objectives: To describe the characteristics, most frequent complications, and outcomes of patients undergoing bilateral lung transplantation.
Methods: A descriptive and retrospective analysis of post-lung transplant patients admitted to the Intensive Care Unit/Recovery Unit of the University Hospital of Gran Canaria Dr. Negrín, from the start of the lung transplant program in July 2023 to December 2024. Demographic and clinical data, transplant-related values, and major complications were collected. Descriptive statistical analysis was performed using absolute frequencies for categorical variables, while continuous variables were summarized using means and standard deviations (SD).
Results: A total of 23 patients underwent bilateral lung transplantation (only one under emergency level 0), with a predominance of male patients (69.6%) and a mean age of 58.35 years (SD ± 6.80). The main underlying disease leading to transplantation was chronic obstructive pulmonary disease (56.5%), followed by diffuse interstitial lung disease (39.1%) and idiopathic pulmonary fibrosis (4.3%). Regarding the surgical procedure, the average ischemia time was 336.43 min (SD ± 104.95) for the right lung and 369.87 min (SD ± 86.39) for the left lung. Extracorporeal circulation support was required in 52.2% of patients, although only 21.7% needed it to be maintained postoperatively (VV ECMO 17.4% and VA ECMO 4.3%), with an average duration of 1.96 days (SD ± 4.87). Post-transplant, 100% of patients developed primary graft dysfunction upon admission, with a predominance of grade 0 (34.8%) and grade 3 (30.4%). The most frequent complication was renal failure (47.8%, of which 13% required continuous renal replacement therapy), followed by pneumonia/tracheobronchitis (21.7%/13%) and diaphragmatic paresis (17.4%). Only 2 patients (8.7%) required reoperation due to bleeding. The average duration of mechanical ventilation was 10.13 days (SD ± 14.18), with 6 patients (26.1%) requiring percutaneous tracheostomy. The mean ICU/Recovery Unit stay was 25.43 days (SD ± 34.95), with an overall survival rate of 78.3%.
Conclusions: In our first year of experience, 23 patients with a primary diagnosis of COPD underwent transplantation, with a survival rate of 78.3%. All patients developed some degree of PGD, with renal failure being the most common complication.

A systems approach to neurotrauma pathways in Mulago Hospital, Kampala

L. Hobbs[1], D. Karusoke[2], J. Menya[3], A. Hackenberg[4], K. Kohler[5], A. Kwizera[2], T. Bashford[1]

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***733***

Introduction: Trauma is a global cause of morbidity and mortality and has been estimated to cause 9% of all deaths. (1) The global distribution of adverse health outcomes is heavily skewed towards low- and middle-income countries (LMICs), which show a rising epidemiological burden superimposed upon fragile health systems. Traumatic brain injury (TBI) is one of the top three causes of injury-related death and disability, with huge implications for neurosurgical, perioperative, and intensive care services. (2). Uganda is a low income country in East Africa which has seen intensive investment by domestic and overseas partners in the areas of both neurosurgical and intensive care provision. (3, 4) Trauma is a leading cause of mortality and morbidity, largely as a result of road traffic accidents, with the majority of the patients referred to Mulago National Referral Hospital (MNRH). Previous work has explored the epidemiology of trauma, TBI, and intensive care provision in Uganda, (5,6,7) but has not explored patient pathways in light of these development efforts.
Objectives: Our aim was to understand the clinical pathways of different patient populations that significantly contribute to the trauma burden within MNRH. Specifically, we sought to understand the different journeys undertaken by those patients with TBI as opposed to other traumatic injury, including pre- and intra-hospital pathways.
Methods: We collated information on all acutely injured adult patients that were admitted to MNRH over a 5-month period in 2024 using embedded data collectors interrogating routinely collected facility data. This included basic demographic details, along with treatment pathways and patients' physical location within the hospital. The data were analysed using R/RStudio (8) by a mixed research team consisting of clinical experts, data scientists, and health system engineers from MNRH, Makerere University, and the University of Cambridge. The research was approved by the Mulago Hospital Institutional Research Ethics Committee (MHREC 2023-103) and the Uganda National Council for Science and Technology (UNCST HS3598ES).
Results: A total of 602 patients were enrolled into the dataset of whom 52% were aged 18-35 years and 65% had suffered a road traffic accident, with assaults (20%) and falls (10%) the next most common mechanisms of injury. The majority (55%) suffered neurotrauma, followed by lower (30%) and upper (18%) limb injuries. Of patients admitted with neurotrauma, 61% arrived by ambulance and 10.3% via police transport. 42% underwent emergency surgical intervention straight from the emergency department, with 1.5% subsequently admitted to intensive care. A snapshot survey of intensive care beds being occupied by patients with TBI suggests an occupancy of 35%. Nearly 85% of patients were cared for on the specialist neurological or spinal ward after admission. Figure 1 illustrates these intra-hospital journeys as a Sankey flow diagram.
Conclusions: These results suggest that TBI remains a major disease burden in MNRH, requiring significant neurosurgical, perioperative and intensive care capacity, in line with the previous studies.(9) The small percentage of patients admitted to ICU in this data set may be reflective of functional ICU capacity, the large burden of TBI patients on dedicated neurosurgical wards and the number of inter-hospital critical care transfers. Our results indicate that there is a growing use of pre-hospital and ambulance services, which reflects a national priority

and is promising for reducing time critical delays in TBI management. Understanding the pathways patients take during admission with neurotrauma allows assessment of trauma capacity throughout the hospital. Future work is required to coordinate the acute patient pathway to ensure this increased access results in improved clinical outcomes, and to better understand how to manage the resulting burden of ICU care in the context of constrained resources.

Sankey flow diagram of patient pathways through Mulago NRH

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***734***

Introduction: A common complication of neurocritical care patients is acute respiratory distress syndrome (ARDS) associated with impaired oxygenation and increased mortality. The use of positive end-expiratory pressure (PEEP) plays a critical role in the management of ARDS, preventing alveolar collapse and improving gas exchange. PEEP augmentation is always challenging in brain injured patients and has been poorly studied.
Objectives: To investigate the effect of PEEP on respiratory mechanics and arterial blood gases (ABG) parameters in neurocritical care patients with ARDS.
Methods: An interventional, prospective clinical study was conducted in a Greek ICU, including 18 neurocritical care patients with ARDS. GCS on admission, APACHE II and LIS score were recorded. We performed a gradual augmentation of PEEP level from 5 to 8, 12 and 16 cmH2O. At each PEEP level, static mechanical ventilation (MV) [plateau pressure (Ppl), driving pressure (ΔP), static respiratory system compliance (Cst)] were recorded. ABG samples were obtained after 20 min and PaO2/FiO2 ratio (PFR) was calculated. During these maneuvers, we ensured normal intracranial pressure and adequate cerebral perfusion pressure in all patients, as measured via an intraparenchymal catheter.
Results: Included 18 patients (8 ICH, 6 TBI, 4 SAH) had a median age of 60 years [49-69], median ICU admission GCS 7 [4, 8], median APACHE II score 20 [17, 21.75] and median LIS score 2 [1.75, 2.25]. We were not able to detect a uniform pattern of change in ΔP as PEEP level was increased (Fig. 1). Alterations in ΔP were marginally significant between PEEP 8-PEEP 16 ($p = 0.042$, 95%CI 1, 2.5) and PEEP 12-PEEP 16 ($p = 0.047$, 95%CI – 2, – 1) pairs of PEEP levels (Table 1).

Table 1 (abstract 000734) Comparison of ventilator-derived variables, PFR and PaCO2 between different PEEP levels

Variables	ΔP		Cst		Ppl		PFR		PaCO2	
PEEP pairs	*p*	95% CI	*p*	95% CI	*p*	95% CI	*p*	95% CI	*p*	95%CI
All	< 0.001		0.019		< 0.001		0.113		0.058	
PEEP 5/8	1	− 1, 1.5	1	− 2.17, 2.1	0.001	− 3.5, 2.5	1	− 9.55, 3.88	0.487	-0.95, 0.1
PEEP 8/12	0.484	7.51e−6, 2	0.954	− 2.97, 0.52	< 0.001	4, 5	0.529	− 0.98, 12.8	1	0.66, − 0.7
PEEP 12/16	0.047	− 2, − 1	0.039	1.02, 5.38	< 0.001	− 5, 4.5	1	− 23.9, 8.3	0.185	− 1.75, − 0.05
PEEP 5/12	1	− 1, 2	1	− 4.47, 2.09	0.001	6.5, 8	0.69	− 2.36, 19.8	1	− 0.25, 1.45
PEEP 5/16	0.524	− 0.5, 3	0.198	− 8.38, 0.4	0.001	11, 13.5	0.593	− 3.44, 36.4	0.107	0.6, 3.0
PEEP 8/16	0.042	1, 2.5	0.021	− 7.19, − 1.66	0.001	8.5, 10	0.642	− 3.26, 30.6	0.158	0.3, 2.1

A fall in Cst was observed as PEEP level was increased, particularly regarding higher PEEP (> 8 cmH2O) (Fig. 1). Comparison between PEEP 12-PEEP 16 ($p = 0.039$, 95% CI 1.02, 5.38) and PEEP 8-PEEP 16 pair ($p = 0.021$, 95%CI − 7.19, − 1.66) of PEEP levels was found to be significant (Table 1). A gradual rise in Ppl was detected as PEEP level was increased (Fig. 1). All Ppl comparisons between different PEEP levels were significant ($p < 0.05$) (Table 1). A continuous rise in PFR was detected as PEEP level was increased (Fig. 1). No comparison of PFR between different PEEP levels was significant (Table 1). A gradual rise in PaCO2 was detected as PEEP level was increased (Fig. 1), but no comparison of PaCO2 between different PEEP levels was significant (Table 1).

Conclusions: PEEP augmentation from 5 to 8, 12 and 16 cmH2O altered respiratory mechanics and ABG parameters, leading to a gradual increase in Ppl, PFR and PaCO2, a decrease in Cst, and nonuniform pattern of change in ΔP. Further studies are warranted to confirm these findings in brain injured patients with ARDS.

Quality of care for trauma patients in the ICU-performing bedside surgical procedures

N. Iordache[1]; D. Cohen[1]; V. Nudelman[1]
[1]General Intensive Care Unit, Sheba Medical Center, Emek Haela 9, Ramat Gan, Israel
Correspondence: N. Iordache
Intensive Care Medicine Experimental 2025 **13(Suppl 1)*:736***

Introduction: From October 7th, 2023, our ICU faced a significant increase in trauma admissions, many requiring complex surgical procedures at the bedside, such as debridement, advanced wound care, negative pressure wound therapy (NPWT), and open abdomen management. While some of these are typically performed in the OR, during this period many were conducted in the ICU due to urgency or patient condition. Each procedure required coordination between multiple medical teams including general surgery, plastic surgery, and orthopedics. ICU nurses were not only responsible for critical care but also for managing procedural setup and facilitating communication between teams—all within a dynamic and unpredictable clinical setting.
Objectives: The aim of this quality improvement project was to assess the impact of the increased number and complexity of bedside procedures on ICU nursing practice and interdisciplinary collaboration. Our goal was to identify areas for improvement and develop strategies to support staff and maintain high standards of patient care.
Methods: We retrieved patient records from October 2022 to October 2024 and divided them into two periods: Period I (October 2022–October 2023) and Period II (October 2023–October 2024). We focused on the number and types of complex procedures performed at the bedside as reflected in the documentation. To gain nursing insight, we conducted a focus group with 15 ICU nurses who answered questions regarding procedural burden, team coordination, equipment access, and the nurses' sense of professional capability.
Results: The data showed an increase in both the number and complexity of bedside procedures beginning in October 2023. During period I, 530 patients admitted to the ICU; during period II, 605 patients admitted. The number of documented complex bedside procedures nearly doubled in period II compared to the previous year. This trend was also supported by the clinical impression shared by the nursing staff. Nurses described challenges in maintaining communication with interdisciplinary teams, along with managing time and equipment. While many reported a sense of empowerment, the lack

of defined protocols and logistical support created inefficiencies and stress.
Conclusions: Caring for critically injured ICU patients during high-intensity periods demands coordinated, resource-aware practices. Based on the findings, we propose implementing protocols for common bedside procedures and appointing a procedural coordinator to manage logistics and interdisciplinary collaboration. Introducing targeted simulations on complex bedside interventions could enhance preparedness.

Optimal duration of extracorporeal cardiopulmonary resuscitation for favorable neurological outcomes

JA. Ryu[1]; EY. Kim[1]; YH. Hong[1]
[1]Critical Care Medicine, Samsung Medical Center, Seoul, Republic of Korea

Intensive Care Medicine Experimental 2025 **13(Suppl 1):*737***

Introduction: Determining the optimal duration of extracorporeal cardiopulmonary resuscitation (ECPR) remains challenging, as patient outcomes may vary significantly based on the individual characteristics. We aimed to establish critical time thresholds for achieving favorable neurological outcomes with ECPR across different risk groups, potentially providing more tailored guidance for clinical decision making.
Objectives: We aim to establish critical time thresholds for achieving favorable neurological outcomes with ECPR across different risk groups, potentially providing more tailored guidance for clinical decision-making in ECPR duration.
Methods: This single-center retrospective study analyzed 283 adult patients who received ECPR between 2013 and 2020. Through multivariate analysis of various clinical parameters, we developed a risk stratification model to identify groups with different prognostic profiles. The primary outcome was neurological status at discharge assessed by the Cerebral Performance Categories scale.
Results: In multivariate analysis, age greater than 50 years with asystole (adjusted odds ratio [OR]: 4.89, 95% confidence interval [CI]: 1.41–17.00) or pulseless electrical activity (adjusted OR: 9.70, 95% CI: 2.80–33.60), aspartate transaminase (adjusted OR: 1.52, 95% CI: 1.15–1.99), creatinine (adjusted OR: 2.08, 95% CI: 1.30–3.34), initial lactate (adjusted OR: 1.88, 95% CI: 1.27–3.45), and ECPR duration (adjusted OR: 3.50, 95% CI: 2.02–6.06) were associated with poor neurological outcomes. Based on these findings, we identified three distinct risk groups showing different acceptable ECPR duration thresholds: low-risk (38 min), moderate-risk (27 min), and high-risk (20 min). Notably, no favorable neurological outcomes were observed beyond 70 min in the low-risk group and 90 min in moderate/high-risk groups. Risk group stratification effectively predicted neurological outcomes across different ECPR durations.
Conclusions: Risk-stratified evaluation of ECPR duration provides clinically relevant thresholds for different patient groups, suggesting that continuation of ECPR may be warranted in low-risk patients even with prolonged resuscitation efforts. This approach may enable more personalized decision-making in ECPR implementation.

Age-dependent probability of poor neurological outcomes after extracorporeal cardiopulmonary resuscitation. The solid line represents the predicted probability of poor neurological outcomes based on the patient age, with the shaded area indicating the 95% confidence interval. A marked increase in the probability of poor outcomes is observed around age 50 years, which was subsequently used as a cutoff point for risk stratification. The predicted probabilities were derived from a multivariate logistic regression model adjusted for extracorporeal cardiopulmonary resuscitation duration, aspartate transaminase, initial lactate levels, and first monitored rhythm. The vertical dotted line at age 50 represents the identified threshold for risk stratification.

Relationship between the ECPR duration and probability of poor neurological outcomes stratified by risk group. Risk categories are defined as follows: Low-risk—patients with shockable rhythms and age under 50 years; Moderate risk—patients with shockable rhythms and age 50 years or older, or patients with nonshockable rhythms and age under 50 years; High risk—patients with nonshockable rhythms and age 50 years or older.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***739***

Introduction: Weaning from invasive mechanical ventilation (MV) remains a challenge for the clinician. The best technique of spontaneous breathing trial (SBT) to fulfil safe weaning success (pressure support ventilation (PSV) or T-piece), remains debated. Our aim is to describe characteristics and outcome of patients according to type of SBT chosen by clinicians in daily practice, outside the scope of any controlled study.
Methods: We used data from the observational "WEAN SAFE" study (1), which included 5869 patients receiving MV for more than 2 days in 481 intensive care units in 50 countries between 2017 and 2018. We included patients with at least one documented SBT and evaluated the results of the first SBT by comparing PSV and T-piece. Primary endpoint was the rate of weaning success following the first SBT (extubation within 24 h of the first SBT without reintubation or death within 7 days). Secondary endpoints were extubation rate within 24 h, reintubation rate within 7 days, total duration of MV, in-hospital and intensive care length of stay and mortality.
Results: Among the 5869 patients included in "WEAN SAFE", 4523 had at least one attempt at MV separation. The first of which was an SBT for 2977 patients (66%): 2441 PSV (81%) and 566 T-piece (19%). Demographic characteristics, comorbidities, initial severity and reasons for admission or intubation were similar between groups, apart from a higher proportion of admissions for medical reasons (73% vs. 67%, $p = 0.009$) and intubation for sepsis (26% vs. 22%, $p = 0.038$) in the T-piece group. A comparison of the outcome of the two groups is shown in the table.
Conclusions: In the real-life "WEAN SAFE" cohort, first SBT in PSV was associated with a higher rate of extubation at 24 h and weaning success following the first SBT, with shorter MV and length of stay than with T-piece. However, overall rate of reintubation, weaning success at ICU discharge and mortality did not differ between the two groups. Multivariate analysis will therefore be required to identify explanatory factors for these results.
Weaning results and outcome of patients who underwent a first SBT on pressure support or on a T-piece.

Table 1 (abstract 000739) Diagnostic accuracy of LVOT-VTI in predicting patients' survival

Outcome parameters	Overall population 1st SBT	PSV group	T-piece group	p-value	n
	n = 2977	n = 2411	n = 566		
Extubation within 24 hours of first SBT, n (%)	2342 (86%)	1943 (88%)	399 (78%)	<0.001	2729
Successful weaning following first SBT, n (%)	1959 (77%)	1616 (78%)	343 (71%)	0.001	2555
Overall success of weaning at ICU discharge, n (%)	2555 (86%)	2071 (86%)	484 (85%)	0.865	2977
Reintubation, n (%)	352 (13%)	278 (13%)	74 (14%)	0.293	2729
Overall duration of invasive VM (days)	6.00 [4.00;11.0]	6.00 [4.00;10.0]	8.00 [5.00;13.0]	<0.001	2900
Length of stay in intensive care unit (days)	10.0 [6.00;16.0]	10.0 [6.00;15.0]	13.0 [8.00;21.0]	<0.001	2977
Length of stay in hospital	21.0 [14.0;36.0]	20.0 [13.0;34.0]	26.0 [16.0;43.0]	<0.001	2949
Mortality in ICU, n (%)	403 (13%)	315 (13%)	88 (15%)	0.137	2977
Hospital mortality, n (%)	636 (21%)	499 (21%)	137 (24%)	0.081	2971

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***740***

Introduction: The number of critically ill patients with haematological conditions is rising, and transfusion of blood products is a key component of their management (1, 2). The lack of high-quality evidence

tailored to this patient population has led to inconsistent guideline recommendations and uncertainty regarding transfusion efficacy (3-5). However, despite their significant transfusion needs, data on transfusion practices in these patients remain scarce (5-8). These patients may show differential responses to blood products, such as platelet transfusions, due to their underlying haematological condition and/or treatments. Determining transfusion rates, thresholds, efficacy and underlying reasons and physiological parameters necessitating transfusion is therefore essential.

Objectives: To compare transfusion practices in critically ill patients with and without haematological conditions, and assess the impact of RBC, platelet, and plasma transfusions on clinical outcomes.

Methods: This is a substudy of the International Point Prevalence Study of Intensive Care Unit Transfusion Practices (InPUT)—an international, multicenter, prospective, observational cohort study evaluating worldwide transfusion practices in the ICU (9). Haematological conditions included benign/malignant disease or prior stem cell transplant. The primary outcome was occurrence rates of RBC, platelet, and plasma transfusions. Secondary outcomes included transfusion indications, thresholds, and clinical outcomes.

Results: Of all the patients included in the InPUT-study (n = 3643), 131 (3.6%) had a haematological condition. These patients had higher odds of receiving RBC (odds ratio (OR) 1.58, 95% CI 1.09-2.29) and platelet transfusions (OR 8.32, 95% CI 5.09-13.6,) and lower transfusion thresholds for RBC (7 [IQR: 7-8] g/L) and platelets (median 50 × 10^9 [IQR: 30-50] vs. 55 × 10^9 [IQR: 50-100]). The most common primary reason for RBC transfusion was low haemoglobin (Hb), and in most cases, no overt physiological signs were reported necessitating transfusion at that point (Fig. 1A & B). When a physiological trigger was given, "hypotension" was most commonly reported. Critically ill haematological patients more frequently received plasma and platelet transfusions for prophylactic or procedural purposes, while active bleeding was cited less frequently (Fig. 1C & D). Haematological patients who received a transfusion had higher 28-day mortality and longer ICU stays.

Conclusions: Haematological patients are more likely to receive RBC transfusions than nonhaematological ICU patients, with low haemoglobin levels being the primary reason. Plasma, coagulation factors, and platelet transfusions are mostly given prophylactically. Given the limited evidence on optimal transfusion strategies for haematological ICU patients, our findings underscore the need for further research in this vulnerable population.Reasons and triggers for RBC transfusion, reasons for plasma and platelet transfusion, stratified by presence of a haematological condition

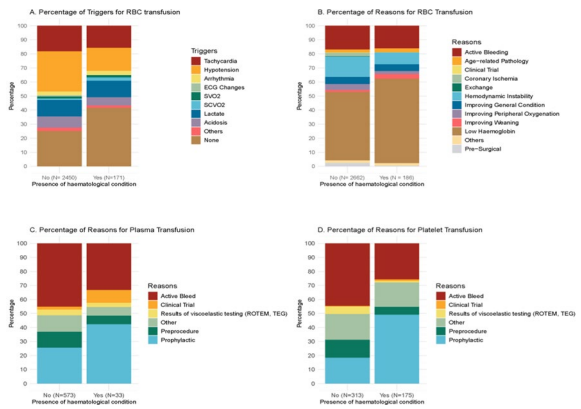

Fig. 1 (abstract 000740) Reasons and triggers for RBC transfusion, reasons for plasma and platelet transfusion, stratified by presence of a haematological condition
Triggers are defined as: Physiological parameters necessitating transfusion.
Reasons are defined as: Clinical reason provided as foundation for the decision to transfuse.

Development of BERT-based Large Language Model (LLM) for triage in the emergency department based on real-world conversation

S. Lee[1]; S. Jung[2]; S. Ahn[1]; P. Jong-Hak[1]; C. Hanjin[1]; M. Sungwoo[1]
[1]Emergency Department, Korea University Ansan Hospital, Jeokgeum-ro, Danwon-gu, Ansan-si, Gyeonggi-do, South Korea, Ansan-si, Republic of Korea; [2]Core Research & Development Center, Korea University Ansan Hospital, Jeokgeum-ro, Danwon-gu, Ansan-si, Gyeonggi-do, South Korea, Ansan-si, Republic of Korea
Correspondence: S. Lee
Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***741***

Introduction: In hospitals and pre-hospital settings, triaged is conducted to focus more available resources on the most urgent patients rapidly. To triage accurately, education and training is required. In the recent years, artificial intelligence (AI) has been attempted to triage patients. However, most studies trained artificial intelligence with the summarized scenarios. It has not been studied whether AI can actually triage a conversation between a healthcare provider and a patient.

Objectives: In this study, we trained large language models to triage between urgent (KTAS 3) or nonurgent (KTAS 4, 5) with real-world clinical conversation from the emergency department.

Methods: The conversations between patients and medical staff were publicly available in anonymized form through the 'AI Hub' provided by the Korea Information Society Agency. We used conversations from the triage level. An example of an extracted triage conversation is shown in Fig. 1. Triage was performed using the Korean Triage and Acuity Scale (KTAS). We trained two BERT-based models to triage between urgent (KTAS 3) or nonurgent (KTAS 4, 5). The first model tokenizes the entire conversation, and the second model is a hierarchical model that tokenizes each sentence and then reprocesses it. We defined the performance metrics as accuracy, precision, recall, and F1-score. To demonstrate its performance, we compared it to the accuracy of ChatGPT GPT-4o. In addition, we demonstrated the explainability of the model we trained using SHapley Additive exPlanations (SHAP).

Results: Out of a total of 5,244 clinical conversations, we extracted 1,057 conversations from the Triage level. Of these, 950 were used for training and validation, and 107 were assigned to the test set. The performance metrics of our models and ChatGPT GPT-4o are shown in Table 1. Our model had an overall accuracy of 69.4% and 75.9%, respectively, as compared to 35.2% for ChatGPT GPT-4o. On Urgent (KTAS 3) patients, the recall of our model was 0.8571 and 0.9610, respectively, as compared to 0.1818 for ChatGPT GPT-4o. The confusion matrix for each model is shown in Fig. 2. When we examined LLM explainability with SHAP, we found that our model actually learned the KTAS classification system. In addition, it focused on clinically meaningful situations such as revisit or referral to a high-level hospital.

Table 1 (abstract 000741) The performance metrics of BERT-based large language models and ChatGPT GPT-4o

Performance metrics		ChatGPT GPT-4o	BERT-based Model 1	BERT-based Model 2
Overall Accuracy (%)		35.2%	69.4%	75.9%
Urgent (KTAS 3)	Precision	0.6667	0.7500	0.7629
	Recall	0.1818	0.8571	0.9610
	F1-Score	0.2857	0.8000	0.8506
Not Urgent (KTAS 4/5)	Precision	0.2759	0.4500	0.7273
	Recall	0.7742	0.2903	0.2581
	F1-Score	0.4068	0.3529	0.3810

Conclusions: We developed a BERT-based LLM to triage in the emergency room based on real conversations and significantly outperformed ChatGPT. The study showed the limitations of traditional LLMs in triaging real-world conversations but also showed that training with real-world conversations can improve them.

No.	Speaker	Conversations
1	Triage nurse	This way please. Take a sit. What makes you come here today?

13	Triage nurse	What kind of pain is it?
14	Patient	It feels like a stab.
15	Triage nurse	Stabbing pain, is it?
16	Patient	Yes
17	Patient	Now my head hurts.
18	Triage nurse	Oh
19	Triage nurse	You have a headache now?
20	Patient	Yes, it feels like someone is poking my head.
21	Triage nurse	So, the pain doesn't extend to this area, does it?
22	Triage nurse	Like to your shoulders.
23	Patient	It passed, downwards.
24	Triage nurse	Passed downwards?
25	Triage nurse	So, the pain is no longer on your chest area?
26	Patient	No, it still hurts
27	Triage nurse	It still hurst
28	Patient	Yes.
29	Triage nurse	Which part of your arm does it hurt?
...	...	...

Early positive fluid balance associates with increased mortality in neurological critically ill patients: a 10-year cohort study

JA. Ryu[1], YH. Hong[1], EY. Kim[1]
[1]Critical Care Medicine, Samsung Medical Center, Seoul, Republic of Korea
Correspondence: J.A. Ryu
Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***743***

Introduction: Fluid management is a critical aspect of care for neurocritically ill patients, yet the optimal approach remains unclear. The relationship between fluid balance and clinical outcomes in these patients requires further investigation, particularly regarding the timing and volume of fluid administration.
Objectives: The objective of this study is to investigate whether early fluid balance patterns and management strategies are associated with clinical outcomes in neurological critically ill patients.
Methods: This retrospective observational study analyzed 2,186 adult patients admitted to the neurosurgical intensive care unit (ICU) from January 2013 to December 2022. We employed generalized additive model (GAM) with cubic spline smoothing to examine nonlinear relationships between fluid balance and mortality. The maximally selected rank statistics method was used to determine the optimal cutoff value for fluid balance. Associations between fluid balance patterns and 28-day mortality were analyzed using multivariable logistic regression model.
Results: Initial analysis identified fluid balance on day 1 as the most significant predictor of mortality, patients with positive fluid balance showed higher 28-day mortality. Nonsurvivors showed significantly higher fluid input throughout the 7-day observation period, particularly during the first 24 h (4444 mL vs 3978 mL, $p = 0.007$). Multivariable analysis confirmed that fluid balance on day 1 remained independently associated with 28-day mortality after adjusting for confounders (adjusted odd ratio 1.705, 95% confidence interval: 1.001–2.905, $p = 0.049$). In addition, the relationship between fluid input day 1 and mortality demonstrated a progressively increasing probability of 28-day mortality with higher fluid volumes.
Conclusions: Early fluid balance, particularly during the first 24 h of ICU admission, shows a significant association with mortality in neurocritically ill patients. These findings emphasize the crucial importance of careful fluid management in the early phase of neurocritical care and suggest that implementation of strict fluid monitoring protocols, especially during the initial period of care, may improve patient outcomes.

Predicted probability of 28-day mortality according to fluid balance on day1

Association between fluid input on day 1 and predictive probability for 28-day mortality.

A Decision shared? Limiting treatment in severe traumatic brain injury

A. Gibbon[1], C. Lopez Soto[2], U. Roy[2]; V. Metaxa[2]
[1]Department of Critical Care, St George's University Hospitals NHS Foundation Trust, London, United Kingdom; [2]Department of Critical Care, King's College Hospital NHS Foundation Trust, London, United Kingdom

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***744***.

Introduction: Decision making around treatment limitation in severe traumatic brain injury (sTBI) is highly challenging, yet integral to the provision of individualised, patient-focused care [1]. A shared decision-making approach is recommended by Critical Care Societies [2, 3] and in the UK is required by the Mental Capacity Act [3]. There is little UK data on approach to treatment-limiting decisions (TLDs) in sTBI.
Objectives: This study aims to describe TLD practice at our institution, a tertiary neurosurgical and major trauma centre in London, UK.
Methods: A retrospective study of all adult sTBI patients admitted to the ICU of a London teaching hospital was carried out. The data collection period was Jan-Dec 2022. Electronic notes were reviewed for TLDs. TLD documentation was reviewed for key aspects of decision-making processes, including shared decision-making with surrogate involvement, multidisciplinary input, consideration of patient values and preferences, conflict, and ethics committee involvement. ICU/hospital mortality data was registered.
Results: One hundred patients were admitted with sTBI during the study period. One patient was excluded due to insufficient records. Of the remaining 99, 48% (n = 48) had one or more TLD implemented. Commonest TLDs were DNACPR (n = 42) and withholding neurosurgery (n = 26). ICU clinicians were key decision-makers, contributing to TLDs in all patients: acting unilaterally in 12/48 (25%), with multidisciplinary input in 30/48 (63%), and with surrogate involvement in 25/48 (52%). Contributing specialties were Neurosurgery (30/48, 63%), Brain Injury Team (2/48, 4%), Emergency Medicine (2/48, 4%), and Oncology (1/48, 2%). Surrogates were family members in 24/25 (96%) cases and an Independent Mental Capacity Advocate in 1. No Advanced Directives were used. Clear documentation of patient value/preference consideration was evident in 9/48 (19%). Conflict was found in 3 cases (6%). All were resolved without legal escalation; one required Brain Injury Team referral. ICU and in-hospital mortality was 38/48 (79%) and 42/48 (87.5%) respectively. All patients without TLDs survived to hospital discharge.
Conclusions: A shared decision-making approach aims for clinicians and surrogates to come to decisions together, maintaining a focus on the individual patient's preferences, goals and values [4]. Our data suggests a need for increased involvement of surrogates in TLD discussions, as well as more explicit documentation, which includes patient values and preferences. Involvement of other specialty teams, such as the Brain Injury Team, may be an under-utilised resource. Significant conflict between the treating team and family is rare, but when present may be an indication for additional specialty input. The study limitations include its retrospective design and reliance on availability and quality of documentation, which may have impacted some study findings. A prospective study would be beneficial to better capture the complexities and quality of TLD processes in sTBI.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***745***

Introduction: Sepsis is a host response to a potentially fatal infection and recognizing predictors of severity can reduce high mortality rates (1,2). Several machine learning methods have shown promise for detecting early stage sepsis and have emerged as an alternative to classical and robust methods such as logistic regressions but prospective validation studies of diverse populations are required to validate their results (3,4).
Objectives: To evaluate the performance of several predictive models of mortality in a cohort of patients diagnosed with sepsis in a tertiary hospital in Colombia.
Methods: Study of a prospective cohort of adults who were admitted to the emergency department with suspected infection, confirmed infection and then developed sepsis after which they were admitted to the ICU between 2021 and 2022 (5). Those over 18 years of age were included and those with comorbidities such as primary immunodeficiencies, those with exposure to antibiotic therapy prior to consultation and terminal illnesses were excluded. Demographic information, comorbidities, symptoms, physical examination and laboratory findings were collected. ICU mortality was the main outcome and a multivariate logistic regression model was constructed, adjusted for confounding factors and with backward direction, in which 23 model iterations were made and the best model with the highest log likelihood Cox-Snell R2 0, 45 and Nagelkerke's R2 of 0.85, then several machine learning algorithms (Random forest (6), support vector machine, k-nearest neighbors and decision tree) were trained with 80% of the data and tested with 20%. Finally, an area under the ROC curve analysis was performed and the models were compared.
Results: The study of a prospective cohort of adults who were admitted to the emergency department with suspected infection, confirmed infection and subsequently developed sepsis after which they were admitted to the ICU between 2021 and 2022 (5). Those over 18 years of age were included and those with comorbidities such as primary immunodeficiencies, those with exposure to antibiotic therapy prior to consultation, and terminal illnesses were excluded. Demographic data, comorbidities, symptoms, physical examination and laboratory results were collected. Approval was obtained from an ethics committee of the hospital institution. ICU mortality was the primary outcome and a multivariate logistic regression model, adjusted for confounders

and backward direction, was constructed in which 23 iterations of the model were performed and the best model with the highest log Cox-Snell R2 0 probability was chosen, 45 and Nagelkerke's R2 of 0.85, then several machine learning algorithms (Random forest (6), support vector machine, k-nearest neighbors and decision tree) were trained with 80% of the data and tested with 20%. Finally, an area under the ROC curve analysis was performed and the models were compared.
Conclusions: Logistic regression was the most robust model for predicting sepsis mortality in this cohort of ICU patients and although Random Forest and decision tree models also perform well they are more difficult to implement in clinical settings, so a simple model may be a better option. It is also important to take into account the limitations of machine learning, especially when dealing with small cohorts, with high false positive rates and as in this case a low incidence of mortality and in the presence of overfitting typical of these models.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***746***

Introduction: Pulmonary infections are among the most common causes of intensive care unit admissions. The resulting hypoxia from these infections is typically managed with mechanical ventilation and antibiotherapy. However, it is known that lung injury associated with mechanical ventilation may lead to bacterial translocation from the alveoli into the bloodstream.
Objectives: In this study, we aimed to investigate whether the prone position, as one of the lung-protective ventilation strategies, could prevent bacterial translocation from the lungs to the bloodstream.
Methods: For this purpose, we designed an experiment in which 22 Sprague-Dawley rats received Escherichia coli (E.coli) inoculation via trachea under mechanical ventilation. The animals were then randomized into two groups: prone (n = 11) and supine (n = 11). Anesthesia was achieved using intraperitoneal xylazine and ketamine. A surgical tracheostomy was performed using a 16-gauge cannula, and baseline ventilation was provided with the settings: TV: 6 ml/kg, PEEP: 3 cmH_2O, RR: 68/min. Carotid arterial cannulation was performed for blood gas sampling, blood cultures, and blood pressure monitoring. After collecting baseline blood gas and culture samples, an E. coli colony was instilled into the trachea. Rats were then randomly assigned to prone or supine positions. Subsequently, injurious mechanical ventilation was initiated with settings: FiO_2: 60%, TV: 12 ml/kg, PEEP: 3 cmH_2O, RR: 68/min. At 0, 15, 30, 45, and 60 min, body temperature, heart rate, blood pressure, oxygen saturation, and peak airway pressure (Ppeak) were recorded, along with serial blood gas and blood culture sampling. At the end of the experiment, euthanasia was performed via cervical dislocation.
Results: There were no statistically significant differences in baseline blood gas parameters between the groups. E. coli growth was detected in the blood cultures of 4 animals in each group. The median time to E. coli growth in blood cultures was 15 min in the supine group and 60 min in the prone group (p = 0.114). In the prone group, 25% of animals showed bacterial growth before 15 min, whereas in the

supine group, all animals had positive cultures within the first 15 min ($p = 0.04$).

Conclusions: Our experimental protocol demonstrated that the prone position delays bacterial translocation from the lungs to the bloodstream when compared to the supine position. This suggests a potential protective role of prone positioning in the setting of ventilator-associated lung injury.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***747***

Introduction: Mortality after cardiac arrest (CA) is mostly consecutive to severe neurological damage. The molecular mechanisms driving brain damage are only partly understood. Predicting this damage after CA would allow tailoring healthcare to each individual. However, the current prognostication strategies are not fully accurate and could benefit from the discovery of novel biomarkers. Circulating RNA molecules appear as promising biomarkers for various diseases, including cardiovascular and neurological diseases (1-3). However, their role in brain damage after CA have not yet been fully characterized.

Objectives: This study aimed to identify and validate blood-based RNA biomarkers as outcome predictors after CA.

Methods: A total of 191 patients of the Luxembourg CA cohort were used in this study (ethical approval 200,803/05). RNA was extracted from peripheral blood samples collected in PAXgene RNA tubes 48 h after CA. RNA expression profiles were characterized using optimized direct RNA sequencing in a sub-group of 50 CA patients: 25 patients who survived without any major neurological sequelae at 6 months after CA (cerebral performance category, CPC 1) and 25 age-, body mass index-, and sex-matched patients who died within 6 months after CA (CPC 5). Sequencing results were validated by quantitative PCR (qPCR) in the remaining 141 patients (57 CPC1 and 84 CPC5). Statistical analyses were performed using R studio. Logistic regression, Kaplan–Meier curves and Cox proportional hazard models were used to evaluate their association with survival time.

Results: Direct RNA sequencing in 50 patients yielded 6.7 M reads/sample, detecting 10,490 genes. We identified 412 differentially expressed genes ($p < 0.05$, |log2 fold-change|> 0.5) between survivors and patients who died within 6 months after CA. Biological pathway analysis highlighted key roles in blood cell development, heme biosynthesis, circulation, immunity, apoptosis, and glucose transport. Two RNA candidates were selected for validation by qPCR in the remaining 141 patients. RNAs 1 and 2 were upregulated in nonsurvivors as compared to survivors (Fig. 1). In logistic regression analysis, RNAs 1 and 2 were significant univariate predictors of 6-month survival (Fig. 2A). The predictive value of RNA 1 and RNA 2 remained significant after adjustment with age, body mass index (BMI), time from CA to return of spontaneous circulation (time CA-ROSC), levels of lactate and neuron-specific enolase (NSE) measured 48 h after CA (Fig. 2B). Adding RNA 1 or RNA 2 to a baseline clinical model (BM) including age, BMI, time CA-ROSC, lactate and NSE improved the prediction of survival, as attested by decreased Akaike Information Criterion (AIC), increased area under the curve, significant net reclassification index (NRI) and integrated discrimination improvement (IDI) (Table 1). Kaplan–Meier survival analysis and log-rank test showed that patients with higher (above median value) expression of RNA1 and RNA2 had lower survival rate compared to those with lower expression ($p = 0.0015$ and $pp = 0.053$, respectively; Fig. 3A). These findings were supported by univariate Cox proportional hazards models, where both RNAs were significantly associated with survival time. However, their significance was lost after being adjusted to other clinical variables (Fig. 3B).

Table 1 (abstract 000747) Incremental value of RNA 1 and RNA 2 to predict 6-month survival after CA

	AIC	Lr_p	AUC	DeLong_p	NRI	NRI_p	IDI	IDI_p
Baseline model (BM)	96.155	-	0.940	–	–	–	–	–
BM + RNA1	89.172	0.002	0.953	0.34	0.839	1.18E−07	0.04	0.009
BM + RNA2	91.303	0.008	0.950	0.19	0.803	4.70E−07	0.034	0.029

Conclusions: Elevated blood levels of RNA 1 and RNA 2 measured 48 h after CA are associated with an increased risk of mortality within 6 months. The predictive value of these novel RNAs must be confirmed in larger patient populations.

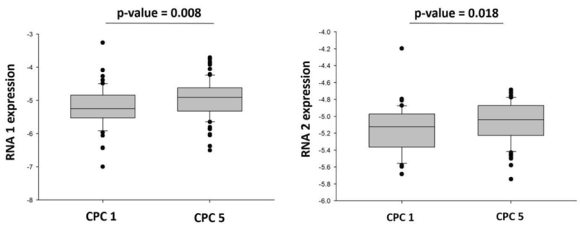

Fig. 1 (abstract 000747) Upregulation of candidate RNA biomarkers in nonsurvivors after CA. Expression levels of RNAs 1 and 2 in patients who survived without neurological sequelae (CPC 1; $n = 57$) and in patients who died within 6 months (CPC 5; $n = 84$) were assessed by qPCR normalized by 18S. *P* values are from Mann–Whitney *U* test

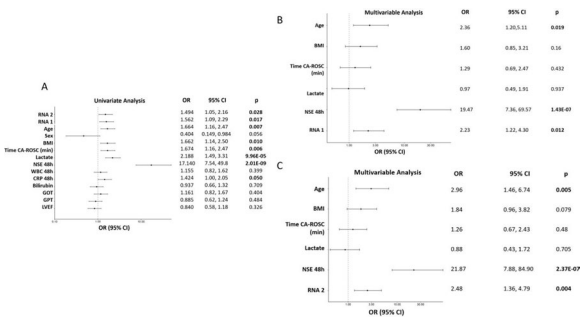

Fig. 2 (abstract 000747) Capacity of RNAs 1 and 2 to predict 6-month survival after CA. Odds ratio (OR) ± 95 confidence intervals (95% CI) and *P* value from univariate (**A**) and multivariable (**B**, **C**) logistic regression analyses conducted in 141 patients are shown in forest plots. *BMI* body mass index, *time CA-ROSC* time from CA to return of spontaneous circulation, *NSE* neuron-specific enolase; *WBC* white blood cell count;

CRP C-reactive protein; *GOT* Aspartate aminotransferase; *GPT* Alanine aminotransferase; *LVEF* Left ventricular ejection fraction

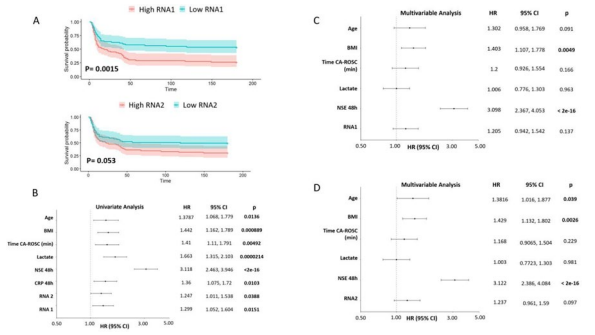

Fig. 3 (abstract 000747) Association of RNA1 and RNA2 expression with survival after CA. **A** Kaplan–Meier survival curves for RNA1 and RNA2 stratified by high and low expression levels. High RNA1 expression (above median value) was significantly associated with reduced survival ($p = 0.0015$, log-rank test), while RNA2 showed a trend toward significance ($p = 0.053$). **B** Forest plot from univariate Cox proportional hazards analysis showing that RNA1 (hazard ratio HR = 1.299, $p = 0.0151$) and RNA2 (HR = 1.247, $p = 0.0388$) were significantly associated with survival. **C, D** In multivariable Cox regression analyses adjusted for clinical covariates, RNA1 ($p = 0.137$) and RNA2 ($p = 0.097$) did not remain significantly associated with survival

Machine learning-based prediction of acute kidney injury in neurocritically ill patients undergoing hyperosmolar therapy

JA. Ryu[1], EY. Kim[1], YH. Hong[1]
[1]Critical Care Medicine, Samsung Medical Center, Seoul, Republic of Korea
Correspondence: J.A. Ryu
Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***748***

Introduction: Acute kidney injury (AKI) is a pivotal concern in neurocritical care, impacting patient survival and quality of life. This study harnesses machine learning (ML) techniques to predict the occurrence of AKI in patients receiving hyperosmolar therapy, aiming to optimize patient outcomes in neurocritical settings.
Objectives: Our study employed ML techniques to predict AKI in neurocritically ill patients undergoing hyperosmolar therapy. Utilizing historical patient data and sophisticated algorithmic models, ML can offer a novel approach to uncover complex interactions and risk factors not easily identifiable through traditional analysis. Our goal is to harness ML to offer insights that could significantly improve patient management in neurocritical care settings.
Methods: We conducted a retrospective cohort study of 4,886 patients who underwent hyperosmolar therapy in the neurosurgical intensive care unit (ICU). Comparative predictive analyses were carried out using advanced ML algorithms—eXtreme Gradient Boosting (XGBoost), Gradient Boosting Machine (GBM), Random Forest (RF)—against standard multivariate logistic regression. Predictive performance was assessed using an 8:2 training–testing data split, with model fine-tuning through cross-validation.
Results: The XGBoost algorithm notably outperformed both the GBM and RF, as well as traditional logistic regression in predicting AKI, achieving a sensitivity of 95.9% and specificity of 36.2%. When applied to an independent test set, it maintained an accuracy of 85.9%, with a *C*-statistic of 0.821 and a Kappa statistic of 0.365. The multivariate logistic regression analysis, while informative, showed less predictive strength as compared to the ML models. Delta chloride levels proved to be the most influential predictor, with additional significant variables including pH, age, serum osmolality, bicarbonate, and the osmolar gap.
Conclusions: The study affirms the value of ML in clinical diagnostics, with XGBoost providing a reliable tool for AKI prediction in neurocritical patients. The prominence of delta chloride among the predictive variables underscores its potential as a biomarker for AKI risk in this patient population.

Predictive performance of eXtreme gradient boosting (XGBoost), stochastic gradient boosting (GBM), and random forest (RF) machine learning model for poor neurologic outcome. Sens = sensitivity, Spec = specificity, ROC = receiver-operating characteristic

The top variables contributing to the predictive performance of each model. The magnitude of the model performance reduction reflects how dependent the model is on particular variable. The importance of variables is scaled so that the maximum value is 100. Delta chloride was defined as the difference between the initial chloride level and the highest chloride level observed during the patient's stay in the intensive care unit. Sodium level, serum osmolality, and chloride level were defined as the highest values recorded during the patient's ICU stay. XGBoost = eXtreme gradient boosting, GBM = Stochastic Gradient Boosting, APACHE II = Acute Physiology and Chronic Health Evaluation.

Intensive Care Medicine Experimental ***2025*** **13**(**Suppl 1**):***750***

Introduction: In Japan, the withdrawal of life-sustaining treatment, particularly palliative extubation, remains limited and controversial. Our medium-sized regional hospital, which includes emergency and cardiovascular centers, has promoted goal-concordant care for over a decade, inspired by clinical practices in the U.S. When patients' goals cannot be achieved, we consider withdrawing life-sustaining treatments, including palliative extubation. We emphasize careful decision-making through advance care planning (ACP) and shared decision-making (SDM) with patients and families. However, few studies have thoroughly investigated the actual decision-making process involved in palliative extubation. Therefore, we aim to report our institution's experience, with particular focus on this process.
Objectives: To describe our experience with palliative extubation, focusing on its decision-making process at a facility where it is routinely practiced.
Methods: This was a single-center retrospective study. We reviewed ICU patients from January 2017 to December 2023. For those who underwent palliative extubation, we collected data on demographics, clinical course, medications used at extubation, time from extubation to death, and decision-making processes, including participants in ACP and SDM. We also analyzed annual trends in palliative extubation among in-hospital deaths following ICU admission.
Results: Palliative extubation was performed in 62 patients. The median age was 79 years (IQR: 68.5-85); 66.1% were male. The median hospital stay was 15 days, ICU stay 6.5 days, and mechanical ventilation duration 133.5 h. Cardiovascular disease was the most common diagnosis (48.3%), followed by respiratory disease (21.0%). The median time from extubation to death was 34.2 h. Fentanyl was used in 79.0% of cases, and midazolam in 6.5%. ACP was documented with patients in 35.5% of cases (including prior discussions), most commonly with patients' adult children (71.0%) and spouses/partners (50.0%). SDM involved patients' adult children in 72.6% and spouses/partners in 50.0%; in only one case was the patient directly involved in the final decision-making to withdraw care. Multidisciplinary conferences were held in 62.9% of cases; in three cases without family, all included team

discussions. The rate of palliative extubation among ICU deaths rose from 4.0% in 2018 to 13.9% in 2023, with an overall rate of 8.0%.
Conclusions: Palliative extubation is increasingly practiced at our institution as part of goal-concordant care. Our structured approach involving ACP, SDM, and multidisciplinary input supports ethically sound decision-making. These findings may help inform and encourage broader adoption of palliative extubation practices in Japan.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***752***

Introduction: Complement activation has been implicated as a contributor to lung injury (1). Membrane-bound complement regulatory proteins, including decay-accelerating factor (DAF), control complement activation thus ensuring the balanced activation of the complement cascade and mitigating complement-mediated injury (2). Few reports have assessed a possible role of CRegPs in mediating acute lung injury (ALI). Most studies have reported findings primarily in mice but the variation of CRegPs expression in different rodents raises questions over their functional role across species.
Objectives: The aim of the present study was to assess the role of DAF on extent of LPS-mediated acute lung injury in the rat, using a transgenic rat model of DAF deficiency.
Methods: Male Sprague–Dawley rats, 180 g in body weight, were used in this study. Animals were reared in accordance with the European Union Directive for the care and use of laboratory animals. WT and *Daf*-/- rats were injected intraperitoneally with 8 mg/kg of LPS prepared from Escherichia coli O111:B4 under isoflurane anesthesia. Control mice received sterile saline solution. Four rats were included in each group. Rats were euthanized under anaesthesia at 16 h post injection and blood samples were obtained from the abdominal inferior vena cava. Serum, BALF and lung tissue samples were obtained. Hematoxylin/eosin staining was performed on lung tissue sections of WT and *Daf*-/- control and LPS receiving rats. IL-6 and IL-10 levels were determined in BALF samples by ELISA immunoassays. Protein levels were determined by immunohistochemistry and western blotting in lung tissue sections and protein lysates respectively.
Results: LPS administration to wild-type (WT) rats caused histopathological lesions indicative of acute lung injury and significantly increased the number of infiltrating inflammatory cell infiltrates without an increase in tissue complement (C3/C3b protein) levels. The total number of cells and Interleukin (IL)-6, but not IL-10 levels, also increased, in bronchoalveolar lavage fluid (BALF) samples in response to LPS. In DAF-deficient rats (*Daf*-/-), DAF protein levels in lung tissue were undetectable in both control and LPS-treated animals. However, DAF absence resulted in increased C3/C3b protein levels in *Daf*-/- control rats, compared to their WT controls. LPS administration to *Daf*-/- rats exacerbated lung injury without an effect on C3/C3b levels. Baseline tissue protein levels of the anaphylatoxin 5a receptor 1 (C5aR1) in *Daf*-/- rats were higher as compared to those in WT controls but this difference was not significant. LPS administration to either group had no effect of on C5aR1. DAF deficiency had no effect on baseline protein levels of the membrane-bound complement regulator, CR1-related gene/protein Y, (Crry). LPS administration increased Crry protein expression levels to a similar extent in both WT and *Daf*-/- rats.
Conclusions: DAF deficiency increases endogenous C3/C3b and C5aR1 protein levels in lung tissue. LPS-induced inflammatory response and lung injury are augmented in *Daf*-/- rats without further increase in C3/C3b and in the absence of significant changes in the expression of membrane-bound complement regulatory proteins, DAF and Crry, or the anaphylatoxin receptor, C5aR1.

Right ventricular injury during VV-ECMO for severe ARDS: does time matter?

R. McDonald[1]; JA. Fowles[2]; R. Gatherer[2]; F. Caetano[2]
[1]School of Clinical Medicine, University of Cambridge, Cambridge, United Kingdom; [2]Department of Anaesthesia and Intensive Care, Royal Papworth Hospital NHS Foundation Trust, Cambridge, United Kingdom
Correspondence: R. McDonald
Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***753***

Introduction: Right ventricular injury (RVI) is prevalent in patients with severe ARDS and is associated with significant mortality [1]. Despite the theoretical RV-protective effect of VV-ECMO, RVI may persist or worsen. The timing and optimal monitoring of RVI in these patients is not well established [2].
Objectives: To characterise the incidence and temporal patterns of RVI in patients receiving VV-ECMO for severe ARDS. To compare clinical characteristics and outcomes between acute and delayed RVI.
Methods: A single-centre retrospective study of patients admitted to a tertiary centre with refractory ARDS requiring VV-ECMO between April 2022 and April 2024, who had at least one echocardiogram performed. RVI was diagnosed via presence of any of: impaired RV function on visual assessment; RV dilatation; right to left ventricular end-diastolic area greater than 0.6 with septal dyskinesia. RVI was divided into acute (if present on admission) and delayed (developed later during the ECMO run). Results were analysed using R Studio version 2024.12.1.
Results: A total of 40 patients were included (median age 39.5 years [IQR 30-49]; 45% male). RVI was observed in 63% and was associated with higher ICU mortality (48% vs 13%, p = 0.04).
72% had acute RVI, mostly diagnosed at admission [0-5 days]. The remaining had delayed RVI (46 days after admission [19-65]). Patients with acute RVI were younger (p < 0.01), were intubated for fewer days prior to ECMO cannulation ($p = 0.01$), and had a trend to present with higher troponins at admission (Table 1). No significant differences were observed on Murray Score, but a trend to lower RESP Score was observed in the delayed RVI group ($p = 0.05$).
While differences in mortality were not statistically significant, delayed RVI was linked to longer ECMO runs ($p < 0.01$) and longer ICU length of stay (p < 0.01)—Table 1.

Table 1 (abstract 000752) Characteristics of acute vs delayed RVI

Characteristic	Acute RVI (*n* = 18)	Delayed RVI (*n* = 7)	*P* value
Age (years)	31.5 (27-40)	54 (42-55)	< 0.01
Male sex	28% (*n* = 5)	57% (*n* = 4)	0.205
BMI (kg/m^2)	25.1 (20.8-40.5)	28.7 (26.9-33.0)	0.317

Characteristic	Acute RVI ($n = 18$)	Delayed RVI ($n = 7$)	*P* value
Days intubated pre-cannulation	1 (0-2)	7 (2-12)	0.012
High sensitivity troponin at admission (ng/L)	358 (166-975.5)	56 (20-300.5)	0.082
Murray score	3 (3-3.8)	3.25 (2.8-3.3)	0.610
RESP score	4 (3-5)	2 (-1-4)	0.052
Mortality	39% ($n = 7$)	71% ($n = 5$)	0.202
ECMO duration (days)	8 (4-21)	58 (22-116)	< 0.01
ICU length of stay (days)	11 (5-44)	112 (28-147)	< 0.01

Conclusions: Right ventricular injury was common among patients receiving VV-ECMO for severe ARDS being associated with higher ICU mortality. Two patterns of RVI were observed. Acute RVI, reflecting disease-driven RV strain prior to ECMO initiation, and delayed RVI which developed during the ECMO run. The latter is likely to reflect incomplete resolution of ARDS and development of lung fibrosis. Although this is likely to reflect natural disease progression, early identification of delayed RVI and therapeutic intervention might aid reversal and improve survival.

Effect of frailty on primary, secondary outcomes, length of stay and delirium for elderly surgical patients admitted post operatively in the ICU

P. Antoniou[1], K. Tsoumani[1], E. Sioziou[2], S. Mantzoukis[1], R. Georgiou[1], G. Gerasimidis[1], D. Lepida[1], E. Kosma[1], K. Bakas[1], A. Liarmakopoulou[1], O. Ygropoulou[1], D. Rizos[1], O. Mousafiri[1]

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**)***:754***

Introduction: Elder surgical patients admitted postoperatively in the Intensive Care Unit (ICU) are a distinct group of patients, more diverse and more demanding, bearing many comorbidities and a limited capacity to thrive. Frailty is a major hinderance of post operative outcomes and can change the course of ICU stay for most of the elderly surgical patients.
Objectives: The aim of this retrospective study is to determine whether frailty alters outcomes and length of ICU stay for patients older than 65 y.o admitted in the ICU after elective major surgery.
Methods: A total of 40 patients > 65 y.o that had elective major abdominal and neck surgery were included in the study. The type of surgery, their demographics, comorbidities, length of ICU stay, outcome, APACHE II score, Clinical Frailty score, SOFA score, blood tests and delirium occurrence with Confusion Assessment Method for the intensive care unit (CAM-ICU) were recorded retrospectively and were statistically analyzed.
Results: Of the 40 patients, the median age was 75.5 years (65-95), the number of female and male patients was equal. Median APACHE II score was 13.5 ± 2.8 and media SOFA score 6. Most patients had CFS score of 4 and 5 (68.4% of all patients). The median Length of ICU stay was 4 days and median days on mechanical ventilation (MV) was 2.5 days. 86.8% of the patients were discharged from the ICU and all of them were discharged later from the hospital. Comparing frailty within two groups, the nonfrail (CFS 1-4) vs the frail (CFS 5-9), no statistically significant difference regarding survival and in hospital death was observed. However, the frail group had longer LOS (median 3.2 vs 6.9 days) and needed more days on MV (median 1.5 vs 5). Most of the patients with delirium occurrence in the ICU after surgery belong to the frail group (28% vs 5.5%).
Conclusions: Frailty alone may not alter surgical outcomes in the ICU, as the severity of the surgical intervention seems to play an important role to survival. However, significant differences exist in the LOS and MV need of frail patients and more of them may develop post operative delirium in the ICU. More studies and the developement of a specific for the elderly post-op score is needed to precisely predict outcomes for this subgroup.

The impact of agency nursing on patient centered outcomes: a cohort study

J. Bartock[1], A. Green[1], O. Rachoin[2], A. Bordogna[3], A. Davoodi[3], JS. Rachoin[1]
[1]Critical Care Medicine, Cooper University Hospital, Cooper Plaza, Camden, NJ, USA, Camden, United States of America; [2]Data Management, Rachoin Consulting, New Sehaile, Lebanon; [3]Medical Education, Cooper University Hospital, Cooper Plaza, Camden, NJ, USA, Camden, NJ, USA, United States of America
Correspondence: J. Bartock
Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**)***:755***

Introduction: Over the last few years, we have seen an exponential increase in the number of traveling nurses in the USA, especially during the pandemic. Reliance on temporary staffing weakens organizational investments in clinical nursing competencies and their influence on specialized care. There is a paucity of data on the impact of Traveling ("Agency") nurses on quality of care and outcomes in hospitalized patients.
Methods: We retrospectively analyzed hospital staffing data at our institution, a large tertiary care center, from 2019 to 2023. We investigated the relationship between nurse staffing ratios, agency nursing, hospital-acquired infections (HAIs), and patient safety indicators (PSIs). We analyzed the association between staffing indices and different PSI and HAI using Spearman's Correlation. The variable agency percent

was divided into three groups: < 5%, 5-10%, and > 10%. We then compared the total number of PSI and number of infections using a one-way ANOVA.

Results: The average total monthly Agency shifts increased in all areas between 2019 and 2023. In the Critical care areas (CCA), it went from 4 (SD = 3.1) to 70 (SD = 81) (peaked in 2022 at 186). In the medical surgical areas (MSA), it increased from 65.8 (SD = 36.5) to 796.6 (SD = 245.6), in the ED from 1.5 (SD = 0.8) to 339.8 (SD = 100.6), and overall from 70.9 (SD = 36.7) to 1,206 (SD = 353.5). As a percentage of total nursing shifts between 2019 and 2023, the Agency nursing shifts increased in the CCA from 0.2% to 2.4% (peaked in 2022 at 7%), in the MSA from 1.3% to 14.2%), in the ED from 0.1% to 31.3% and overall from 0.9% to 12.7%. PSI events varied over the years and increased from 7.1 (SD = 2.4) events per month in 2019 to 9.3 (SD = 5.2) events per month in 2023. For HAI, ventilator-associated pneumonia (VAP) increased from 0.6 (SD = 1) in 2019 to 3.5 (SD = 1.1) in 2023, clostridium difficile (C. diff) from 7.2 (SD = 1.4) in 2019 to 9.3 (SD = 2.8) in 2023, and MRSA from 1.4 (SD = 1.7) in 2019 to 3.3 (SD = 2.1) in 2023. On the other hand, central-line associated bloodstream infections (CLABSI) and catheter-associated urinary tract infection (CAUTI) rates decreased over time from 1.4 (SD = 0.7) and 2.4 (SD = 1.2) in 2019 to 0.7 (SD = 0.6) and 1.5 (SD = 0.9) in 2023, respectively. The overall number of infections increased between 2019 (15.8 [SD = 1.7]) and 2023 (20.5[SD = 3.3]). In the CCA, increased agency nursing was significantly correlated with VAP number (0.27 [0.0-0.5], $p = 0.04$), C. diff (0.4 [0.15-0.6], $p = 0.001$), and total number of infections (0.32[0.07-0.54], $p = 0.013$). For the hospital, a positive correlation was also observed between the percentage of agency and all PSI (0.37 [0.11; 0.58], $p = 0.005$).

Conclusions: From 2019 thru 2023, in our institution, we demonstrated a reduction in quality metrics measured by Patient Safety Indicators (PSIs) and nosocomial infections which correlated with the rinse in the percentage of travel, "Agency", nursing across our major adult clinical units. Travel, "Agency", nursing provides the immediate support necessary to sustain clinical services to a health care system faced with staffing shortages and/or unanticipated surges in patient volume. However, it is hard to ignore that by increasing the number of nurses unfamiliar with our health care system, unit-based protocols, and unit-based competencies our instituion saw a significant reduction in quality surrounding patient centered outcomes. This study should highlight the need to understand the nature of the relationship between travel "Agency" nurses and staffing indices with specific outcomes in order to establish preventative strategies.

Critical care and hematologic malignancies: analyzing symptoms and understanding distress

J. Plessl[1], L. Munshi[2], K. Metcalfe[1], C. Dale[1], S. Mayo[1]
[1]Lawrence S. Bloomberg Faculty of Nursing, University of Toronto, Toronto, Canada; [2]Interdepartmental division of critical care medicine, University of Toronto, Toronto, Canada
Correspondence: J. Plessl
Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***756***

Introduction: Patients with hematologic malignancies (HMs) are admitted to intensive care units (ICUs) with complications of their cancer or cancer treatment(1). Prior research has improved care and decreased mortality(1), yet an understanding of their symptom experiences has not been established(2). Symptom control is crucial for HM patients in the ICU. Uncontrolled symptoms may cause increased

distress including pain, agitation, anxiety, hunger, and insomnia, and can negatively impact quality of life and survivorship(3,4).
Objectives: This study aimed to identify symptoms and distress levels of patients with HMs in the ICU. Research questions included: (1) What symptoms do HM patients experience in ICUs?; (2) How distressing are physical and psychological symptoms?; and (3) What patient and ICU characteristics are associated with distress?
Methods: A cross-sectional study was conducted in a 27-bed ICU in Toronto, Canada, from March 2023 to January 2025. Demographic data was obtained from chart review. The Memorial Symptom Assessment Scale Short Form (MSAS-SF) was completed by participants and measured symptoms and symptom distress subscales. Eligible participants were ICU patients (> 17y) diagnosed with a HM, who could complete the MSAS-SF verbally or by hand. Demographic data was analyzed using descriptive statistics. A univariate analysis evaluated relationships between variables and the MSAS-SF Global Distress Index subscale.
Results: Sixty-eight participants consented, with a mean age of 58.5y (SD ± 14.4). Common HM subtypes included acute leukemia (38%) and lymphoma (32%). Respiratory failure was the ICU admission etiology for 50% of our sample ($N = 34$) and 43 participants (63.2%) received mechanical ventilation (MV) or noninvasive ventilation in ICU, with a low level of organ failure (SOFAhem 4.81). The mean ICU stay was 9.5 days (SD ± 8.7), and mean time between ICU admission and participation was 4.7 days (SD ± 4.4). Frequently endorsed symptoms included a lack of energy (88.2%), dry mouth (83.8%), drowsiness (72.7%), and shortness of breath (70.6%). Mean MSAS-SF symptom subscale scores indicted a high level of distress among physical symptoms (1.61 ± 0.80, range 0-3.53), psychological symptom frequency (1.56 ± 1.06, range 0-3.67), and the global distress index (1.89 ± 0.88, range 0-3.72), as indicated by subscale scores > 1 (5). Trends show increased distress with continuous renal replacement therapy, MV, and a previous stem cell transplant.
Conclusions: HM patients in ICU commonly experience a lack of energy, dry mouth, drowsiness, and shortness of breath. Clinicians should focus on symptom assessment and management to support patient needs. This study highlights the importance of understanding the unique symptom profile of HM patients in ICU to provide targeted interventions. Future research with larger, multicenter samples is warranted.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):*758*

Introduction: Family participation in the care of a patient in the intensive care unit (ICU) can have a positive impact on mental, physical, and cognitive health impairments for both patients and family members (1). In addition, it can positively influence satisfaction with care (1). However, needs in care and communication regarding family participation can be strongly affected by the cultural background of patients and family members (2,3). With knowledge of these needs, an ICU professional can better align with diverse cultural backgrounds (3).
Objectives: To gain insight into the experiences, perspectives, and expectations of ICU professionals regarding culturally sensitive family participation.
Methods: A qualitative study using semi-structured interviews was conducted between December 2024 and April 2025. A purposeful sample of ICU healthcare professionals at a teaching hospital in the Netherlands was included. Interviews were transcribed and key themes were identified using thematic analysis. All participants provided informed consent.
Results: We interviewed nineteen healthcare professionals; fourteen ICU nurses, one intensivist, one physical therapist, two spiritual caregivers, and one medical social worker. The median age of the healthcare professionals was 46 (IQR 32-52) years and 68% were female. The median time working in the ICU was 10 (IQR 5-16) years. Six healthcare professionals had an Islamic background, four a Christian background, one a humanistic background, and eight were nonreligious. Four main themes emerged: (1) opinions in participation of family; (2) culturally sensitive care; (3) communication challenges and; (4) supportive needs. All respondents value family participation in ICU care. Although the new open visiting policy enhances participation, challenges remain. Healthcare professionals primarily develop family engagement approaches through personal experience, creating inconsistent practices. Cultural backgrounds of staff, patients, and families shape expectations and communication, with professionals reporting uncertainty when addressing specific cultural or religious needs. ICU nurses and physicians should more often and earlier seek the assistance of medical social work and spiritual care for support. To address this uncertainty and ensure more effective, culturally sensitive care, this highlights the necessity for cultural diversity training for ICU staff.
Conclusions: ICU professionals are generally positive about family participation and recognize the importance of culturally sensitive care. Facilitating family participation depends on effective communication, while it can be challenging to align family expectations with the possibilities within healthcare logistics. Nurses and physicians need greater awareness and reflexivity regarding how they communicate with families, ensuring their interactions are both empathetic and clear. Family participation in the ICU requires a flexible, culturally sensitive approach.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***759***

Introduction: Sleep disruption is common in intensive care unit (ICU) and is associated with poor outcomes. Noise and nurse care have been reported to disrupt sleep. Night "Quiet-time" postponing and clustering nonurgent care has been tested to improve sleep but results are contrasting and no studies have used objective sleep measurement using EEG.
Objectives: We hypothesized that using a real-time automated sleep monitoring system guiding nursing rounds and nurse care would improve sleep of ICU patients.
Methods: We conducted a prospective monocenter before-after study including critically ill awake patients free of sedatives. In the usual care group, nursing rounds were performed every 4 h as daily practice. In the treatment group, nursing rounds were guided by a medical device composed by an electroencephalography recorder and sleep scoring system working in real-time connected to a tablet positioned at the doorstep of the room. When patients had a continuous sleep episode longer than 10 min, the tablet indicated to prioritize sleep, suggesting caregivers to delay nonurgent care. When patients were awake, the tablet indicated to prioritize care with no nursing rounds restrictions. All patients underwent sleep recording from 7 pm to 7 am. Room entries were counted using an entry/exit counter. Room entries were counted using an entry/exit counter. The primary outcome was total sleep time.
Results: Among the 81 patients included, 60 were analyzed (30 per group). Age, sex and severity scores at ICU admission did not differ between groups. The main reason for ICU admission was acute respiratory failure (63%). Overall, 55 patients (92%) were included while breathing spontaneously and 5 (8.3%) while intubated with no differences between groups. No patients were delirious at inclusion in both groups. In treated group, no patients had delirium. In usual care group, three patients had a delirium after the first or second night. Overall median sleep time was 203min [97-322] in treated group vs 177min [12-224] with no differences between groups. Median [25th-75th percentile] room entries were 23 [16-31] in the treatment group and 26 per night [20-32] in the usual care group ($p = 0.4$). The proportion of room entries while patients were asleep was 6% [0-13] in the treated group vs 22% [4-32] in the usual care group ($p = 0.015$). After exclusion of the 14 patients in whom sleep episodes were systematically < 10min (10 in treated group and 4 in usual care group), total sleep time was higher in treated group (276min [214-345]) than in usual care group (183min [142-243], $p = 0.008$). Time spent in long sleep episodes was higher in treated group (211min [103-306]) compare to control group (117min [73-189], $p = 0.03$). Automatically scored N3 sleep time was higher in the treatment group (101min [43-154]) than in the usual care group (40min [15-100], $p = 0.037$).
Conclusions: Real-time automated sleep monitoring-guided nursing rounds improves sleep quantity and quality in nonsedated critically ill patients.

Physiotherapy provision and practice: a EuropeAn Intensive CarE Unit (ICU) Survey (PEAiCE) —mapping of ICU physiotherapy in Europe

A. Lewko[1], S. Eggmann[2], P. Nydahl[3], D. McWilliams[4]
[1]Centre for Healthcare and Communities, Coventry University, Coventry, United Kingdom; [2]Department of physiotherapy, Inselspital, Bern University Hospital, Insel Group, Bern, Switzerland; [3]Nursing Research, Universitätsklinikum Schleswig-Holstein, Campus Kiel, Kiel, Germany; [4]Centre for Care Excellence, University Hospitals Coventry and Warwickshire, Coventry, United Kingdom
Correspondence: A. Lewko
Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***763***

Introduction: Physiotherapists play a crucial role in the respiratory management and rehabilitation of patients in the Intensive Care Unit (ICU). However, provision and practice of physiotherapy in ICUs across Europe may vary.
Objectives: (1) To map the current provision of physiotherapy across European ICUs (2) To explore physiotherapists' role and practice in the delivery of respiratory care and rehabilitation in European ICUs.
Methods: An a-priori piloted survey, translated into 11 European languages (English, French, German, Spanish, Portuguese, Polish, Italian, Finnish, Greek, Albanian, Ukrainian), was disseminated via a secure, online platform (JISK V.2). We invited physiotherapy leads, or in their absence medical or nursing leaders, from each ICU through professional societies, networks, and social media. The survey included three sections targeting ICU structure, physiotherapy roles, and current practice. Ethical approval was obtained. Data were analysed descriptively.
Results: The survey was open from 19/02 to 21/07/2024. After duplicate removal, 845 responses from 33 countries were included. The highest number of responses were received from Spain (98/845, 12%), UK (95/845, 11%), and France (89/845, 11%, Fig. 1). The majority of respondents per ICU were physiotherapists (740/845, 88%) working in university hospitals (583/845, 69%) with adult patients (731/845, 87%). Almost in all hospitals, physiotherapists treat patients in ICU (839/845, 99%) but may need a referral to start physiotherapy (437/839, 52%). Less than half were dedicated to ICU (346/839, 41%), although most had specific ICU training (672/740, 91%).The majority of responders performed respiratory assessment regularly (588/740, 80%) and provide both respiratory care and rehabilitation for mechanically ventilated patients (625/739, 85%). Variability was seen regarding respiratory techniques (Table 1). Just over half of all respondents reported to performing suctioning (356/647, 55%), or a manually assisted cough (330/647, 51%) regularly. Regular use of other techniques such as Mechanical Insufflation-Exsufflation (MIE) (128/647, 20%), saline instillation 116/647, 18%), and manual hyperinflation (100/647, 15%) were less frequently reported. Early mobilisation techniques were being regularly performed by responders for ventilated patients (Table 2), including sitting at the edge of the bed (596/703, 85%), standing (557/703, 79%) and walking (304/412, 74%).
Conclusions: Provision of physiotherapy in European ICU is heterogenous, demonstrating a wide variation in expertise and the use of specific techniques. The PEAiCE project has identified various levels of access to specialised ICU physiotherapy, along with a wide variation in expertise or specific techniques. Evidence-based methods, particularly early mobilisation techniques are highly reported across Europe. In contrast, other techniques, for example MIE are less commonly used. This may be due to a lack of research to underpin these techniques, or a lack of specialist training in certain areas.

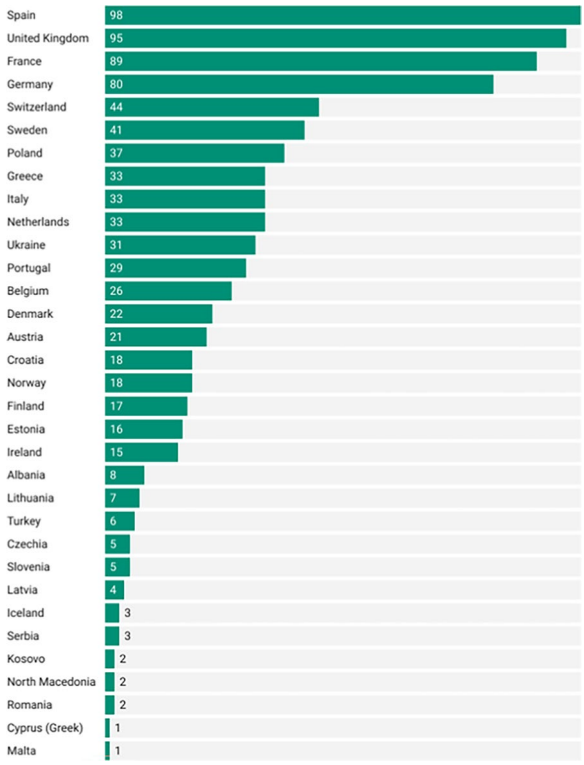

Fig. 1 (abstract 000763) Number of responses by country

Table 1 (abstract 000763) Respiratory techniques used for treating ventilated patients (n = 647)

Technique	Regularly performed N(%)	Occasionally N(%)	Never or not applicable N(%)	Countries where at least 1 physio reported using the technique
Mechanical Insufflation-Exsufflation	128 (20%)	342 (53%)	177 (27%)	27/31
Endotracheal suctioning	356 (55%)	99 (15%)	192 (30%)	27/31
Manual Techniques (e.g. percussion, vibration)	283 (44%)	154 (24%)	210 (32%)	31/31
Saline instillation	116 (18%)	212 (33%)	319 (49%)	25/31
Manual Hyperinflation	100 (15%)	228 (35%)	319 (49%)	26/31
Ventilator Hyperinflation	96 (15%)	141 (22%)	410 (63%)	21/31
Manually Assisted Cough	330 (51%)	248 (38%)	69 (11%)	31/31
Respiratory muscle training	194 (30%)	209 (32%)	244 (38%)	31/31

Table 2 (abstract 000763) Active rehabilitation techniques used for treating ventilated patients

Technique	N	Regularly performed N(%)	Occasionally N(%)	Never or not applicable N(%)	Countries where at least 1 physio reported using the technique
Active exercises in bed	740	436 (59%)	173 (23%)	131 (18%)	32/32
Cycling (cycle ergometer) in bed	740	319 (43%)	269 (36%)	152 (21%)	31/32
Verticalization/standing using a bed or a tilt table	740	260 (35%)	294 (40%)	186 (25%)	31/32
Lateral Transfer out of bed into rehabilitation chair e.g. sliding board	740	201 (27%)	276 (37%)	263 (36%)	31/32
Transfer out of bed into rehabilitation chair with a mechanical lift (hoist)	740	460 (62%)	209 (28%)	71 (10%)	31/32
Neuromuscular electrical stimulation	703	257 (37%)	147 (21%)	251 (36%)	28/31

Prevalence of compassion fatigue and perceived stress among healthcare workers in the intensive care unit of a Tertiary Hospital in the Philippines

SJ. Eppie[1], JE. Tarongoy[1], JE. Cinco[1]
[1]Acute and Critical Care Institute, The Medical City, Pasig, Philippines
Correspondence: S.J. Eppie
Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***764***

Introduction: Working in a dynamic and challenging department of the hospital might lead to stress and/or compassion fatigue and avoidance behavior among healthcare workers and consequently affect patient care and safety. Wide variations in the prevalence of compassion fatigue have been reported with higher levels of burnout reported among healthcare workers in intensive care units (ICUs) as they are exposed to a high level of job stress.
Objectives: This study aimed to determine the prevalence of compassion fatigue and the level of perceived stress among healthcare workers in the ICU of a tertiary hospital in the Philippines. It also aspired to identify the sociodemographic characteristics associated with perceived stress, compassion fatigue, and compassion satisfaction among ICU healthcare workers.
Methods: This single-center cross-sectional descriptive study was conducted in the ICU of a tertiary hospital in the Philippines from May 1 to July 31, 2024. It included ICU healthcare professionals who voluntarily participated in this study. The Professional Quality of Life Scale was used to measure compassion fatigue and satisfaction level among healthcare professionals, while the Perceived Stress Scale was utilized to gauge healthcare workers' perceptions of their stress levels. Both scales have proven adequate reliability in various studies, with Cronbach alpha of 0.75-0.88 and 0.80-0.86, respectively. Google form was

utilized to allow respondents to complete the questionnaire and sign the consent form.

Results: Out of the 114 total ICU staff, the study included one hundred one ($n = 101$) healthcare workers who completed the study questionnaire. However, five respondents ($n = 5$) were excluded due to pre-existing psychiatric illness. Thus, ninety-six healthcare workers ($n = 96$) were included in the present study, comprising the majority (84%) of the workforce. The majority of the respondents had a mean age of 30.34, with a median age of 30, female, single and had no children. Among the 96 respondents, 64 were nurses (66.67%), 21 were doctors (21.88%), and the remaining 11 were pharmacists (11.46%). For the type of work shift, majority had rotating shifts during their hospital duties (80.21%), worked 40 to 50 h per week (71.87%), and had more than 3 years of ICU service (39.58%). Moreover, 92.71% of the respondents had a monthly income range of Php 21,000 to Php 40,000. The results of the ProQoL and PSS showed an average score of 39.41 ± 5.47 for compassion satisfaction, 25.54 ± 5.99 for burnout, 25.10 ± 6.11 for secondary traumatic stress, and 20.30 ± 5.21 for perceived stress. The levels of compassion satisfaction, burnout, secondary traumatic stress level, and perceived stress were observed to be moderate levels among ICU healthcare workers. None of the respondents scored high on the burnout domain; however, 1 respondent scored high on secondary traumatic stress. Notably, 12 respondents had high scores on the perceived stress scale. A similar study by Hameed et al. reported that healthcare workers in critical care settings had average level of compassion fatigue and compassion satisfaction. Likewise, Alharbi and Alshehry reported that most of the ICU nurses in Saudi Arabia had a moderate level of perceived stress. The factors associated with high compassion fatigue and perceived stress among ICU healthcare workers were determined. The results showed that healthcare workers without children had a higher level of perceived stress ($p = 0.046$). In addition, healthcare workers with higher monthly income (> P60,000) had higher compassion satisfaction ($p = 0.000$) and lower perceived stress level ($p = 0.033$). Higher-income satisfaction and having more children were found to be independent protective variables against severe burnout in a cross-sectional multicenter study done by Wang et. al.

Conclusions: In conclusion, there was a predominance of moderate level of compassion fatigue, perceived stress, and compassion satisfaction among the ICU healthcare workers. This study highlighted the critical insights into the emotional challenges faced by healthcare workers in the ICU.

Table 2 (abstract 000764) Professional Quality of Life and Perceived Stress Scale Scores

	Total (n=96)	
	Mean±SD	
Compassion Satisfaction Level	39.41±5.47 (Median 40)	
Low	--	--
Moderate	62	64.58%
High	34	35.42%
Burnout Level	25.54±5.99 (Median 26)	
Low	31	32.29%
Moderate	65	67.71%
High	--	--
Secondary Traumatic Stress Level	25.10±6.11 (Median 25)	
Low	35	36.46%
Moderate	60	62.50%
High	1	1.04%
Perceived Stress Scale	20.30±5.21 (Median 20.5)	
Low	9	9.38%
Moderate	75	78.13%
High	12	12.50%

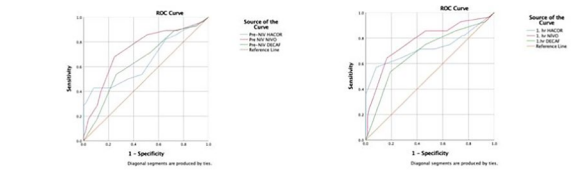
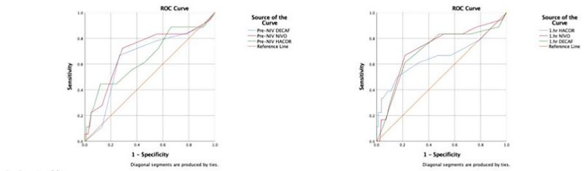
Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***765***



Introduction: Treatment failure increases mortality in patients with respiratory failure who receive noninvasive mechanical ventilation treatment, and predicting success is important. For this purpose, various scores and cutoff values are suggested. Although NIVO (Noninvasive Ventilation Outcomes) Score and DECAF (Dyspnoea, Eosinopenia, Consolidation, Acidaemia and atrial Fibrillation) scores have been shown to predict intubation and mortality in patients with COPD, there are not many studies on their place in the mixed ICU population.

Objectives: The aim of the study is to compare the performances of HACOR(Heart rate, acidosis, consciousness, oxygenation, and respiratory rate) NIVO and DECAF scores in predicting NIV failure, mortality and prolonged intensive care stay in in the mixed ICU patients with respiratory failure and intubation indication.



Methods: In the patients included in the study, HACOR, NIVO, DECAF scores were calculated before noninvasive MV and after 1 h and it was evaluated whether they significantly predicted intubation, mortality and prolonged ICU stay (> 14 days). Then, ROC curve analysis was performed and threshold values were calculated.

Results: 100 patients were included in the study. As a result of statistical analysis, it was concluded that all three scores, both before NIV and after the first hour, significantly predicted intubation (DECAF and NIVO > 3.5, HACOR > 5.5) and ICU mortality (DECAF and NIVO > 4.5,

HACOR > 5.5), and only NIVO score (threshold value > 3.5 for after first 1 h) predicted prolonged ICU stay.
Conclusions: In the mixed ICU patient population, HACOR, NIVO and DECAF scores can predict intubation and mortality, and only NIVO can predict prolonged ICU stay.

Intubation

Mortality

Table 1 (abstract 000765) Predictive values of the scores

	cutoff	sensitivity	specificity	p
NIV FAILURE(INTUBATION)				
Pre-NIV				
HACOR	5.5	68	44	0.02
NIVO	3.5	86	50	<0.001
DECAF	3.5	71	47	0.02
Post-NIV 1. hr				
HACOR	4.5	71	57	<0.001
NIVO	3.5	86	53	<0.001
DECAF	3.5	75	53	0.003
MORTALITY

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***766***.

Introduction: Transfusion practices in critically ill patients often hinge on hemoglobin (Hb) thresholds [1]. While 7 g/dL is widely recommended as a transfusion trigger, real-world practices frequently diverge, influenced by both patient and provider factors [2, 3]. A deeper understanding of these influences can support more individualized transfusion decisions.
Objectives: The primary objective of this study was to identify patient and provider related factors that are associated with early blood transfusion in ICU patients with hemoglobin levels > 7 g/dL. The secondary objective was to develop a predictive model for transfusion decision-making that incorporates clinical parameters beyond the hemoglobin threshold.
Methods: A retrospective analysis was performed using the eICU Collaborative Research Database [4], which includes diverse ICU admissions across the U.S., and the study cohort was identified from 21 ICUs. Out of 14,984 patients initially considered, 2,098 individuals who had received at least one blood transfusion were selected. Following the exclusion of patients with hemorrhagic shock or acute bleeding and ensuring complete data availability, a final study cohort of 1,546 patients was identified. These patients were then stratified into two groups based on their hemoglobin levels at the time of transfusion: Group 1 with Hb < 7 g/dL and Group 2 with Hb ≥ 7 g/dL. A range of patient variables, including age, PaO2, hematocrit, platelet count, prothrombin time (PT)/ international normalized ratio (INR), activated partial thromboplastin time (aPTT), heart rate, mean arterial pressure (MAP), saturation of arterial oxygen (SaO2), APACHE score, and simplified acute physiology score (SAPS) along with provider variables such as ICU bed count, teaching status, physician specialty, and transfusion timing, were analyzed. The predictive performances of these variables were assessed using multivariate logistic regression analysis and gradient-boosted decision tree (XGBoost) model.
Results: Over half of the patients who received a blood transfusion (55.4%, $n = 857$) had hemoglobin levels at or above 7 g/dL. Multivariate logistic regression analysis using patient and provider variables demonstrated significant associations, achieving an AUC of 94.5%, a precision of 88.9%, and an F1 score of 0.882 (Fig. 1). The XGBoost model further uncovered complex, nonlinear interactions, identifying infusion time, physician specialty, patient heart rate, and hospital bed capacity as the most predictive variables (Fig. 2).
Conclusions: Our study suggests that transfusion practices in the ICU do not uniformly adhere to the 7 g/dL hemoglobin threshold and are

influenced by a range of clinical variables. Predictive modeling offers a promising tool for guiding more individualized transfusion decisions, potentially improving consistency and outcomes. Future efforts should focus on refining and validating these models while accounting for provider behavior and mortality outcomes.

Introduction: Sepsis-associated encephalopathy (SAE), a critical complication in ICU patients, leads to high mortality and cognitive impairment.
Objectives: Mitochondrial dysfunction and neuroinflammation are central to SAE pathogenesis, yet the regulatory role of FUNDC1 and therapeutic potential of melatonin remain undefined.
Methods: Wild-type, FUNDC1 knockout (KO), and FUNDC1-overexpressing (OE) mice were subjected to LPS-induced SAE. Cognitive function was assessed via Morris water maze and open field tests. Mitochondrial morphology, autophagy markers (LC3-II, Beclin1, P62), pyroptosis-related proteins (NLRP3, caspase-1, IL-1β), and energy metabolism were analyzed using electron microscopy, qRT-PCR, Western blot, and high-performance liquid chromatography. Primary hippocampal neurons and HT22 cells under LPS stimulation were used for in vitro validation.
Results: In SAE mice, FUNDC1 expression was significantly reduced ($p < 0.01$), accompanied by impaired mitophagy (decreased LC3-II and Beclin1, increased P62; $p < 0.01$), mitochondrial dysfunction (elevated ROS, reduced ATP; $p < 0.01$), and enhanced pyroptosis (upregulated NLRP3, caspase-1, and IL-1β; $p < 0.001$). Melatonin treatment significantly restored FUNDC1 levels, promoted mitophagy, and suppressed pyroptosis ($p < 0.001$). FUNDC1 KO mice exhibited severe cognitive deficits with prolonged escape latency, reduced platform crossings, which were ameliorated by melatonin. In vitro, FUNDC1 KO neurons showed reduced viability and mitochondrial membrane potential, both rescued by melatonin (all $p < 0.01$).
Conclusions: This study identifies FUNDC1 as a pivotal regulator of mitochondrial quality control and pyroptosis in SAE. Melatonin mitigates neuronal injury by restoring FUNDC1-mediated mitophagy and inhibiting NLRP3 inflammasome activation, offering a novel therapeutic strategy for SAE.

A nomogram model to predict the pulmonary embolism risk related to genetic polymorphisms in pregnant women

H. Sun[1], W. Huang[2], Y. Li[3]
[1]Anesthesiology, Shanghai Sixth People's Hospital, shanghai, China; [2]Critical Care Medicine, Shanghai Xuhui Central Hospital, Zhongshan-Xuhui Hospital, Fudan University, shanghai, China; [3]Critical Care Medicine, Tongji University Affiliated Shanghai Tenth People's Hospital, shanghai, China
Correspondence: H. Sun
Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***768***.

Introduction: Pulmonary embolism (PE), the most serious presentation of venous thromboembolism (VTE), is associated with a high rate of mortality and expense [1-3]. Pregnancy could increases the risk of VTE by four to five times.Globally, PE-related deaths during pregnancy account for 3% of all pregnant deaths. Clinical studies on pregnant women with PE are scarce.
Objectives: The aim of this study was to analyze the clinical impact of genetic polymorphisms and establish a predictive model for pregnant women.
Methods: A total of 53 pregnant women with PE were enrolled between September 2022 and August 2023. Using the propensity score matching method, 106 consecutive pregnant women without VTE were 1:2 matched. We categorized the patients into the model group (n = 120) and the internal validation group (n = 39) in a 3:1 ratio. We collected the basic information, relevant laboratory test results, history of previous illnesses, and other clinical information from both the groups and assessed and followed up on the outcome of the treatment of pregnant women with PE.
Results: Our study showed that 4G/4G homozygous mutations increased the risk of pregnant PE fourfold (OR = 4.46, 95% CI = 1.59-12.50, P = 0.004), whereas the 4G allele mutation increased the risk twofold (OR = 2.33, 95% CI = 1.35-4.04, P = 0.002). Statistically significant differences were observed in the recessive (4G/4G vs. 5G/4G + 5G/5G) and additive (4G/4G vs. 5G/4G vs. 5G/5G) models (OR = 3.76, 95 CI% = 1.53-9.28, P = 0.004 and OR = 2.07, 95% CI = 1.23-3.49, P = 0.006, respectively). We established a nomogram to predict the risk of pregnant women with PE by four predictive features including plasminogen activator inhibitor-1 (PAI-1) genetic polymorphisms, international normalized ratio, antithrombin-III activity, and platelet count. The area under the curve (AUC) of the nomogram was 0.821 (0.744-0.898). The AUC of the internal validation group was 0.822 (0.674-0.971). Decision curve analysis revealed that the nomogram has a higher net benefit in the following threshold: probability interval of ≥ 15%.
Conclusions: The PAI-1 4G/4G genotype is an independent risk factor for pregnant women with PE. And the presence of the 4G allele can increase the risk of PE. Constructing a thrombosis risk prediction model for pregnant women in China is important, and our prediction model could serve as a valuable reference for early intervention strategies.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***769***

Introduction: Guidelines for the Provision of Intensive Care Services (1) recommend a physiotherapist to patient ratio of 1:4 in intensive care units (ICU). With a need to direct limited resources, scores to determine patients most at risk of post-op pulmonary complications are being increasingly used for general surgery populations (2). Formerly, on our cardiothoracic ICU, the surgical postoperative screening tool (SPOST) was utilised to screen all postoperative cardiac patients. Clinically, we have identified that the SPOST may; however, overestimate risk in cardiac surgery patients due to high scores related to anaesthesia duration or high initial prophylactic use of oxygen in the immediate post-operative period. The Coventry Cardiac Screening Tool (CCST) was created based on available evidence to simplify risk prediction by replacing numerical values with a straightforward 'Yes/No' assessment for each factor. A previous project was completed to compare the SPOST and the CCST, demonstrating the CCST resulted in a higher proportion of cardiac surgery to be screened out, without adversely affecting re-referral rates. Collectively, as a team, decision was made to replace the SPOST with the CCST for screening cardiac surgery patients.
Objectives: To evaluate the effectiveness and feasibility of using the CCST to identify high risk patients requiring physiotherapy following cardiac surgery.
Methods: All patients undergoing cardiac surgery between 16th December 2025 and April 2025 were included in the analysis. The CCST was completed by all members of the cardiothoracic physiotherapy team on the first postoperative day following cardiac surgery. Patients identified as low risk received nurse led postoperative mobilisation, with no physiotherapy involvement. Patients who were deemed at high-risk received standard physiotherapy including respiratory interventions and mobilisation. Data was analysed to establish proportion of patients that were screened out, alongside the re-referral rate for those patients deemed to be low risk.
Results: A total of 103 patients were included in the analysis, of which 57 (55%) were deemed low risk and screened out of the physiotherapy service. Of these 14/57 (25%) were re referred for physiotherapy due to respiratory complications such as an increase in oxygen requirements or changes on CXR. Interestingly, of those patients deemed to be low risk only 4/14 (29%) met the department standard of mobilising out of bed on the first postoperative day.
Conclusions: The Coventry Cardiac Screening Tool resulted in just over half of all patients being deemed low risk and screened out of the physiotherapy service. Whilst this helped to free up capacity and physiotherapy service delivery, rates of day 1 mobilisation were low in those patients screened out and around one in four were ultimately re referred for physiotherapy input. Future work will aim to improve nursing staff education to support early mobilisation, as well as reviewing the key components of the tool with an aim to improve identification of high-risk patients.

Introduction: Hemoadsorption (HA) is an adjuvant therapy of life-threatening sepsis. Novel HA device, Efferon LPS cartridge containing a porous polymeric adsorbent with surface-immobilized LPS-selective ligand, has demonstrated therapeutic benefits in adult patients with septic shock (SS) [1].
Objectives: To study feasibility of HA using Efferon LPS NEO, pediatric version of the cartridge, in children with sepsis.
Methods: This multicenter study (NCT05707494) compared the clinically relevant effects of HA in pediatric patients with sepsis. A total of 78 children (aged 1-204 months) were included. Of these, 32 received HA (hemoadsorption group, HAG), while 46 received standard of care (control group, CG). Patients in the HAG received two hemoadsorptions using the Efferon LPS NEO cartridge, with a total cumulative treatment duration of 18 h. The primary endpoint was the effect of HA on the pediatric Sequential Organ Failure Assessment (pSOFA) score.
Results: At baseline (day 0), there were no significant differences between the HAG and CG in the following parameters: mean pSOFA score—10.1 (SD 3.5) vs 9.6 (2.8), respectively; incidence of vasopressor use—78% vs 85%; median vasopressor-inotropic score (VIS) among patients in SS—35 (IQR 14-90) vs 36 (15-86); and mean oxygenation index (PF ratio)—242 (SD 144) vs 236 (174) mmHg. The groups also showed no significant differences in pediatric risk of mortality (PRISM) scores, the incidence of acute kidney injury, the use of invasive mechanical ventilation (IMV), or key coagulation parameters. The primary endpoint was achieved: on day 7, the mean pSOFA was 4.9 (SD 4.6) in the HAG and 7.8 (4.2) in the CG, $p = 0.006$. Patients in the HAG discontinued IMV and vasopressor support significantly faster ($p = 0.003$ and $p = 0.001$, respectively); half of the patients were weaned from IMV by day 6 vs day 37, and off vasopressors by day 3 vs day 9 in the CG. In patients with SS, it was accompanied by a marked reduction in vasopressor requirements by day 3: the median VIS was 0.6 (IQR 0-7) in the HAG, compared with 10 (1-65) in the CG, $p = 0.004$. On day 3, the mean PF ratio was significantly higher in the HAG compared with the CG: 314 (SD 144) vs 238 (99), $p = 0.012$. By day 2, patients in the HAG demonstrated a significant reduction in inflammatory markers concentrations: mean serum C-reactive protein decreased from 189 (SD 110) mg/L to 130 (93) mg/L, $p = 0.003$; median interleukin-6 decreased from 700 (IQR 112-4339) to 42 (11-158) pg/mL, $p < 0.001$; and median tumor necrosis factor-alpha decreased from 19 (4.7-66) pg/mL to 6.0 (1.7-17) pg/mL, $p < 0.001$. The 28-day mortality rate was 35% in the control group and 9% in the HA group, OR = 0.2 (95%CI 0.05-0.74), $p = 0.008$.
Conclusions: Efferon LPS NEO decreased severity of multiple organ failure and improved survival in pediatric sepsis. The promising results of this study support the need for adequately powered RCTs to evaluate the potential benefits of HA.

The utility of controlling nutritional status (CONUT) score as a preoperative risk assessment in patients with rheumatic heart disease

P.J. Romero[1]
[1]Critical Care Medicine, Philippine Heart Center, Quezon City, Philippines
Correspondence: P.J. Romero
Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***771***

Introduction: Rheumatic heart disease (RHD) remains a significant burden in developing nations, often leading to complications such as heart failure and malnutrition. The Controlling Nutritional Status (CONUT) score, a screening tool initially developed for hospitalized patients, has garnered attention as a prognostic marker in various medical conditions. Its parameters—serum albumin, total cholesterol, and lymphocyte count—are derived from commonly requested biochemical and immunologic tests. However, its role in predicting outcomes for patients undergoing surgery for RHD remains unclear. This retrospective cohort study aimed to assess whether the preoperative CONUT score could serve as a risk assessment tool in this population.
Methods: A total of 93 adult patients who underwent valve surgery for rheumatic heart disease were included in this retrospective cohort study. Medical records from the Philippine Heart Center, spanning January 2022 to January 2024, were reviewed. Patients were selected through purposive sampling, with inclusion based on the availability of complete preoperative laboratory results required to compute the CONUT score. Postoperative outcomes, including mortality and complications, were also collected.
Results: The study found that patients who experienced clinical outcomes were significantly older than those who did not, but there were no notable differences in gender, BMI, valve involvement, comorbidities, or laboratory values between the two groups. The mean CONUT score was 3, indicating mild nutritional risk for most patients, but it did not significantly predict clinical outcomes such as prolonged hospital stay, bleeding, or infections. Although four patients died and one experienced a stroke, these outcomes were excluded from the odds ratio analysis due to statistical limitations. Overall, the CONUT score was not a significant determinant of adverse outcomes in this cohort.
Conclusions: Although the CONUT score has demonstrated prognostic value in other medical conditions, its utility in predicting outcomes for RHD surgery was not validated in this study. Other validated screening tools for nutritional assessment may be more suitable in this population. Prompt surgical intervention remains crucial in managing RHD, especially given the association between age and adverse outcomes. However, this study's limitations, including its retrospective design and small sample size, warrant further prospective validation studies in larger patient cohorts to elucidate the role of nutritional assessment in RHD management.

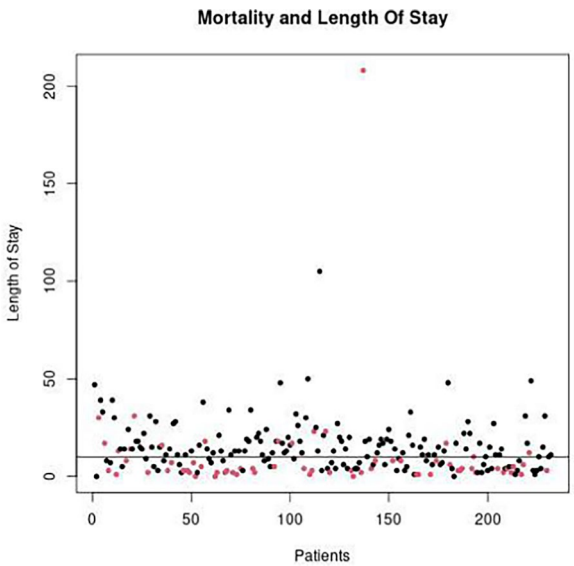
Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***772***



Introduction: Traumatic Brain Injury (TBI) is the commonest cause of death and disability in the under 40's living in high income countries. (1) There are 1.3 million people in the UK living with disability resulting from TBI.(1) The evolution of the TBI whilst in our ICU are poorly understood.
Objectives: This work is an ongoing attempt to describe and understand the progression of the disease during the ICU stay.
Methods: Identified all the patients admitted to our ICU with a diagnosis of TBI from the first of June 2022 to the 31st of May 2023. The data was analysed using R (R-foundation at r-project.org). For numerical data, we used descriptive statistics: minimal and maximum values, medians and means, standard deviations or interquartile range. Comparisons of normally distributed data were done with t-test for probability. For Not normally distributed data we used the Wilkinson test of probability. We established a p value of < 0.05 to demonstrate statistical significance.
Results: 232 Patients with TBI were admitted to our ICU during the observation period. Mean age was 53.91 years (SD 18). 66 patients died during their ICU stay (ICU mortality of 28.4%). The average length of stay (LOS) was 13.84 days (SD 17.57). The LOS between ICU survivors and nonsurvivors was different (means 15.48 vs. 9.68. $p < 0.08$). The average Mean Arterial Pressure (MAP), and the average body temperature, was significantly lower in the nonsurvivors (MAP means 85.07 mmHg SD 9.34 vs. 92.86 mmHg SD 11.91 P = 4.946 e22 − 07, Temperature means 36.53 oC SD 0.59 vs. 37.03 oC SD 0.31. $P = 1.272e - 08$). Nonsurvivors in ICU, had significantly higher average serum glucose, average Na levels, and average PaO2 (Average glucose 8.3 SD 1.21 mmol/dl vs. 7.6 SD 1.21mmol. P = 0.00015, average Na level 148.21 SD 5.88 mmol/L vs. 140.95 SD 4.05 mmol/L. $P = 1.985e - 14$, and average mean paO2 14.67 Kpa SD 4.6 vs. 11.58 Kpa SD 1.46. P = 1.862e − 06). 41 (17.6%) patients in the entire group had Intra Cranial Pressure (ICP) monitors placed. In this group, the average ICP was significantly higher in the patients that died.(23.65 mmHg SD 10.4 vs 13.7 mmHg SD 6.61. P = 0.006). Survivors had significantly higher arterial PH (7.44 SD 0.02 vs. 7.39 SD 0.07. P = 4.119e − 07) and had lower serum lactate concentration (1.00 SD 0.26 vs. 2.06 SD 2.48. P = 0.0010). There was no difference in the PaCO2 levels.
Conclusions: We had an in-ICU mortality of 28.4%, Nonsurvivors are more likely to die within 10 days of ICU admission. The MAP and temperature were lower in nonsurvivors. Glucose, Na and PaO2 were higher in nonsurvivors. Survivors had higher PH and lower lactate concentrations. 17.6% of patients had ICP monitoring in place. Nonsurvivors had higher ICP.

Intensive Care Medicine Experimental 2025* 13(Suppl 1):*773

Introduction: Assessing resting energy expenditure (REE) is essential for providing appropriate nutritional support to critically ill adult patients admitted to the ICU. This study aimed to evaluate the accuracy and correlation of various equations as clinical support tools by comparing them with REE measured through indirect calorimetry.
Methods: In this prospective study, 14 mechanically ventilated (MV) critically ill patients were admitted to adult intensive care units. We performed 24-h indirect calorimetry to obtain a gold standard EE. Simultaneously, we collected 24-h ventilator-derived VCO2, extracted the respiratory quotient of the administered nutrition. REE and respiratory quotient (RQ) were measured on the 1st, 3rd, 5th, and 7th day of ICU admission. Measured REE values was compared to several equations (Weight-based, Harris-Benedict, Ireton-Jones, and calculation formula EE based on ventilator-derived VCO2) using intraclass correlation coefficients (ICC) and Bland-Altman analysis.
Results: The highest REE was observed on day 5 (32.5 ± 10.3 kcal/kg), followed by day 3 (32.0 ± 19.0 kcal/kg), day 7 (31.3 ± 14.5 kcal/kg), and day 1 (28.8 ± 8.2 kcal/kg). The highest RQ was seen on day 7 (0.70 ± 0.04), followed by day 1 (0.69 ± 0.04), day 5 (0.68 ± 0.04), and day 3 (0.68 ± 0.05). Among the predictive equations, calculation formula EE based on ventilator-derived VCO2 showed more precise and higher correlation with measured REE on all days than the predictive equations (ICC—Day 1: 0.78; Day 3: 0.84; Day 5: 0.74; Day 7: 0.81).

Variables	Day 1		Day 3		Day 5		Day 7	
	REE	ICC95% (CI)	REE	ICC95% (CI)	REE	ICC95% (CI)	REE	ICC95% (CI)
Indirect calorimetry	2052 ± 639		2301 ± 1178		2465 ± 630		2252 ± 929	
calculation formula EE based on ventilator-derived VCO2	1756 ± 556	0.78 [0.47-0.92]	1909 ± 957	0.84 [0.6-0.94]	1948 ± 601	0.74 [0.37-0.9]	2178 ± 1093	0.81 [0.53-0.93]
Weight-based equation	1788 ± 301	0.35 [– 0.12-0.72]	1837 ± 318	– 0.01 [– 0.5-0.5]	1963 ± 350	– 0.04 [– 0.53-0.47]	1875 ± 319	0.04 [– 0.46-0.54]
Harris–Benedict equation	1885 ± 335	0.55 [0.07-0.83]	1915 ± 340	0.02 [– 0.48-0.53]	1933 ± 363	0.19 [– 0.34-0.63]	1916 ± 359	0.09 [– 0.42-0.58]
Ireton–Jones equation	1645 ± 288	0.37 [– 0.16-0.74]	1821 ± 362	– 0.01 [– 0.51-0.5]	1643 ± 288	– 0.06 [– 0.54-0.46]	1638 ± 290	– 0.07 [– 0.55-0.45]

Conclusions: Calculation formula EE based on the ventilator-derived VCO2 is accurate and more precise than frequently used predictive equations. Therefore, this calculation formula may be considered a useful alternative to indirect calorimetry for nutritional planning and management in critically ill patients with mechanical ventilation.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***774***

Introduction: There is a debate in current literature regarding the association between hypophosphatemia (Pi < 2.5 mg/dL) and mortality(1). The kidney handling of phosphate in this setting has been scarcely studied. Fractional Tubular Reabsorption of Phosphate (TRP) is considered a marker of tubular efficiency in phosphate reabsorption. Tubular Maximum of Phosphate to Glomerular Filtration Rate (TMP/GFR), is considered the serum cutoff level below which no urine phosphate excretion is expected(2).
Objectives: Describing the association between TMP/GFR and hypophosphatemia development in critically ill patients, and its association with mortality.
Methods: A prospective observational study in an 18-bed mixed medical-surgical ICU in a tertiary university-affiliated hospital. Urine collection was performed from midnight to 06:00 in the first five days of admission of all patients admitted ventilated to the ICU. Patients whose ICU admission lasted more than 48 h were included. Patients who had hypophosphatemia during their first admission day and patients with urological manipulations were excluded. Urine collection volume, creatinine and phosphate levels were evaluated. Serum creatinine and phosphate were assessed each morning. 6 h Creatinine Clearance (CrCl6hr) and TMP/GFR were calculated. The amount of phosphate and calories provided to the patient were recorded daily. Using time-varying COX regression analysis, the factors associated with hypophosphatemia development and 90d mortality were evaluated.
Results: 145 patients were included in the analysis, 75 (51.72%) of them developed hypophosphatemia during their first five admission days. These patients were younger, had lower APACHE2 score, lower kidney SOFA score, and suffered more from trauma. Their TMP/GFR was lower (Table 1). 90d mortality of patients with hypophosphatemia was lower (21.33 vs 44.28%, p = 0.003). Hypophosphatemia was found to be significantly associated with decreased mortality (HR 0.76, 95% CI 0.58, 0.99) after adjustment to baseline covariates; TMP/GFR was not found to be significantly associated with mortality in such analysis (Fig. 1). Univariate analysis for hypophosphatemia development demonstrated several significantly associated covariates: Age, BMI, hospital LOS before ICU admission, APACHE2, Admission SOFA, Admission category, daily SOFA score, daily CrCl, TRP, and TMP/GFR. Among the significant covariates in the univariate analysis, only TMP/GFR was found significant in the multivariate analysis (Fig. 2).
Conclusions: Hypophosphatemia development after 1 day of ICU admission was found to be associated with decreased mortality. TMP/GFR was the only examined covariate significantly associated with hypophosphatemia, regardless of renal phosphate reabsorption. This might merely reflect the obvious association between phosphate level and TMP/GFR. As no other variable was associated with hypophosphatemia, it might be suggested that hypophosphatemia development is a recovery marker.

Table 1 (abstract 000774) Baseline characteristics

	Patients with hypophosphatemia	Patients without hypophosphatemia	p-value

Introduction: Fibrinogen is administered to treat bleeding due to trauma, because it is the precursor of fibrin, which is needed to form a blood clot. However, results on efficacy of fibrinogen are conflicting. Fibrinogen also has other properties, which depends on its isoform. High molecular weight (HMW) form (340 kDa), comprising 60-70% of the plasma concentration. When in the circulation, also other isoforms occur, such as γ′, which comprises around 10% of total circulating fibrinogen. γ′ has other functions then HMW, such as binding to cells as well as some anti-coagulant properties. We hypothesized that fibrinogen therapy would reduce endothelial leakage via decreasing inflammatory cytokines and NETosis in rat polytrauma and those different fibrinogen isoforms have differential effects.
Objectives: To investigate the effect of HMW (wild-type (WT), recombinant), fibrinogen γ′ (recombinant) and standard fibrinogen (mixture of isoforms, represents physiological ratio) on endothelium, inflammation and coagulation parameters in rat poly-trauma model.
Methods: After anesthesia, trauma was inflicted on rats of 350 g by femur fracture and clamping of the gut and liver. Blood was withdrawn to induce shock with a mean arterial pressure of 40 mmHg. After 1 h, rats were randomized to resuscitation with crystalloids supplemented with either fibrinogen standard (Fibryga, Octapharma), fibrinogen WT (Fibriant BV) or fibrinogen γ′ (Fibriant BV), all in a dose of 50 mg/kg. Controls received vehicle. At the end of the experiment, 70-kDa fluorescein isothiocyanate-labeled dextran was injected to determine endothelial leakage. Blood samples were taken to assess markers of endothelial damage, inflammation and ROTEM. Organs were harvested to quantify pulmonary FITC–dextran leakage.
Results: The trauma model was characterized by an increase in lactate, cytokines, markers of endothelial damage, leakage in the lung, and kidney edema. All fibrinogen groups significantly mitigated vascular leakage in the lung compared to the trauma control ($p < 0.01$, Fig. 1) and decreased sVCAM-1 levels as compared to the trauma control ($p < 0.05$). Traumatic injury resulted in an increase in syndecan-1 ($p < 0.05$), which was not seen after fibrinogen administration (all isoforms, Fig. 1). Fibrinogen WT resulted in lower IL-6 levels as compared to trauma ($p < 0.05$). Fibrinogen standard reduced TNF levels as compared to trauma ($p < 0.01$). Both fibrinogen WT and fibrinogen γ′ groups showed a decrease in MPO–DNA complex levels ($p < 0.01$). Fibrinogen γ′, but not the other fibrinogen isoforms, resulted in increased EXTEM CT and lower FIBTEM A10 compared to both sham and trauma ($p < 0.05$, data not shown).
Conclusions: All types of fibrinogens decrease vascular leakage following trauma, associated with a reduction in inflammation and NETosis. Differential fibrinogen isoforms had different effects on coagulation, inflammation, and endothelial function. These findings shed a new light on the role of fibrinogen in trauma and may partially offer an explanation for conflicting findings in the recent trials. Future studies on the efficacy of fibrinogen should consider its pleiotropic functions.

Correspondence: V. Pisarev
Intensive Care Medicine Experimental 2025 13*(Suppl 1):*776

Introduction: Calprotectin (CP), a heterodimer of S100A8/S100A9 molecules, accounts nearly for 45% of the cytosolic protein of neutrophils. Calprotectin is released upon activation of neutrophils and plays an important role in developing inflammatory responses. Elevated levels of calprotectin have been found in blood plasma of patients with rheumatoid arthritis, COVID-19, sepsis and pneumonia. The predictive value of calprotectin for the development of nosocomial pneumonia (NP) has not been studied.
Objectives: Our goal was to evaluate the informative value of CP as a predictive biomarker for NP in patients with sequelae of severe brain injury who have been treated for the latter pathologies in another hospital and admitted to our hospital with no clinical signs and KT/MRT patterns of pneumonia (Pn).
Methods: The observational study included 297 patients with consequences of severe brain damage and no Pn on admittance; of them, 110 patients were diagnosed with NP later and 187 patients did not develop Pn. The age of patients Me (IQR) was 65 (48-74) years, women 55%, SOFA score on admission, Me (IQR): 2 (1-3). Of these samples, plasma specimens from 58 patients were randomly selected for determining calprotectin concentration on admittance using ELISA. Data were statistically treated (SPSS 27.0), and distribution of variable determined; Fisher exact test, Chi-square statistic, log rank test, ROC analysis and univariate/multivariate regression analysis.
Results: Increased lethality was associated with NP development (n = 19) vs control (patients resistant to NP during hospitalization, $n = 39$): 22% vs 5.%, $P < 0.001$, OR = 4.94 (95%CI: 2.26 to 10.79). On admittance, patients that developed NP later, exhibited increased calprotectin level (ng/ml) compared to control: 705 (470-868) vs 434 (326-596), $p = 0.002$. Fisher exact test showed OR = 13.3(3.03 -58,07) for increased CP and patients who developed Pn after 10 days in the hospital (late Pn vs no Pn, $p = 0.0003$) (Fig. 1A). Similar predictive values were received for SOFA as a predictor on admittance for a late NP development by Fisher test (Fig. 1B). ROC analysis also revealed most increased values for both CP and SOFA (AUC = 0.758 (95% CI: 0.6-0.9), $P = 0.003$, and AUC 0.744 (95%CI: 0.599-0.89), $P = 0.0023$, respectively, Fig. 1C). Univariant logistic regression proved the best prediction for independent predictors, SOFA and CP. However, multivariate logistic regression analysis left only two significant NP predictors, CP and age, with OR = 1.002 (95%CI: 1-1.003), $P = 0.037$, and OR = 1.005 (1.001-1.008), $P = 0.008$, respectively. Finally, bivariate regression (CP and age) revealed only significant link of NP to CP concentration on admittance, with OR = 1.006 (95% CI: 0.97-1.044), $P = 0.037$, while for the age $P = 0.75$.
Conclusions: Data demonstrate a strong trend for CP to serve as a novel candidate biomarker to predict late NP on admittance for patients with consequences of brain catastrophes.

Prognostic value of biomarkers on admittance to predict nosocomial pneumonia: **A**—Calprotectin as a predictor, Fisher test; **B**—SOFA as a predictor, Fisher test; **C**—ROC analysis to compare biomarkers showed significance on univariate logistic regression

Intensive Care Medicine Experimental 2025* 13(Suppl 1):*777

Introduction: Evidence regarding the use of the prone positioning (PP) maneuver in acute respiratory distress syndrome (ARDS) during the immediate postoperative period of cardiac surgery is limited.
Objectives: This study aims to analyze the efficacy of the PP maneuver, its complications, and the incidence of mediastinitis in this patient group.
Methods: A retrospective descriptive study was conducted on patients requiring PP in the immediate postoperative period of cardiac surgery from 2004 to 2024. Descriptive statistics and paired numerical comparisons were performed using the Student's t-test, with multivariate analysis via logistic regression and generalized linear models. Statistical analysis was conducted using JASP.
Results: A total of 39 patients requiring PP were analyzed. The mean age was 68 years, and 77% of the patients were male. Risk factors for mediastinitis included osteoporosis (7.7%), chronic obstructive pulmonary disease (15.4%), diabetes (15.4%), antiplatelet use (23%), body mass index (median 26), and internal mammary artery use (30.8%). The pre-existing risk of mediastinitis was moderate, with a median Med-Score 24 of 8 (IQR 6-10). Indications for surgery included aortic dissection (31%), valve surgery (23%), mixed surgery (21%), coronary revascularization (15%), and endocarditis (8%). Forty-nine percent of surgeries were urgent. The mean cardiopulmonary bypass time was 101.6 min, and the aortic clamping time was 64 min. Postoperative infections occurred in 92.31% of patients, with respiratory infections being the most common (76.9%). The most common cause of ARDS was ventilator-associated pneumonia (49%). The median number of PP cycles was 1, with a mean duration of 24 h. Pre-PP PaO2/FiO2 was 75, increasing to 174 at 4 h and 185 at the end ($p < 0.001$). The dosing of vasoactive drugs showed no significant changes before and after PP. Reported PP complications included orotracheal tube obstruction (2.5%), sternal ulcers (2.5%), and pneumothorax (5.12%). Three patients developed mediastinitis, with only one occurring post-PP, in association with sternal dehiscence (2.56%). Mortality was 46%, with no significant difference by cause ($p = 0.068$). Multivariate analysis revealed that higher age and baseline PaCO2 levels were associated with increased mortality ($p = 0.016$ and $p = 0.032$, respectively).
Conclusions: Prone positioning in the postoperative period of cardiac surgery is a safe and effective maneuver, with an incidence of mediastinitis lower than expected for this high-risk group. Mortality was associated with older age and higher baseline PaCO2 levels during PP.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***778***

Introduction: The Global Burden of Disease report reveals that nearly 50 million cases of sepsis occur worldwide annually, with sepsis-related deaths comprising 19.7% of all global fatalities1. From the late twentieth century to the early twenty-first century, clinical trials of sepsis therapies targeting the immune system were largely unsuccessful, partly due to the unaddressed heterogeneity in patients' underlying immune imbalances.2,3. The previous study had shown that changes in various T cell subsets during the onset of sepsis have clinical predictive value 4. The distinct manifestations of CD8 + T cell functional subsets and activation subsets are closely associated with the prognosis of sepsis 5 6. Nonetheless, the role of repeated measurements of CD8 + T cell subsets in predicting prognosis over time, as well as the impact of these indicators on overall T cell function in sepsis patients, remains unclear. Dynamic monitoring may be pivotal in identifying future immunotherapy targets and distinguishing immune-suppressed state. In the present study, we aim to predict the 28-day mortality rate in sepsis patients using cluster analysis based on CD8 + CD28 + /CD8 + % (CD28T8%), CD8 + CD38 + /CD8 + % (CD38T8%), and CD8 + DR + / CD8 + % (DRT8%). In addition, we investigated the specific molecular mechanisms involved using Olink proteomics.
Objectives: Each enrolled patient provided informed consent. ICU patients were included if they met the following criteria (Supplement Fig. 1): aged over 18 years, ICU stay exceeding 24 h, and fulfillment of the 2016 sepsis definition established by the American and European Societies of Critical Care Medicine, which characterizes sepsis as life-threatening organ dysfunction caused by a dysregulated host response to infection7. Organ dysfunction was defined as an acute change of ≥ 2 points in the Sequential Organ Failure Assessment (SOFA) score. Demographic data, SOFA scores, Acute Physiology and Chronic Health Evaluation (APACHE) II scores, chronic comorbidities, laboratory results, sources of infection, and 28-day mortality were extracted from electronic medical records within 24 h of admission. Patients were carefully excluded if they met the following criteria: (1) aged less than 18 years; (2) ICU stay of less than 24 h; (3) pregnant or breastfeeding; (4) receiving glucocorticoids or immune suppressants.
Methods: The study included 220 ICU patients with sepsis (2023.08-2024.05). K-means clustering analysis based on CD8 + CD28 + / CD8 + %, CD8 + CD38 + /CD8 + %, and CD8 + DR + /CD8 + % was used to categorize patients into two groups. Clinical data were collected and analyzed for 28-day mortality prediction. Fifteen patients from each group were selected for Olink proteomics analysis to investigate differentially expressed proteins and conduct functional enrichment analysis.
Results: Using K-means clustering analysis based on CD8 + T cell subset phenotypes, patients were divided into Group 1 (n = 74) and Group 2 (n = 146), with Group 2 demonstrating significantly higher 28-day mortality compared to Group 1 (32.3% vs 17.6%, P < 0.001). Further dynamic trend analysis revealed that patients exhibiting continuously decreasing CD8 + CD28 + /CD8 + % and increasing CD8 + CD38 + /CD8 + % had the poorest prognosis, with a 28-day mortality rate of 50%. The combined measurement of CD8 + CD28 + / CD8 + % and CD8 + CD38 + /CD8 + % showed enhanced prognostic value (AUC = 0.676) compared to individual measurements, indicating the importance of monitoring multiple T cell subset markers. In addition, Olink proteomic analysis identified IL-12Rβ1 as a key molecular mediator closely associated with CD8 + T cell function and activation subsets, providing insights into the underlying mechanism of immune dysfunction in sepsis patients.
Conclusions: CD8 + T cell subset phenotypes serve as important prognostic indicators in sepsis, with IL-12Rβ1 potentially being a key molecule affecting CD8 + T cell function, providing a new potential target for sepsis monitoring and immunotherapy.

The 28-day mortality rate was assessed in relation to the levels of CD28T8% and CD38T8% on different days, categorized by their trend. ROC analysis of parameters predicting 28-day mortality rate. All DEPs in immune response biomarkers between Group 1 and Group 2. **A**, **D** Protein expression in Group 1 (n = 15) and Group 2 (n = 15). **B** Volcano plot visualization of DEPs based on 92 immune-response-related biomarkers. **C** Heatmap illustrating the expression of 92 inflammation-related proteins. **E** Differential levels of IL12RB1 between the two groups

Intensive Care Medicine Experimental 2025* 13(Suppl 1):*780

Introduction: In situ simulation (SIM) training in the Intensive Care Unit (ICU) has emerged as an effective method to improve staff confidence and performance in managing ICU emergencies [1]. At Northwick Park Hospital, we implemented ICU simulation in situ as part of a quality improvement initiative to better prepare ICU staff for high-pressure situations [2]. The dynamic nature of ICU highlights the need for realistic training [3]. By replicating real-life emergencies in the actual clinical setting, staff can build confidence, and reinforce decision-making skills, as well as critical competencies [2].
Objectives: The study consists of two phases. First phase evaluates participants' experience and confidence levels before and after SIM sessions for managing ICU emergencies. It aims to assess pre-existing experience, the effectiveness of simulation sessions, areas for improvement, and feedback for future training. Phase two will analyse the sustainability of confidence levels six months post-simulation for specific clinical scenarios.
Methods: We conducted pre- and post-SIM surveys among 36 healthcare professionals—doctors, advanced critical care practitioners (ACCPs), and nurses in a total of four ICU SIM sessions between November 2024 and March 2025. These surveys were designed to identify previous ICU SIM exposure, areas of clinical experience, confidence in managing ICU emergencies, and perceived learning impact. We used Likert-scale responses and open-ended questions for qualitative insights [4]. Responses were anonymized and surveyed using descriptive and thematic analysis [5]. In the second phase, we will gather qualitative feedback via Likert scale response and open-ended questions [4].
Results: The study involved 36 candidates: 17 doctors, 11 nurses, 8 ACCPs on various ICU experience levels: 9 beginners with < 6 months experience, 16 intermediates with 6-36 months experience, and 11 with > 3 years of experience. Only 11 participants had previously taken part in an in-situ ICU simulation (Fig. 1). The average confidence score was 3.6 out of 5 with 4 candidates scoring low on confidence self-assessment scale, 15 reporting neutral and 14 reporting feeling confident prior SIM (Fig. 2). Post-SIM feedback was highly positive, with 72% rating the training as highly effective. Confidence improvement was evident regardless of prior ICU experience. The intermediate group showed the most notable gains, with 8 individuals experiencing a marked increase in confidence. Among beginners, 4 participants felt significantly more confident, and 5 felt moderately improved (Fig. 3).
Conclusions: These results prove the simulation's effectiveness in building confidence and reinforcing learning outcomes across diverse clinical team. The measurable gain in self-reported confidence highlights the value of incorporating simulation into routine training. Particularly for those with limited and intermediate ICU experience.

Introduction: Postoperative hypotension following cardiovascular surgery with cardiopulmonary bypass (CPB), referred to as vasoplegic syndrome, is characterized by decreased systemic vascular resistance with a concomitant increase in cardiac output. The syndrome leads to diminished catecholamine responsiveness and increased capillary permeability, which contribute to an elevated risk of adverse outcomes and significantly impact patient prognosis. Depletion of endogenous vasopressin has been suggested as a potential cause of the syndrome, with particularly low postoperative vasopressin levels observed in children.
Objectives: To assess the effect of perioperative low-dose vasopressin administration on postoperative course and clinical outcomes after pediatric cardiac surgery with CPB.
Methods: This retrospective study was approved by the Japanese Red Cross Medical Center Institutional Review Board (No. 1647). Among 119 children who underwent cardiac surgery with CPB at our institution between September 2021 and January 2025, 60 patients since May 2023 received perioperative vasopressin (Group V), and 59 patients did not (Group C). In Group V, vasopressin was initiated at 0.0003 U/kg/min during CPB weaning, and was discontinued with tapering by the first postoperative day. Milrinone was started at 0.5 μg/kg/min in the operating room and continued in the intensive care unit. Postoperative course and clinical outcomes were compared between the two groups.
Results: One patient in Group C (1.7%) died of low output syndrome due to high pulmonary blood flow, and No one in Group V died. Group V had a lower incidence of tachyarrhythmias (3 [5%] vs. 12 [20%]; $p < 0.05$). There was no difference in the need for peritoneal dialysis and extracorporeal oxygenation, and in the incidence of necrotizing enterocolitis, deep sternal wound infection, and digital ischemia. Fewer patients required epinephrine administration in Group V (5 [8%] vs. 17 [29%]; $p < 0.01$). Inotrope score was lower in Group V. (Postoperative day 0; 5 [3-6] vs. 10 [6-11], day 1; 3 [1-4] vs. 5 [3-8], day 2; 2 [0-3] vs. 3 [2-5], $p < 0.001$) (Fig. 1), and inotrope administration duration was shorter in Group V (3 [1-5] vs. 5 [3-7] days, $p < 0.01$). Total transfusion intake was reduced in Group V (30 [19-44] vs. 54 [35-70] mL/kg, $p < 0.001$)(Fig. 2), and each type of transfusion was also reduced (RBC: 12 [5-20] vs. 25 [17-39] mL/kg, $p < 0.001$, FFP: 12 [8-18] vs. 16 [10-23] mL/kg, $p < 0.05$, Platelet: 4 [0-8] vs. 7 [1-10] mL/kg, $p < 0.05$). Chest tube drainage volume by day 2 was lower in Group V (23 [15-36] vs. 30 [21-48] mL/kg; $p < 0.05$), and drain tube duration was shorter in Group V (3.5 [3-6] vs. 5.0 [4, 5] days, $p < 0.05$).
Conclusions: Perioperative low-dose vasopressin in pediatric cardiac surgery with CPB was safe, and was associated with reduced postoperative tachyarrhythmias, inotrope requirements, transfusion intake and chest drainage duration.

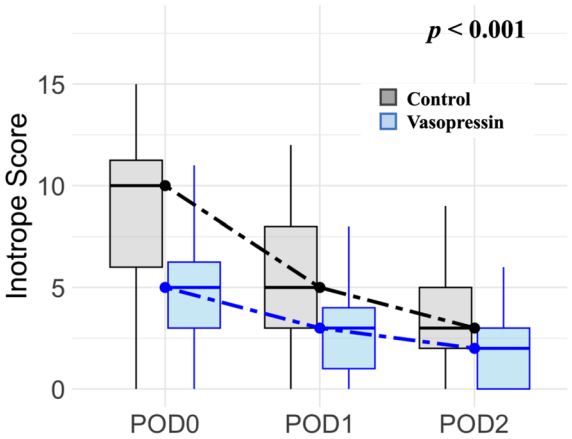

Fig. 1 (abstract 000781) Time course of Inotrope Score
Inotrope score = dopamine dose (μg/kg/min) + dobutamine dose (μg/kg/min) + 100 × epinephrine dose (μg/kg/min).

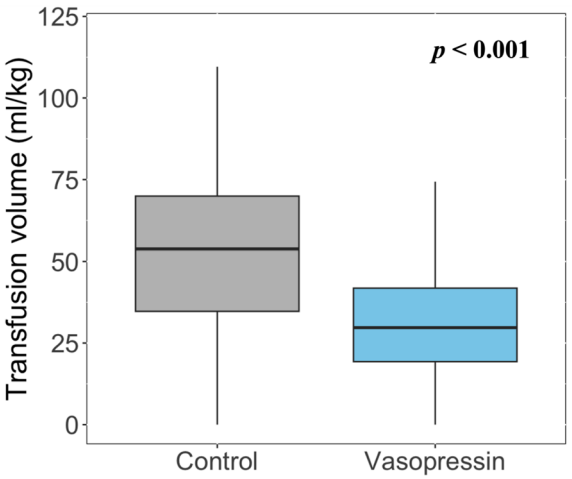

Fig. 2 (abstract 000781) Comparison of cumulative transfusion volume by day2

Introduction: Toxoplasmosis is a life-threatening infection in immunocompromised patients. The direct detection of *Toxoplasma gondii* DNA using PCR has revolutionized the diagnosis of this condition and has been routinely used since almost two decades. While pyrimethamine-sulfadiazine remains the gold standard treatment, alternative regimens are available, offering different routes of administration and safety profiles.
Objectives: We aimed to describe the characteristics and prognosis factors of ICU-admitted patients with PCR-confirmed toxoplasmosis. Specifically, we aimed to study the impact of different treatment regimens on outcomes.
Methods: TOXIC (TOXoplasmosis in the ICu) is a multicenter retrospective case series conducted across 46 European ICUs between January 2012 and January 2023, involving consecutive adult patients with confirmed toxoplasmosis requiring ICU care. Inclusion criteria were 1) age $\geq$ 18 years 2) a severe infection, defined by at least one organ failure (Sequential Organ Failure Assessment sub-score $\geq$ 2) on ICU admission 3) a positive *Toxoplasma gondii* PCR result in any fluid or tissue sample collected within 7 days before or after ICU admission. The primary endpoint was mortality at 90 days after ICU admission.
Results: Among the 210 included patients, the main reasons for ICU admission were neurological failure (n = 119, 56.7%) and respiratory failure (n = 69, 32.9%). The most common underlying conditions were HIV infection (n = 119, 56.7%) with a median CD4 count of 20/µl [IQR 8-44] and hematological malignancies (n = 67, 31.9%), primarily allogeneic hematopoietic stem cell transplantation recipients (n = 50/67, 74.6%). These two populations exhibited distinct clinical, biological and prognosis characteristics. On ICU admission, 58 patients (27.6%) had a concomitant opportunistic infection, with *Pneumocystis jiroveci* pneumonia being the most common (n = 31, 14.8%). Therapeutic management included a pyrimethamine-based regimen (n = 131, 62.7%) or trimethoprime-sulfamethoxazole (n = 67, 32.1%), administered for a median of 42 [IQR 22-58] days. During ICU stay, 143 patients (68.1%) required invasive mechanical ventilation, 90 (42.9%) required vasopressors/inotropes and 47 (22.4%) required renal replacement therapy. At 90 days, 75 (35.7%) patients died. Treatment discontinuation due to toxicity occurred in 11% (22/210) of patients. Overall, ICU and one-year mortality were 29.5% and 47.7%, respectively. Survival analysis is currently underway to identify prognosis factors associated with D90 mortality, including the potential effectiveness of different antiparasitic treatment regimens.
Conclusions: Toxoplasmosis is associated with a dismal prognosis in critically ill patients and impacts immunocompromised patients differently, depending on the underlying condition. Different antiparasitic treatments are currently used, but their relative effectiveness requires further evaluation.

Topic: Infections and prevention

Use of hemoadsorption in acute liver failure as a bridge to liver transplantation. preliminary results

L. Blanco[1], Z. Molina-Collado[1], J. Ginestal-Calvo[1], C. Galiano[1], I. Saez de la Fuente[1], S. Chacón Alves[1], JA. Sanchez-Izquierdo[1]

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***783***

Introduction: Hemoadsorptive therapy (HAT) is an extracorporeal blood purification technique designed to remove inflammatory mediators and toxins. In acute liver failure (ALF), where severe dysfunction leads to toxin accumulation and a dysregulated inflammatory response, HAT may represent a promising therapeutic strategy, potentially allowing stabilization of the patient while awaiting liver transplantation (LT).
Objectives: To describe the utility and safety of HAT in ALF patients as a bridge to LT.
Methods: A retrospective observational study was conducted between 2022 and 2025, including ALF patients who underwent HAT prior to urgent LT. HAT was initiated upon poor response to conservative treatment and continued until LT. Demographic, etiological, and analytical variables were collected before HAT and every 12 h until LT. Results are presented as proportions, medians with interquartile ranges, and means with 95% confidence intervals. Statistical analysis was performed using a Wilcoxon test (SPSS software, version 30.0.0).
Results: 11 patients were included, 55% female, with a median age of 34 years (28.5-42). The leading cause of ALF was toxic origin (55%). Median severity scores were: APACHE II 11 (9-23), SAPS II 41 (30-56,5), MELD 42 (37.5-43.5), and King's College Criteria 2 (1-2.5). After listing, LT was performed after a median of 1 day (1-2.5). HAT was maintained for a median of 31.5 h (27.5-43). A statistically significant decrease was observed in creatinine ($p = 0.009$) and lactate ($p = 0.05$) within the first 12 h, with a nonsignificant downward trend in transaminases. Coagulation parameters and pH remained stable. Thrombopenia ($p = 0.02$) occurred after HAT initiation, without hemorrhagic complications requiring treatment interruption.

	Creatinine	GOT	GPT	Lactate	pH	INR	Platalets (10^3)
0 h (mean, median)	1,8(0,5-3,2) 1(0,54-3,12)	4912(643-9181) 2200(1215-7120)	4230(1775-6684) 3020 (1611-7883)	5,9(1,7-10,1) 2,5(2,1-8,9)	7,35(7,24-7,45) 7,41(7,2-7,44)	4,1(2,9-5,3) 3,9(3-5)	157(70-244) 145 (70-219)
12 h (mean, median)	1,4(0,5-2,2) 0,7(0,4-2,4)	3095(932-5257) 1913(548-5774)	3586(1350-5822) 3122 (788-5598)	3,1(1,9-4,3) 2,9(1,6-3,7)	7,39(7,7,33-7,44) 7,4(7,36-7,42)	4,3(2,8-5,9) 3,8(3,2-4,4)	103(67-159) 82 (68-107)
24 h (mean, median)	1,3(0,2-2,3) 0,7(0,5-2)	2085(507-3663) 1508(378-3075)	2799(801-4797) 1972(850-4288)	2,6(1,8-3,4) 2,5(2,2-2,6)	7,38(7,32-7,44) 7,4(7,34-7,43)	4(2,6-5,5) 4(2,7-5,2)	106(40-172) 92(43-117)

Median ICU stay was 8 days (5.5-10), and hospital stay was 20 days (15.5-25). ICU mortality was 9.1%, involving one patient after LT, not attributable to HAT

Conclusions: In this preliminary series, HAT in ALF as a bridge to LT appears safe and potentially useful, with significant improvements in creatinine and lactate. Although thrombopenia was observed—also common in liver dysfunction—no relevant bleeding complications occurred. These findings suggest HAT may help stabilize patients in a critical phase, gaining time until LT. Larger prospective studies are needed to confirm findings and assess prognostic impact.

Introduction: Cystatin C is more sensitive than serum creatinine to rapidly detect acute changes in renal function.
Methods: We analysed the values of Cystatin C as an early marker of CN in a sample of 71 patients at risk of developing this pathology, recording its increase in relation to the time after exposure to a contrast medium (24 h after the performance of a coronary intervention). According to the KDIGO guidelines: the increase (Δ) of Cystatin C greater than or equal to 10% 24 h after exposure to contrast medium (Δ Cys C ≥ 10%) was the best cut-off value for early identification of patients at risk of CN.
Classic definition of CN: exists whenever a relative increase of 25% or more, or an absolute increase of 0.5 mgr/dl or more, in serum creatinine from baseline is present at 48-72 h after exposure to contrast medium.
Results: As shown in the accompanying table, we found that 61% of patients with Cystatin C increases ≥ 10% developed CN according to the classical definition, reaching statistical significance (p = 0.004).
Conclusions: Cystatin C could be a reliable marker for early diagnosis and prognosis of contrast-induced acute kidney injury.
Cys C levels in the first 24 h post-catheterisation in relation to the development of CN

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***785***

Introduction: Current resuscitation approaches to treating trauma-induced bleeding includes early transfusion of plasma. In clinical practice, several products are used. Fresh frozen plasma (FFP) is derived from a single donor, while solvent detergent plasmas (SDP) is pooled from multiple donors. Observational studies suggest a benefit from SDP over FFP. An explanation may be that SDP contains a high amount of glycine. Our hypothesis is that a high amount of glycine in plasma is beneficial in trauma via conserving endothelial integrity and decreasing inflammation.
Objectives: To investigate the effect of glycine in plasma product on endothelium and inflammatory parameters in rat poly-trauma model.
Methods: After anesthesia, trauma was inflicted on rats by femur fracture and clamping of the gut and liver. Shock was induced via blood withdrawal, aiming to reach mean arterial pressure of 40 mmHg. After 1 h, animals were randomized to resuscitation with rat plasma or glycine supplemented rat plasma (50 mg/kg). The aim of the resuscitation was maintaning MAP > 65 for 2 h. At the end of the experiment, for determining endothelial leakage, 70-kDa fluorescein isothiocyanate-labeled dextran was injected. Blood and organ samples were taken for determination of markers of endothelial damage, inflammation and organ injury.
Results: Trauma induced endothelial leakage, which was prevented by plasma with glycine, but not by plasma alone. Similarly, in glycine group, syndecan-1 levels were significantly decreased ($p < 0.05$). Both plasma and glycine groups showed decreased sVCAM-1 levels ($p < 0.01$, Fig. 1). Plasma supplemented with Glycine, but not plasma, decreased IL-6 levels significantly compared to trauma ($p < 0.05$). Both plasma ($p < 0.05$) and plasma + glycine groups decreased NETosis markers ($p < 0.01$) and trend towards lower TNF levels (Fig. 2).
Conclusions: Plasma supplemented with glycine confers superior conservaton of endothelial integrity, at least in part via reduction of inflammation marker levels. Results suggest a mechanism underlying the observation of the benefit of SDP plasma on the endothelium in trauma.

Intensive Care Medicine Experimental ***2025*** 13(**Suppl 1**):786

Introduction: Vasopressin (AVP) is the second-line vasopressor currently recommended by the Surviving Sepsis Campaign [1, 2] for refractory shock. In the recent years, following the results of the ATHOS-3 trial [3], Angiotensin II (Ang-II) has also emerged as a second-line vasopressor alternative in selected patients to maintain adequate mean arterial pressure (MAP) and reduce norepinephrine (NE) requirement.

Objectives: To compare the kinetics in macro-hemodynamic parameters and the reduction of the NE dosage in patients with refractory shock receiving second-line treatment with AVP or Ang-II.
Methods: Patients older than 18 years, admitted to the ICU between May 2024 and March 2025 with refractory shock, eligible for second-line treatment with AVP or Ang-II, were included in an ongoing prospective registry study. We analyzed clinical, hemodynamic and echocardiographic data collected before the initiation of the second vasopressor infusion and at 3 and 6 h post-administration.
Results: A total of 48 patients were analyzed: 38 received AVP and 10 Ang-II. The median age was 63 (56;72) years, 73% were male, with an APACHE II score at admission of 25 (22;30). Baseline characteristics were comparable between the two populations (Table 1). The NE dose significantly decreased over time in both groups. Specifically, in the Ang-II group, a significant reduction was observed at 3 h (p = 0.01) and 6 h (p = 0.03), while in the AVP group, a significant decrease was noted only at 3 h (p = 0.02). Analyzing the differences between groups at each timepoint, in the first 3 h a reduction in NE dosage was observed, which was significantly greater in the Ang-II group compared to the AVP group [median difference -31.6% (-40; -24) vs. -6% (-36; 0); p = 0.03]. This reduction persisted at 6 h, along with a concomitant decrease in the Vasoactive-Inotropic Score (VIS score), although the difference between the groups was no longer statistically significant. This reduction in catecholamine load was primarily attributed to the addition of the second vasopressor, as reflected by a similar fluid balance in both groups and a simultaneous decrease in the need for resuscitative fluids during the first 6 h (Fig. 1). Meanwhile, MAP and cardiac index remained stable over time.
Conclusions: In this prospective cohort of patients with refractory shock, a significantly greater reduction in NE dosage at 3 h was observed in the Ang-II group compared to the AVP group, while macrohemodynamic parameters remained stable between the two groups. This reduction in NE load was achieved without the need for additional fluid resuscitation and with a similar fluid balance.

Intensive Care Medicine Experimental 2025 **13(Suppl 1):*787***

Introduction: Progressive oxidative stress is one of the major drivers of dysregulated host response in sepsis [1]. Compounds containing thiol groups (-SH-) buffer the oxidative load and hence, thiol levels have been studied as a potential marker of the body's oxidative stress. Serum albumin is the largest carrier of thiol groups [2]. There is a paucity of literature analysing thiol homoeostasis in patients with sepsis and septic shock [3].
Objectives: To assess serum thiol levels as a biomarker for prediction of outcome in patients with sepsis & septic shock.
Methods: In this ongoing prospective observational study, all consecutive adult patients diagnosed with sepsis or septic shock at ICU admission were included after written informed consent. Data collected included age, gender, SOFA scores at admission and outcome at 28 days of ICU admission (survivor or nonsurvivor). On days 1 and 5 of ICU admission, 2 ml of blood sample was collected for measuring Serum-Free Thiol (SFT, in micromol/L) levels using Ellman's Method [4] and serum albumin (in g/dL). Albumin-corrected SFT was calculated by dividing day 1 and day 5 SFT levels by their corresponding serum albumin levels. $P < 0.05$ was considered statistically significant.
Results: During the study period (July 2024–February 2025), 32 patients met the inclusion criteria. The median age was 42.0 years (IQR: 29.5-63.2). Twenty (62.5%) patients were male. Mean SOFA score at admission was 7.8 ± 3.4. At 28 days of ICU admission, 20 patients (62.5%) survived. **SFT in survivors and nonsurvivors:** At day 1, SFT levels were significantly higher in nonsurvivors compared to survivors (nonsurvivors: median 49.77 [IQR: 45.27-61.85], vs. survivors: median 41.87 [IQR: 37.00-48.76]; $p = 0.011$). Similarly, at day 5, non-survivors exhibited significantly higher levels (nonsurvivors: median 56.79 [IQR: 53.39-67.67], vs. survivors: median 43.55 [IQR: 34.03-52.79]; $p = 0.008$). **Albumin-corrected SFT in survivors and nonsurvivors (Figure):** At day 1, albumin-corrected SFT levels were significantly higher in nonsurvivors compared to survivors (nonsurvivors: median 21.32 [IQR: 18.02-24.74], vs. survivors: median 15.00 [IQR: 13.02-17.80]; $p = 0.0054$). Similarly, at day 5, non-survivors exhibited significantly higher levels (nonsurvivors: median 20.29 [IQR: 16.92-24.13], vs. survivors: median 15.15 [IQR: 13.43-19.43]; $p = 0.0493$).
Conclusions: The interim analysis shows that nonsurvivors have significantly higher levels of both SFT and Albumin corrected SFT than survivors on days 1 and 5 of ICU admission. Elevated thiol levels in nonsurvivors may reflect a compensatory upregulation of thiol production in the initial stages of sepsis [1], representing an effort by the body to counteract overwhelming inflammation and oxidative damage.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**)***:790***

Introduction: Mechanical ventilation in critically ill children is a life-saving intervention, however, it carries the risk for ventilator-induced lung injury (1). Increased applied mechanical power (MP) encompasses all parameters, including volume, pressure, flow, resistance and respiratory rate, and despite the adoption of lung protective strategies, adverse outcomes remain high (2,3).
Objectives: This study aims to investigate the applied MP in critically ill children and its associations with risk factors and PICU outcomes.
Methods: A retrospective single-centre study was conducted in an academic pediatric ICU between 2017 and 2024. All patients < 18 years of age consecutively admitted to PICU, who required invasive controlled mechanical ventilation for at least 24 h were included. Demographic, clinical-laboratory data, fluid balance, mechanical energy and power in constant and decreasing flow ventilation modes, at 0 h-12 h-24 h-36 h-48 h-60 h-72 h time points, along with outcome indicators were recorded.
Results: The study included 235 children {60.4% boys, median age 4.5 (IQR 2-11), PELOD-2 6 (IQR 4-8), Pediatric ARDS N = 87 (37%)}. The 28-day mortality rate was 8.9%, and the PICU length of stay was 10 days (IQR 5-18). Longitudinal trends in constant-flow ventilation modes, showed that MP was lower compared to decreasing flow models ($p < 0.001$). Normalized to ideal body weight MP was significantly higher in the PARDS group compared to the no-PARDS group ($p < 0.001$), at all time points ($p < 0.001$). Also, the severity of PARDS was significantly associated with applied MP in decelerating flow ventilation models (Fig. 1). The same correlation was found in square flow models as well. The total fluid overload at 72 h of PICU hospitalization differed significantly between the PARDS group (7.7% vs. no-PARDS 5.3%; $p = 0.017$). Positive correlations were identified between fluid accumulation and MP at 24 h ($r = 0.207$, $p = 0.002$), 48 h ($r = 0.230$, $p = 0.001$), and 72 h ($r = 0.156$, $p = 0.05$). The duration of mechanical ventilation was independently associated with age ($p = 0.014$), clinical severity (PELOD-II, $p = 0.018$), and the presence of PARDS ($p = 0.025$). Mortality at 28 days was not associated with the applied MP. ROC analysis revealed that clinical severity (AUROC 0.864, $p < 0.001$), multiple organ failure (AUROC 0.768, $p < 0.001$), and *P/F* ratio at 12 h (AUROC 0.633, $p = 0.023$) were significant predictors of 28-day mortality.
Conclusions: Decelerating flow ventilation models, pediatric ARDS and increased severity of PARDS are associated with higher mechanical power. Fluid accumulation is positively correlated with MP. Our data do not show that outcome indices are associated with the applied mechanical power. Further studies on continuous monitoring of mechanical power in controlled modes are needed, in order to clarify the relationship with clinical outcomes in the pediatric population.

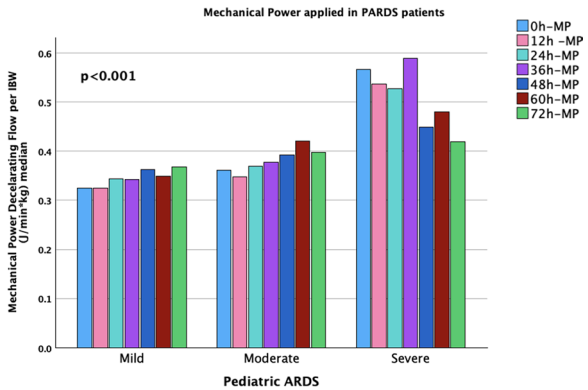

Fig. 1 (abstract 000790) Applied mechanical power differed in children with PARDS ventilated with decelerating flow-controlled mode

Introduction: The TRAIN1 study reported that patients with an acute brain injury (ABI) and anaemia randomized to a liberal transfusion strategy were less likely to have an unfavourable neurological outcome than those randomized to a restrictive strategy. However, whether the timing of transfusion can impact this association, remains to be studied.
Objectives: To explore associations between time from randomization to nadir haemoglobin that triggered transfusion and neurological outcomes in ABI patients.
Methods: This is a post hoc analysis of the TRAIN study, a multicentre, open-label randomized clinical trial, conducted in 72 intensive care units across 22 countries, investigating the impact on neurological outcome of two different haemoglobin threshold (7 g/dl vs. 9 g/dl) in ABI patients. We performed a logistic regression analysis adjusted for age, Glasgow Coma Scale (GCS) on admission, group of randomizations (liberal vs. restrictive) and diagnosis (traumatic vs. nontraumatic brain injury) to assess the impact of time to Hb nadir and neurological outcome. Unfavourable neurological outcome was defined as a Glasgow Outcome Scale Extended of 1-4.
Results: Our cohort included 820 ABI patients, most with a diagnosis of traumatic brain injury($n = 486$, 59.3). Median GCS on admission was 5 (IQR 3.00-8.00). The median Hb nadirvalues was 8 g/dL (IQR 7.10-8.40). Patients with unfavourable outcome (median 7.7 IQR 7.0-8.3) had lower nadir Hb levels ($p < 0.001$) compared to patients with favourable outcome (median 8.0 IQR 7.2-8.6) at 6 months. In a multivariable analysis, nadir Hb was not associated with the occurrence of unfavourable neurological outcome at 6 months (OR 1.03; IC (0.83–1.28); $p = 0.79$). Haemoglobin nadir occurred at a median of 3 days (IQR1.00-8.00) after randomization; patients with unfavourable outcome (median 3 IQR 1-8)had a statistically similar duration of the time from randomization to the nadir when compared with patients with favourable outcome (median3 IQR 1-7) at 6 months ($p = 0.13$). Similarly, no independent relationship was observed between timing

of Hb nadir from randomizationand neurological outcome (OR 1.00; IC (0.97- 1.02); $p = 0.77$).
Conclusions: In this post hoc analysis of the TRAIN study, the lowest haemoglobin value and the timing to reach such value were not associated with neurological outcome.

Improving clinical deterioration recognition by using electronic medical record integrated spot monitors: a pilot study

L. Carenzo[1], N. Martinetti[1], L. Moschitto[1], M. Gazzara[2], F. De Fazio[3], M. Cecconi[1]
[1]Anesthesia and intensive care, IRCCS Humanitas Research Hospital, Milan, Italy; [2]Biomedical Engineering, IRCCS Humanitas Research Hospital, Milan, Italy; [3]Quality and Data Monitoring, IRCCS Humanitas Research Hospital, Milan, Italy

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***795***

Introduction: Early recognition of patient deterioration is crucial in hospital settings, where timely intervention can prevent adverse outcomes (1). Proactive monitoring of vital signs is essential for this purpose. Spot monitors are portable devices that enable healthcare staff to quickly assess key health parameters such as blood pressure, pulse rate, temperature, and oxygen saturation during patient evaluations across various settings.
Objectives: We hypothesized that the implementation of electronic medical records integrated spot monitors (integrated SM) could improve the identification of potentially deteriorating patients in hospital wards by improving the availability of Early Warning Score (EWS) measurement in a tertiary academic centre.
Methods: In this single center, retrospective study, patients > 18 years-old admitted to medical and surgical wards between July 2021 and July 2024, who had at least one EWS calculated during their hospital stay, were included in the study. Our pre–post analysis consists of a comparison of patients whose parameters were registered with manual registration (= pre-technology) vs integrated SM (= post-technology). Primary outcome was time efficiency in the registration of EWS, measured as prevalence of expired EWS. An expired EWS was defined as an EWS registered with more than 30 min delay from the expected time of registration, according to the hospital protocol. Secondary outcomes were the following: prevalence of expired EWS, stratified for type of patient (medical vs surgical), mortality in the wards and need for intensive care.
Results: 757,495 EWS registrations and 34,709 patients were included in the study. A significant reduction in expired EWS was seen after the introduction of the technology: 50,532 (31.9%) pre-technology vs 165,568 (27.6%) post-technology ($p < 0.001$). (Fig. 1). A significant reduction was confirmed stratifying patients for type of admission, medical vs surgical ($p < 0.001$). (*Fig. 2*). There was no significant difference in terms of mortality or admission to the intensive care unit.
Conclusions: Our results show that the use of integrated SM led to a more efficient registration of EWS and a significant reduction in expired EWS. However, no significant changes were observed in clinical outcomes such as mortality or intensive care needs. To our knowledge, no relevant changes in terms of ward staff expertise, training or resources occurred during the study time. More data will be needed to clarify whether integrated SM are a cost-effective investment for hospitals.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***796***

Introduction: The use of extracorporeal membrane oxygenation (ECMO) systems as a bridge to lung transplantation (LT) has increased in the last decade. The aim of this study is to describe the

characteristics, relevant data, in-hospital mortality and mid-term survival of patients receiving ECMO therapy as a bridge to LT.
Objectives: To describe the characteristics, relevant data, in-hospital mortality and mid-term survival of patients receiving ECMO therapy as a bridge to lung transplantation (LT).
Methods: Method: Retrospective study (2020–2024). We included all patients treated with ECMO, either venovenous (V–V) or venoarterial (V–A), as a bridge to LT admitted to ICU. Characteristics, mortality, and survival (30 days and 6 months after LT) were analyzed. Data were obtained from the electronic medical record. Categorical variables: percentage (absolute value); quantitative variables: mean ± standard deviation (SD) or median (IQR 25-75).
Results: Fifteen patients were included. Mean age: 59 ± 9 years, 60% (9) male. Most common comorbidity: pulmonary hypertension (40%; 6). Thirteen patients (86%) were under home oxygen therapy. Before ICU admission, 87% (13) received high-flow oxygen. Median pre-ICU hospital length of stay: 4 (3-14) days.Upon ICU admission, 43% (6) were undergoing pre-transplant evaluation, 35% (5) were on the transplant waiting list, and 26% (4) had not yet started evaluation. All patients were admitted to the ICU due to isolated respiratory failure. Femoro-jugular V–V ECMO was employed in all cases. Six patients (40%) required mechanical ventilation (MV). Half were successfully weaned and two needed to be tracheostomized before LT. During pre-transplant ECMO, 86% (13) reached a RASS of 0, and 66% (10) participated in active physiotherapy. Pre-transplant mortality was 26% (4), with the remaining 74% (11) undergoing transplantation. Median ICU stay before LT: 5 (4-10) days. Median pre-transplant days on MV and ECMO: 4.5 (2-22) and 4 (2-4), respectively.ECMO was used intraoperatively in all cases (11). Three patients left the operating room without ECMO, 7 continued on V–V, and one was converted to V–A ECMO. Post-transplant durations of the ECMO run and MV were 4 ± 3 and 14 (4-74) days, respectively. Nine patients required tracheostomy after LT. One patient died post-transplant.Median ICU stay (pre- and post-transplant): 27 (8-42) days. In-hospital mortality for the full cohort: 33% (5). Survival at 30 days and 6 months post-transplant: 66% (10) and 60% (9).
Conclusions: The survival rate in our cohort (66%) is comparable to published data (50-80%) and demonstrates that ECMO as a bridge to LT in selected candidates is associated with favorable outcomes.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***798***

Introduction: Music is an emerging noninvasive therapeutic tool in clinical settings, shown to modulate stress responses, enhance mood, and aid pain management, particularly in patients with limited communication. Electroencephalography (EEG) provides a quantitative evaluation of neural activity and can be implemented at the bedside in critically ill populations. This study investigates the dose-response relationship between music and brain activity.
Objectives: The objective of this study is to examine how rhythmic structure and genre influence neural activity, as measured by EEG, in healthy adults. This will allow us to determine the relative influence of different musical elements, providing a more granular understanding of how music interventions can be optimized for critically ill, noncommunicative populations.
Methods: EEG data were recorded from healthy subjects (n = 40) using a 32-channel BrainCap MR system. Subjects listened to four music genres: Western "classical" instrumental, ambient, English popular, and foreign (Spanish, Japanese, French) popular, each with high and low beat salience, and during 3 conditions with varying attentional loads (eyes closed-EC; eyes open-EO; Purdue peg board test-PG) to examine how rhythmic structure influences neural engagement and attention. EEG data were securely stored and analyzed using MATLAB®-based preprocessing for filtering, rereferencing, artifact reduction, and spectral decomposition. Distributions of 26 EEG metrics were examined using medians and interquartile ranges. The Kruskal–Wallis test was used to compare EEG metrics across groups.
Results: Higher Relative Alpha Power in low-attention conditions like ambient music, low salience (median = 1.13), compared to high-attention states like English pop, high salience (median = 3.32), suggests that certain music genres may promote a calm, wakeful neural state, which is valuable for patient comfort in ICU settings. In contrast, elevated Relative Delta Power in high-load conditions and low signal variability may reflect more pathological or sleep-like brain states, indicating that certain music under high cognitive demand could potentially disrupt neural regulation in vulnerable populations. Approximate Entropy (ApEn), a measure of signal complexity, increased as attentional load intensified ($p = 5.6 \times 10^{-5}$; see Fig. 1). This upward trend suggests that more cognitively demanding tasks elicit greater signal complexity in EEG activity. Attentional load, a surrogate for patient acuity, was statistically significant across conditions, underscoring the relevance of ApEn as a potential marker for neural engagement in lab and clinical settings.
Conclusions: The results underscore the importance of tailoring musical interventions in the ICU not only by genre but also by considering beat salience and environmental demand, guiding the use of EEG-informed music therapy in clinical populations and research contexts.

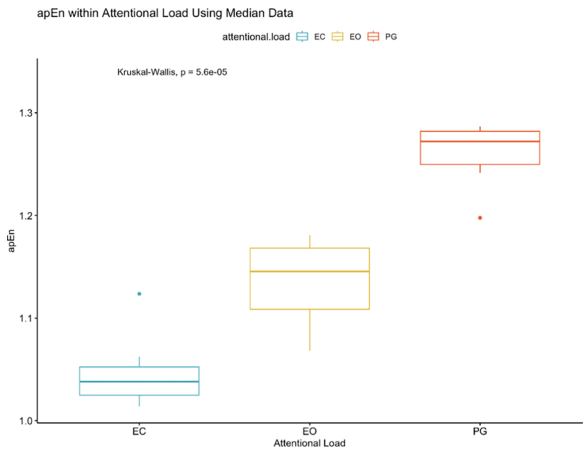

Fig. 1 (abstract 000798) Approximate Entropy (ApEn) increases with attentional load. A Kruskal–Wallis test showed a significant difference across conditions ($p = 5.6 \times 10^{-}5$)

Comparison of the accuracy of ISS and APACHE II scores in predicting mortality in trauma patients admitted to ICU

M. Karajizadeh[1], G. Sabetian[2], MR. Yousefi[1], S. Niknejad[2], F. Zand[3]
[1]Trauma Research Center, Shiraz University of Medical Sciences, Shiraz, Islamic Republic of Iran; [2]Dept. of Critical Care Medicine, Trauma Research Center, Shiraz University of Medical Sciences, Shiraz, Islamic Republic of Iran; [3]Department of Critical Care Medicine, Anesthesiology and Critical Care Research Center, Shiraz University of Medical Sciences, Shiraz, Islamic Republic of Iran
Correspondence: G. Sabetian
Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***799***

Introduction: Injury Severity Score (ISS) and the Acute Physiology and Chronic Health Evaluation II (APACHE II) are prominent tools for assessing patient's survivability and predicting mortality (1-4). ISS remains valuable for anatomical injury assessment but shows limitations in capturing dynamic physiological changes (4); whereas APACHE II evaluates 12 physiological variables, age, and previous health status to generate a score that correlates with mortality risk (5).
Objectives: this study delves into the comparison of the accuracy and predictive power of ISS and APACHE II scores in predicting mortality in trauma patients admitted to icu at the largest trauma center in southern Iran during 2024-2025.
Methods: A total of 1427 ICU patients were enrolled in the study. The study group was divided into deceased and survived groups. ISS and APACHE II were calculated and compared using IBM SPSS v27 and MedCalc v22. Median and interquartile range (IQR) and mean and standard deviation (SD) were reported for nonparametric and parametric variables, respectively. Area under the receiver-operator curve (ROC), sensitivity, and specificity were reported for the scoring systems. *P* value under 0.05 was considered significant.
Results: Of 1427 patients, 211 were deceased. Median (IQR) of the patients' age was 50 (31-71). unlike gender, the age of the patients was significantly different among the two groups. 1.8% of patients had acute renal failure. Median (IQR) of GCS, creatinine, FiO2, pH, potassium, sodium, heart rate, mean arterial pressure, respiratory rate, temperature, WBC count and hematocrit are as follows: 12 (6-14), 1 (0.86-1.17), 45% (40%-45%), 7.42 (7.37-7.46), 4.2 (4.2- 4.5), 139 (136-142), 99 (88-111), 102.5 (93-113), 20 (19-23), 37.5 (37-37.8), 12.1 (9-15.9), 36.3% (31.8%-41.1%).The details of ROC analysis of the scoring systems are summarized in Table 1; both of which could predict ICU mortality. APACHE II was significantly more accurate ($P < 0.0001$) (Fig. 1).

Table 1 (abstract 000799) ROC characteristics of the scoring systems

Characteristics	APACHE II	ISS
P value	< 0.001	< 0.001
area under the ROC	0.827	0.604
sensitivity (95% CI)	73.1 (64.9-80.2)	54.5 (47.5-61.4)
specificity (95% CI)	78.5 (75.8-81.1)	61.8 (59.0-64.6)
positive likelihood ratio (95% CI)	3.4 (2.90-3.98)	1.43 (1.24-1.65)
negative likelihood ratio (95% CI)	0.34 (0.26-0.45)	0.74 (0.63-0.86)

Conclusions: As demonstrated in this study, both APACHE II and ISS were capable of predicting mortality in trauma patients admitted to ICU. APACHE II showed a higher accuracy than ISS, which is aligned with previous studies, in which both systems showed proper sensitivity and specificity, but APACHE II's inclusion of physiological variables gave it an edge in ICU mortality prediction; nevertheless, ISS demonstrated stronger performance in polytrauma cases with multiple severe injuries (4, 6, 7). the accuracy and availability of APACHE II makes it a proper tool for risk assessment among ICU patients, especially in trauma setting. Further meta-analysis and cohort studies are required to confirm these findings. Furthermore, using machine learning and advance wearable monitoring devices that measure vital signs, trauma scoring systems can reduce the mortality and morbidity risk of trauma patients.

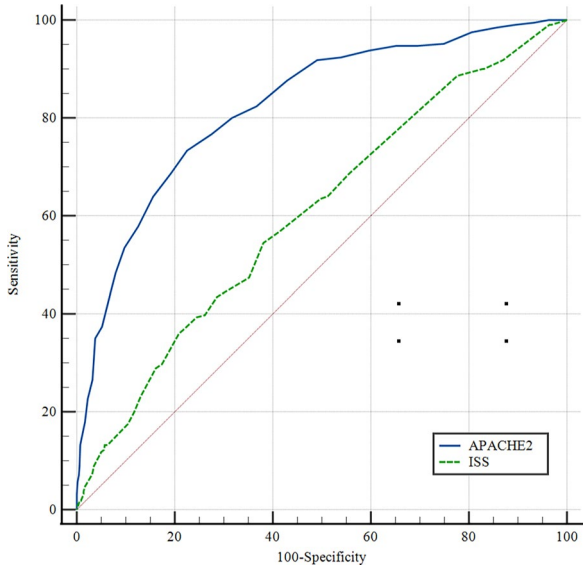

Fig. 1 (abstract 000799) Receiver-operator curve of the ISS and APACHE II scores

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**)***:800***

Introduction: Studies reported variation in end-of-life (EOL) practices and legislation across European intensive care units (ICUs) [1-3].
Objectives: As part of the Enhancing Palliative Care in ICU (EPIC) project, we conducted a Europewide survey to address the following questions: (1) "How much of ICU everyday practice is palliative care (PC) and how is it practiced?"; and (2) "How do clinicians perceive the medico-legal framework for therapy limitations, patient autonomy and EOL discussions with patient/family?
Methods: A descriptive, open, anonymous survey with 180 questions was administered to ICU healthcare professionals (HCPs). HCPs were invited via e-mail, and social media channels of the European Society of Anaesthesiology and Intensive Care. Questionnaire was set up at a website using LimeSurvey. Survey database was hosted by CHARITE, Berlin. A sample of ≥ 500 HCPs from > 20 European countries was targeted. Participants provided data on their age, gender, religion, country, professional focus/grade, and ICU type/number of beds. Countries/study data were grouped according to Northern, Central and Southern Europe.1 Participants shared their perceptions of (1) PC practice (i.e. physical/psychosocial aspects of care, EOL communication/planning, family role/support, and system-level support); (2) laws pertaining to advance directives, terminal analgesia/sedation, treatment limitations, euthanasia, and EOL decision-making; and (3) specific EOL practice elements of EOL practice score [3]. Responses were graded by + 1 when positive and by 0 when negative, thereby enabling determination of primary outcomes, i.e. the PC/legal and EOL practice scores. Data analyses included comparisons of participant/ICU characteristics, and PC/legal/EOL practice scores among Northern, Central and Southern Europe. Predictors of high PC/legal scores (defined as positive response-rates ≥ 2/3 of total corresponding responses) were determined by generalized estimating equations (GEE) analyses.
Results: 518/860 (60.2%) HCPs from 40 European countries responded to all survey sections. HCPs' professional focus/grade and numbers of ICU beds differed among European regions (P = 0.005 to < 0.001). Median PC, legal and EOL practice scores were, respectively, 4-6%, 35-75% and 29% higher in Northern compared to Central and Southern Europe (P < 0.001) (Table 1). Predictors of high PC score were European region [Northern vs. Southern, odds ratio (OR) = 2.15, (95% confidence interval:1.20-3.86)] and EOL practice score [OR = 1.18 (1.12-1.25)] (P = 0.01 to P < 0.001). Predictors of high legal score were age [OR = 1.07 (1.05-1.09)], gender [OR = 0.51 (0.31-0.83)], religion [OR = 1.58 (1.33-1.87)], European region (Northern vs. Southern) [OR = 2.71 (1.36-5.44)], professional grade [OR = 0.75 (0.56-0.99)] and EOL practice score [OR = 1.21 (1.13-1.28)] (P = 0.046 to < 0.001).

Table 1(abstract 000800) Results on primary outcomes

		Region of Europe			
	Total	**Northern**	**Central**	**Southern**	***P* value**
Palliative care score, median (IQR)*	23 (20-25)	24 (21.5-25)	23 (20-25)	22.5 (18.5-25)	< 0.001
Legal score, median (IQR)**	13 (4.5-28.5)	25.5 (17.5-32.5)	16.5 (6.5-31)	6.5 (2.5-18)	< 0.001
EOL practice score, median (IQR)	5 (2-9)	7 (4-10)	5 (2-9)	5 (1-9)	0.003

EOL, end-of-life; *, **: maximum possible respective values: 27, 39

Conclusions: Perceptions of PC practice were strikingly similar across Europe. The frequent absence of a clear EOL legal framework was evident, especially in Southern Europe. Future studies should assess the interplay between PC awareness/practice and EOL legislation.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**)***:801***

Introduction: Acute respiratory distress syndrome (ARDS) is a prevalent and life-threatening condition in the intensive care unit (ICU). Despite advances in mechanical ventilation management, the mortality rate of ARDS remains relatively high [1, 2]. Right ventricular dysfunction (RVD) is a severe complication that often develops as a secondary manifestation of ARDS. Previous studies have demonstrated an approximate prevalence rate of 20-50% for acute RVD in ARDS patients, which is associated with worse organ function and higher mortality compared to patients with normal right ventricular function [3-5]. The implementation of airway pressure release ventilation (APRV) has been used in patients with ARDS for over three decades [6, 7]. Research has shown that APRV facilitates alveolar recruitment and significantly improves oxygenation in patients with ARDS by maintaining high airway pressure (Phigh) during inspiration and briefly releasing pressure during expiration. This mode helps optimize both lung ventilation and perfusion [8-10]. However, there is currently no evidence to suggest that APRV can reduce mortality in ARDS patients. Owing to the elevated mean airway pressure and increased intrathoracic pressure associated with APRV, concerns remain regarding its potential impact on right ventricular function and hemodynamics, which limits its clinical application. Moreover, it remains unclear whether APRV that is not accompanied by spontaneous breathing affects right ventricular function. Animal experiments have shown that APRV can improve systemic blood flow and organ perfusion during

spontaneous breathing, indirectly suggesting that it may improve cardiac output and protect the right ventricle. However, there is a lack of research on whether APRV affects right ventricular function in ARDS patients, especially in the early stages of ARDS, when deep sedation and even neuromuscular blocking agents are administered to avoid spontaneous breathing. In this study, we aimed to investigate the impact of APRV on right ventricular function in patients with moderate to severe ARDS during the early stage of mechanical ventilation using transthoracic echocardiography (TTE), compared to low tidal volume (LTV) ventilation.

Objectives: To evaluate the impact of APRV compared to LTV on the incidence of RVD in patients with moderate to severe ARDS during the early phase.

Methods: Patients diagnosed with moderate or severe ARDS according to the 2014 Berlin definition and anticipated to require mechanical ventilation for more than 48 h were allocated to either the APRV or LTV group for ventilation. Baseline data, including demographics, hemodynamic parameters, ventilator settings, respiratory mechanics, arterial blood gas analysis results, and echocardiographic data, will be collected from the enrolled patients. Echocardiographic data, hemodynamic parameters, ventilator settings, respiratory mechanics parameters, and arterial blood gas analysis results will be reassessed and recorded at 24 and 48 h after enrollment. The primary outcome was the incidence of RVD at 24 h after enrollment. The secondary endpoints included hemodynamic parameters, oxygenation, respiratory mechanics, and clinical outcomes.

Results: 60 patients were included and randomized to the APRV or LTV ventilation group (30 per group). APRV was not associated with an increased incidence of RVD compared to the LTV at either 24 h [23.3% (7/30) vs. 36.7% (11/30), respectively; $P = 0.398$] or 48 h [20.0% (6/30) vs. 26.7% (8/30), respectively; $P = 0.760$]. By 24 h, the APRV group demonstrated improved oxygenation (PaO2/FiO2 ratio: 280.20 ± 102.67 vs. 210.42 ± 68.19, $P = 0.003$), with this advantage persisting at 48 h (295.00 ± 94.56 vs. 233.42 ± 67.93, $P = 0.005$). While no spontaneous breathing was observed in either group at 24 h, the APRV group demonstrated significantly higher spontaneous breathing rates by 48 h (53.3% vs 26.7%, $P = 0.035$). Regardless of spontaneous breathing status, the incidence of RVD did not differ significantly between APRV and LTV groups.

Conclusions: Compared with conventional LTV, APRV in patients with moderate to severe ARDS did not increase the incidence of right ventricular dysfunction or compromise hemodynamic stability.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**)***:802***.

Introduction: Low cardiac output syndrome (LCOS) remains a frequent and severe complication following cardiac surgery, associated with poor outcomes1. A 2012 consensus2 defined different LCOS subtypes based on severity and clinical presentation.
Objectives: To describe the characteristics, management, and outcomes of patients developing LCOS in the immediate postoperative period after cardiac surgery, and to analyze differences between its subtypes.
Methods: We performed an observational study using a prospectively collected database of adult patients admitted to the ICU after cardiac surgery between February 2022 and October 2023. Demographics, preoperative status, surgical features, and ICU outcomes were recorded. LCOS cases were identified and classified into clinical LCOS, monitored LCOS, or cardiogenic shock according to the 2012 consensus. Statistical comparisons were made using ANOVA or Kruskal–Wallis for continuous variables and chi-square tests for categorical variables.
Results: Of 594 patients, 128 (21.5%) developed LCOS: 49 clinical (38.3%), 13 monitored (10.2%), and 66 cardiogenic shock (51.6%). Overall, 63% were male; 65% had hypertension, 25.4% diabetes, and 56.6% dyslipidemia. Most patients were NYHA class II (61.5%) or III (25.8%), with a median LVEF of 59% (IQR 50-64) and median EuroSCORE II of 2.3 (IQR 1.28-4.36). Most common surgical procedures included CABG (22.6%), valve replacement (17.2%), and aortic surgery (10.9%), with a median CPB time of 134 min (IQR 103-176). Patients with LCOS had significantly longer ICU (7 vs 3 days, $p < 0.001$) and hospital stays (16 vs 10 days, $p < 0.001$), and higher mortality ($p < 0.001$) (Table 1). Among LCOS subtypes, cardiogenic shock patients required longer mechanical ventilation (11.25 vs 2.09 vs 2.16 days, $p < 0.001$), higher norepinephrine doses (0.66 vs 0.27 vs 0.29 mcg/kg/min), more vasopressin use (85.7% vs 15.4% vs 12.2%, $p < 0.001$), and higher dobutamine doses (10.83 vs 8.18 vs 6.8 µg/kg/min, $p < 0.001$). They also showed higher rates of renal failure requiring renal replacement therapy (50% vs 15.3% vs 8.8%, $p < 0.001$), longer ICU stay (10 vs 8 vs 5 days, $p < 0.001$), and higher mortality (24.6% vs 0% vs 4.1%, $p = 0.003$) (Table 2).
Conclusions: LCOS is a prevalent complication after cardiac surgery and is associated with worse clinical outcomes, including increased ICU and hospital stay and higher mortality. Cardiogenic shock represents the most severe LCOS phenotype, with significantly greater need for advanced therapies such as renal replacement therapy and hemodynamic support, and a poorer prognosis.

Table 1 (abstract 000802) Comparison between patients with and without low cardiac output syndrome (LCOS)

Variable	Without SBGC (n=466)	With SBGC (n=128)	p-value
ICU length of stay (days, median)	3	7	<0.001
Hospital length of stay (days, median)	10	16	<0.001
Mortality (%)	4.5%	17.2%	<0.001
Duration of mechanical ventilation (days, median)	1.2	4.5	<0.001
Maximum norepinephrine dose (µg /kg/min, mean)	0.16	0.49	<0.001
Vasopressin use (%)	8.8%	56.3%	<0.001
Maximum dobutamine dose (µg/kg/min, mean)	6.2	9.3	<0.001
Renal replacement therapy required (%)	7.1%	32.8%	<0.001

Table 2 (abstract 000802) Comparison of clinical variables and outcomes among SBGC subgroups

Variable	Clinical SBGC (n=49)	Monitored SBGC (n=13)	Cardiogenic Shock (n=66)	p-value
Duration of mechanical ventilation (days, median)	2.09	2.16	11.25	<0.001
Maximum norepinephrine dose (µg /kg/min, mean)	0.27	0.29	0.66	<0.001
Vasopressin use (%)	15.4%	12.2%	85.7%	<0.001
Maximum dobutamine dose (µg/kg/min, mean)	8.18	6.8	10.83	<0.001
Renal replacement therapy required (%)	15.3%	8.8%	50.0%	<0.001
ICU length of stay (days, median)	8	5	10	<0.001
Mortality (%)	0%	4.1%	24.6%	0.003

Incidence and risk factors of post traumatic cerebral infarction in pediatric patients- a retrospective study

S. Bhardwaj[1], R. Mishra[1], R. Prasath[1]
[1]Neuroanaesthesia and Neurocritical care, National Institute Of Mental Health & Neuro Sciences (NIMHANS), Bengaluru, India
Correspondence: S. Bhardwaj
Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**)***:803***

Introduction: Incidence of pediatric stroke in India is 13-33/100,000 per year. Childhood stroke is associated with high mortality and serious morbidity for the survivors. Traumatic brain injury (TBI) has been reported to be an important cause of childhood stroke or post traumatic cerebral infarction (PTCI). The precise frequency of PTCI, however, is often debated in adult TBI, and even less is known about its frequency in pediatric TBI. Most common mode of pediatric brain injury in India is road traffic accident (47%), followed by fall from height (39%), assault/battered baby and others (14%). It is generally

believed that PTCI is an important contributing risk factor to secondary injury and, consequently, to poor outcome.

Objectives: Primary objective of this study will be to calculate the incidence of post traumatic cerebral infarction in children. Secondary objectives will be to find out the association between post traumatic cerebral infraction and outcome at discharge in pediatric patients. Other secondary objectives are to find out the risk factors of PTCI in pediatric TBI.

Methods: This is a retrospective chart review of all pediatric patients admitted with traumatic brain injury (TBI) in a tertiary care hospital between January 2016 to August 2021. Institutional ethics board approval with number NIMHANS/33rd IEC (BS&NS DIV.)/2021 was obtained. Patients < 18 years with isolated moderate to severe TBI were included for chart review. We defined patients with "isolated TBI" as TBI patients with or without injuries to other body regions of abbreviated injury score (AIS) (Appendix 1) severity 2 or < 2. Adult patients, patients with penetrating injury and patients with injuries to other body regions of AIS severity of 3 or more are excluded. Data were collected from eligible patient charts. Data collection included patient demographics (age, sex, approximate weight and height, mode of injury, time duration from TBI to presentation to hospital). Clinical details included, Glasgow coma scale (Appendix 2), pupillary size and reaction, blood pressure, diagnosis and Computed tomography (CT) findings. Clinical outcome of included patients at discharge were assessed using King's Outcome Score for Childhood Head Injury (KOSCHI) (Appendix 3). In the study centre, imaging protocol for all pediatric patients with history of head injury, would be an initial computed tomography (CT) in the Emergency Department followed by subsequent CT surveillance during hospital stay. Diagnosis of PTCI will be made on non-enhanced CT scan based on a well-demarcated or fairly discernible region of hypodensity following specific vascular territory.

Results: During the study period, 408 charts of patients with moderate to severe head injury were analysed. Of these 36 (8.8%) patients were diagnosed with PTCI before discharge or death. Among all study patients, 74% were male, with median age was 12 year (range 2 months to 18 years). The most common cause of TBI was fall from height (49%) followed by road traffic accident (RTA) (41%) and other causes (10%) (fall of an object, assault or any other cause). Demographic data of patients with PTCI and no PTCI are given is Table 1. PTCI group had younger patients as compared to no PTCI group. Similarly, mean GCS on admission was lower in PTCI group than the no PTCI group. Patients with PTCI have an odds ratio of 10.5 (P < 0.001) (95% CI 4.83-22.8) for having poor outcome. Death in patients with PTCI is (13/36) 36% whereas death in patients without PTCI is (7/372) 1% with a P value of 0.0001 (odds ratio 29, 95% CI 10.7-81). Table 2 shows univariate analysis of risk factors for PTCI in pediatric patients Table 3 shows multivariate logistic regression analysis of risk factors for PTCI in pediatric patients. Most striking risk factors of PTCI in our patient population are injuries like subdural hematoma/contusion/diffusion axonal injury (OR 12, CI 0.7-4.2, p = 0.006), fall from height as the mode of injury (OR 6, CI 1.9-3.7) and intraoperative hemodynamic instability (OR 14, CI 0.8-4.4, P = 0.004).

Conclusions: Incidence of PTCI is higher in pediatric patients 9% as compared to adults which is around 2%. Mode of injury, severity of injury and intraoperative hemodynamic state are the significant determinants of PTCI. Future prospective studies are indicated.

Table 1 (abstract 000803) Demographic data of patients with PTCI and without PTCI

Variable	With PTCI (N=36)	No PTCI (N=372)	P value

	Abnormal extension(decerebrate)	2
	No response	1

Appendix 2 (abstract 000803) Glasgow coma scale

KOSCHI category	Definition
1.Death	
2. Vegetative	The child is breathing spontaneously and may have sleep/wake cycles. He may have non purposeful or reflex movements of limbs or eye. There is no evidence of ability to communicate verbally or non verbally or to respond to commands
3. Severe disability	a) The child is atleast intermittently able to move part of the body/eyes to command or make purposeful spontaneous movements; for example, confused child pulling at nasogastric tube, lashing out at carers, rolling over in bed. May be able to communicate but not yet able to carry out any self activities such as feeding b) Implies a continuous high level dependency, but the child can assist in daily activities; for example can feed self or walk with assistance or help to place items of clothing. Such a child is fully conscious but may still have a degree of post traumatic amnesia
4. Moderate disability	a) The child is mostly independent but needs a degree of supervision/ actual help for physical or behavioral problems. Such a child has overt problems; for example, 12 year old with a moderate hemiplegia and dyspraxia insecure on stairs or needing help with dressing b) The child is age appropriately independent but has residual problems with learning/behavior or neurological sequelae affecting function. He probably should have special needs assistance but his special needs may not have been recognized/met. Children with symptoms of post-traumatic stress are likely to fall into this category.
5. Good recovery	a) This should only be assigned if the head injury has resulted in a new condition which does not interfere with the child's well being and/or functioning ; for example • Minor headache not interfering with social or school functioning • Abnormalities on brain scan without any detectable new problem • Prophylactic anticonvulsants in the absence of clinical seizures • Unsightly scarring of face/head likely to need cosmetic surgery at some stage • Mild neurological asymmetry but no evidence of affect on function of limb. Includes isolated change in hand dominance in young child b) Implies that the information available is that the child has made a complete recovery with no detectable sequelae from the head injury

Intensive Care Medicine Experimental 2025 **13(Suppl 1)*:805***

Introduction: Veno-arterial extracorporeal membrane oxygenation (VA-ECMO) is mechanical circulatory support where by venous blood is withdrawn and via membrane lung, returned oxygenated and decarboxylated to the aorta; its applications in cardiogenic shock (CS) are numerous. Given the high mortality risk of CS with conventional treatment and significant risks with VA-ECMO, careful risk:benefit assessment is required. Previously 3 distinct clinical phenotypes (non-congested/ cardio-renal/ cardiometabolic) have been derived from machine learning analysis of a large CS multicentre international registry ($n = 1959$). Phenotyping CS could improve risk stratification and define individualised mortality risk profiling.

Objectives: Retrospective analysis of clinical records to demonstrate that identification of CS phenotype might help better define patients who would derive benefit from VA-ECMO.

Methods: This audit was formally registered locally. Anonymised clinical data were extracted from the referral portal and electronic medical records; consent was not sought from patients. Coding data were cross checked against an online referral system to capture all VA-ECMO patients. Based on the previously established tools for CSWG-SCAI shock phenotype and shock stage severity were categorised.

Results: Between October 2023 and November 2024, 21 patients (median age 45 years, 13 male) received VA-ECMO for acute CS during their ICU admission, or retrieved on mobile ECMO. Indications were heart failure (24%), acute myocardial infarction (19%), fulminant myocarditis (10%), and other (47%). 17 patients (81%) had initial peripheral canulation, 12 patients (57%) had femoral access and femoral return. 6 patients (28%) had hybrid V–AV with additional venous return. 12 patients (57%) had distal perfusion catheter at initiation. 9 patients (23%) required mechanical LV venting, 5 with LVAD impella, the remaining via IABP. CSWG-SCAI shock stage at time of VA cannulation were category E in 81% of patients. The Vasoactive-Inotropic Score ranged from 5 to 331. CSWG-SCAI shock phenotype was non-congested (19%); cardio-renal (9%); and cardio-metabolic (71%). Within each phenotype associated mortality were 25%, 50% and 28%, respectively [Fig. 1]. SCAI category D and E had associated 25% and 47% mortality, respectively. 6 (28%) patients died in ICU, 5 (23%) whilst on ECMO. 15 (71%) patients survived to ICU discharge or repatriation. Median time on ECMO amongst survivors was 6.1 days (2–13). 6 patients had an in hospital cardiac arrest with return of spontaneous circulation, one patient was ECMO-CPR.

Conclusions: In the cohort of 21 VA-ECMO patients 71% met the clinical characteristics of the cardio-metabolic phenotype; the mortality outcome compares favourably to similar clusters described in multicentre CS registries. VA-ECMO may have a greater efficacy in this cardio-metabolic phenotypic cluster but larger categorisation and analysis is required before any statical significance can be determined.

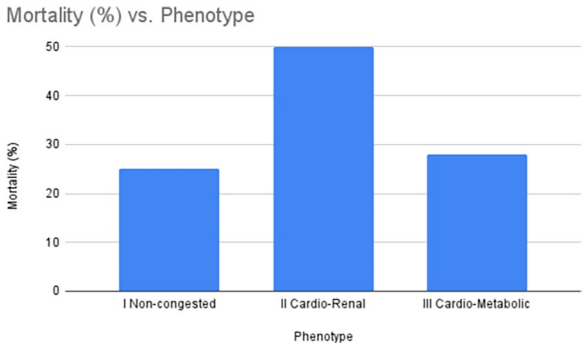

Fig. 1 (abstract 000805) In-hospital mortality in the 3 distinct phenotypes of cardiogenic shock (CS) of VA-ECMO patients
Phenotype I (noncongested) 1/4 25%, phenotype II (cardiorenal) 1/2 50%, and phenotype III (cardiometabolic) 6/15 (28%). Phenotype validated to in-hospital mortality across 2 international multicenter registries of CS attributable to acute myocardial infarction and acute-on-chronic heart failure.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***806***

Introduction: Mirror image artifact occurs due to the reflection of ultrasound waves at strong acoustic interfaces, particularly at the diaphragm–lung or pleura–liver interfaces [1]. This artifact may mimic pulmonary pathology and has the potential to lead to pneumonia misdiagnosis and unnecessary interventions [2]. The incidence of this artifact in the paediatric febrile neutropenia population is currently unknown. Therefore, we analyzed data from a prospective study on lung ultrasound to determine the incidence of mirror image artifacts in pediatric neutropenia patients.
Objectives: To evaluate the incidence of mirror image artifacts in paediatric febrile neutropenia patients admitted to the intensive care unit (ICU).
Methods: The data from a prospective study that was assessing lung ultrasound scores in paediatric febrile neutropenia patients were analyzed for the presence of mirror image artifacts. The original study was approved by an independent ethics committee. A mirror image artifact was defined as the presence of a liver/spleen-like image cranial to the diaphragm, without continuation of the spine (Fig. 1). In contrast, true consolidation was defined by the continuation of the spine cranial to the diaphragm (the "Spine Sign").
Results: Data from a total of 81 patients, comprising 120 observations, with a median age of 7 years (interquartile range [IQR]: 4-12 years), were analyzed. Mirror image artifacts were identified in 37 (30.8%) observations on the right side and 39 (32.5%) observations on the left side.
Conclusions: Mirror image artifact is not uncommon in lung ultrasound examinations of pediatric febrile neutropenia patients. Distinguishing it from true consolidation is critical to avoid pneumonia misdiagnosis and unnecessary interventions.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**)***:807***

Introduction: In mechanically ventilated ARDS patients, changing position from semi-recumbent to supine-flat reduces overdistension, leading to improved respiratory mechanics and CO2 clearance. In ARDS patients with obesity, a higher PEEP is usually required to counter-act the increased pleural pressure and prevent alveolar collapse. Thus, in this population, trunk inclination may exert different effects.
Objectives: The aim of this study was therefore to compare the effects of changes in trunk inclination between ARDS patients with and without obesity.
Methods: We performed a secondary analysis of two observational studies (1;2) on deeply sedated, paralyzed, mechanically ventilated patients with COVID-19 ARDS. Patients underwent three 15-min steps, where trunk inclination was changed from semi-recumbent (40° head-of-bed) to supine-flat (0° head-of-bed) and, back to semi-recumbent at constant ventilatory settings. Partitioned respiratory mechanics and gas exchange were assessed at the end of each step. The overall population was divided in obese and nonobese according to a BMI of 30 kg/m2 and a comparison of the variations in respiratory mechanics and PCO2 was performed.
Results: Two groups of 15 patients were analysed. BMI was 35 ± 3 kg/m2 in the group with obesity *vs.* 25 ± 3 kg/m2 in the group without ($p < 0.001$). PEEP was significantly higher in the group with obesity (15 ± 2 *vs.* 12 ± 2 cmH2O, $p = 0.013$). Despite the different baseline PEEP, variations in respiratory mechanics and CO2 clearance induced by changes in trunk inclination were similar in the two populations (**Fig. 1**). In both groups observed variations were fully reversible once placed back in semi-recumbent position.
Conclusions: Trunk inclination seems to exert similar effects in patient with and without obesity. Further studies are needed to confirm these findings in larger populations, possibly with higher BMI.

The effect of fluid removal on muscle performance and weakness: a pilot study

N. Arancibia[1], R. López[2]
[1]Servicio de medicina fisica y rehabilitacion, Clinica alemana, santiago, chile, Santiago, Chile; [2]Departamento de Paciente Crítico, Clinica Alemana, Vitacura, Chile

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**)***:808***

Introduction: Fluid overload in critically ill patients has been associated with muscle edema, decreased tissue quality, and the potential development of intensive care unit-acquired weakness (ICU-AW). Ultrafiltration (UF), as part of continuous renal replacement therapy (CRRT), may help reverse these effects by removing excess extracellular volume.
Objectives: The objective was to evaluate the acute effect of ultrafiltration on ultrasound-based muscle parameters and global muscle strength in critically ill patients undergoing renal replacement therapy.
Methods: A total of 18 critically ill patients undergoing continuous renal replacement therapy (CRRT) with ultrafiltration (UF) were prospectively enrolled. Muscle ultrasound parameters—including

rectus femoris and vastus intermedius thickness, cross-sectional area, echogenicity, and connective tissue content—were assessed at ICU admission (T1) and again 36 h later (T2). Global muscle strength was evaluated at both time points using the Medical Research Council Sum Score (MRC-SS).

Results: Statistically significant post-UF changes were observed in muscle thickness (rectus femoris: 1.74 to 1.56 cm, $p = 0.030$; vastus intermedius: 1.14 to 0.95 cm, $p < 0.01$), echogenicity (91.7 to 78.3, $p < 0.0001$), and subcutaneous tissue thickness (1.98 to 1.78 cm, $p < 0.01$). Global muscle strength (MRC Sum Score) significantly increased after UF (45.0 to 49.0, $p = 0.06$). A positive correlation was found between UF volume (mL/kg) and post-intervention muscle strength ($\rho = 0.71$, $p = 0.0087$), as well as between UF volume and the reduction in muscle echogenicity ($\rho = 0.47$, $p = 0.04$).(Fig. 1). ROC curve analysis showed that a UF volume ≥ 82.12 mL/kg predicted an MRC Sum Score > 46 points, with an **area under the curve (AUC)** of 0.982 (95% CI: 0.928-1.000, $p = 0.04$), sensitivity of 92.9%, and specificity of 100%, indicating excellent discriminative performance.(Fig. 2).

Conclusions: Ultrafiltration, as part of continuous renal replacement therapy, was associated with acute improvements in muscle ultrasound parameters and global muscle strength in critically ill patients. The UF volume showed a strong correlation with both muscle strength recovery and reduction in muscle echogenicity, suggesting a potential role in reversing fluid-related muscle quality impairment. A UF threshold of ≥ 82.12 mL/kg of real body weight demonstrated excellent predictive accuracy for functional recovery, highlighting its clinical relevance as a potential therapeutic target in the management of ICU-acquired weakness.

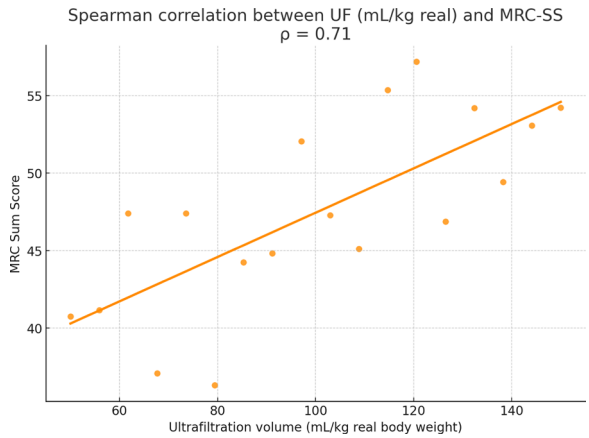

Fig. 1 (abstract 000808) Scatter plot and regression line showing the Spearman's correlation between ultrafiltration volume adjusted by real body weight (mL/kg) and post-intervention global muscle strength (MRC Sum Score). A significant positive correlation was observed ($\rho = 0.71$, $p = 0.00087$)Scatter plot and regression line showing the Spearman's correlation between ultrafiltration volume adjusted by real body weight (mL/kg) and post-intervention global muscle strength (MRC Sum Score). A significant positive correlation was observed ($\rho = 0.71$ $p = 0.00087$)

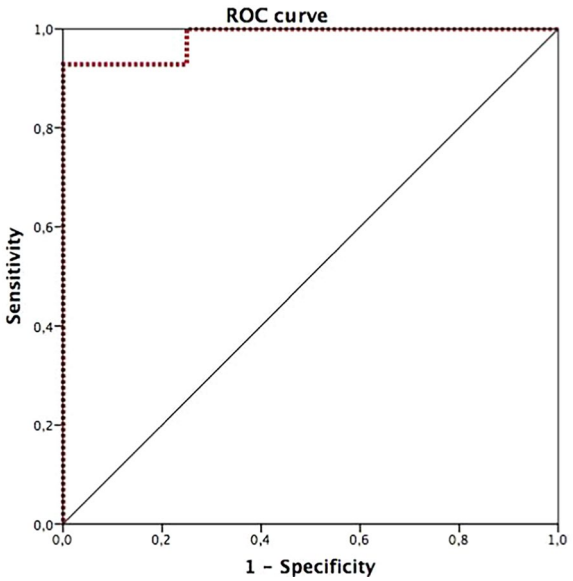

Fig. 2 (abstract 000808) Receiver-operating characteristic (ROC) curve evaluating the predictive performance of ultrafiltration volume adjusted by real body weight (mL/kg) for functional recovery (MRC Sum Score > 46 points) in critically ill patients. The area under the curve (AUC) was 0.982 (95% CI: 0.928-1.000, $p = 0.004$), indicating excellent discriminative ability. The optimal cutoff value was 82.12 mL/kg of real body weight, with 92.9% sensitivity and 100% specificity

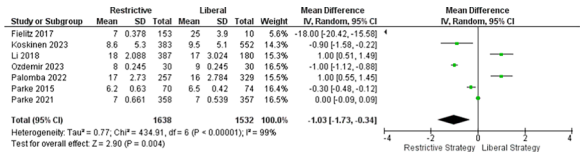
Impact of fluid overload on postoperative outcomes following cardiac surgery: a systematic review and meta-analysis

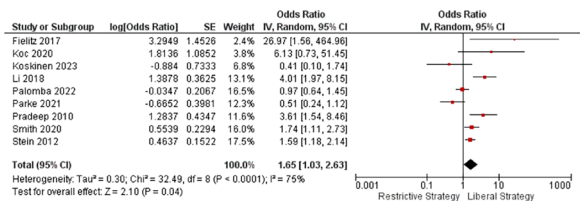
R. Melo[1], A. Cappellaro[2], L. Almeida[3], A. Felicio[1]
[1]Critical Care Unit, HMVSC Dr.Gilson de Cássia Marques de Carvalho, Hospital Israelita Albert Einstein, São Paulo, Brazil; [2]Faculty of Medicine, UNINASSAU BARREIRAS, Barreiras, Brazil; [3]Faculty of Medicine, Universidade Federal Fluminense (Campus Gragoatá), Rio de Janeiro, Brazil
Correspondence: R. Melo
Intensive Care Medicine Experimental 2025 **13(Suppl 1)*:810***

Introduction: Fluid overload has emerged as a critical factor associated with adverse outcomes in critically ill patients, including renal failure, prolonged mechanical ventilation, and increased mortality. Although its impact is well established in conditions such as sepsis and acute lung injury, its role in the context of cardiac surgery remains poorly understood.



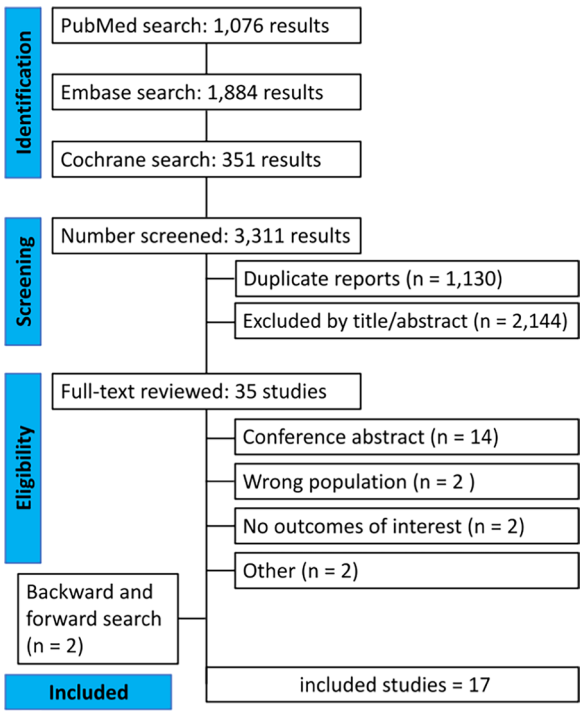
Objectives: We conducted a systematic review and meta-analysis to investigate the effect of fluid overload on postoperative outcomes in patients undergoing cardiac surgery.

Methods: We systematically searched PubMed, Embase, and Cochrane to find clinical trials (CTs) comparing postoperative outcomes in cardiac surgery patients with fluid overload versus those managed with a restrictive fluid strategy. Outcomes of interest included incidence of acute kidney injury (AKI), all-cause mortality, postoperative atrial fibrillation (POAF), intensive care unit length of stay (ICU-LOS), and total hospital length of stay (HLOS). Data were analyzed using random-effects models with 95% confidence intervals (CI).



Results: Of the 3,311 studies initially screened, 17 clinical trials comprising a total of 11,349 patients met the inclusion criteria. Compared with those with fluid overload, patients managed with a restrictive

fluid strategy following cardiac surgery had a significantly shorter HLOS (MD = − 1.03 days; 95% CI: − 1.72 to − 0.33; $p < 0.05$). In addition, fluid overload was associated with a significantly higher risk of all-cause mortality compared to the restrictive group (OR = 1.65; 95% CI: 1.03-2.63; $p < 0.05$). No significant differences in the incidence of AKI were observed between the groups (OR = 1.17; 95% CI: 0.69-1.99; $p = 0.56$). Similarly, no significant differences were found for POAF or ICU-LOS.



Conclusions: In patients undergoing cardiac surgery, a restrictive fluid management strategy was associated with a reduced hospital length of stay and decreased all-cause mortality. These findings support the potential benefits of a restrictive fluid approach in this patient population, warranting further investigation.

Forest plot comparing the mean difference in hospital length of stay between restrictive and liberal fluid management strategies

Forest plot of the odds ratios for mortality associated with restrictive versus liberal fluid management strategies across multiple studies

Intensive Care Medicine Experimental 2025* 13(Suppl 1):*811

Introduction: Infections represent a significant complication in critically injured trauma patients admitted to the ICU, with a notable impact on morbidity and mortality. This study aims to analyze the incidence of infections and associated risk factors in a cohort of patients with severe trauma.

Objectives: To determine the incidence and types of ICU-acquired infections in trauma patients and to identify independent risk factors associated with their development.

Methods: This is an observational study including all trauma patients admitted to a specialized Trauma and Emergency ICU from January 2014 to September 2024. No exclusion criteria were applied. Demographic data (age, sex), trauma mechanism, injury severity scores (ISS, RTS, APACHE), comorbidities at admission (immunosuppression, COPD, cirrhosis, cancer, diabetes), emergency surgical interventions, ICU length of stay, mortality, and infectious complications (pneumonia, urinary tract infection, bloodstream infection) were recorded. Descriptive statistics, Chi-square, Student's t-test, and binary logistic regression were applied.

Results: A total of 2,448 patients were included. The mean age was 44.8 years (SD 17.9), 79.2% were male, and traffic accidents were the most frequent mechanism (38.6%). Severe head trauma (MAIS $\geq$ 3) was present in 42.2%. The overall incidence of ICU-acquired infections was 8.1% (n = 198), with pneumonia being the most common (67.7%). In univariate analysis, factors significantly associated with infection included higher ISS ($p < 0.001$), longer ICU stay ($p < 0.001$), higher APACHE scores ($p < 0.001$), and emergency surgery ($p < 0.001$), especially in patients requiring three types of surgical interventions. Severe head injury (MAIS $\geq$ 3) was also strongly associated with infection ($p < 0.001$), particularly pneumonia (Table 1). In multivariate analysis, independent risk factors for infection were ICU length of stay (OR 1.131, $p < 0.001$), emergency surgery (OR 1.558, $p = 0.005$), and MAIS $\geq$ 3 in the head (OR 2.723, $p < 0.001$) (Table 2).

Conclusions: Infection in critically injured trauma patients is strongly influenced by injury severity, prolonged ICU stay, and multiple surgical interventions. These findings highlight key targets for prevention strategies and optimized ICU management in this high-risk population.

Table 1 (abstract 000811) Association between Head Injury Severity and Infection / Pneumonia

	No Infection	Infection	No Pneumonia	Pneumonia
MAIS head ≥ 3	87.71%	12.29%	91.81%	8.19%
MAIS head < 3	94.86%	5.14%	96.43%	3.57%

Table 2 (abstract 000811) Independent Risk Factors for ICU-acquired Infection (Multivariate Analysis)

Outcome	OR (95% CI)	p-value
ICU length of stay	1.131 (1.111 – 1.152)	<0.001
APACHE score	1.018 (0.997 – 1.039)	0.09
ISS	1.012 (0.997 – 1.027)	0.12
MAIS head ≥ 3	2.723 (1.976 – 3.753)	<0.001

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**)***:815***

Introduction: Acute liver failure (ALF) is a life -threatening condition characterized by rapid deterioration of liver function, often leading to multiorgan failure and high mortality rates.. Identifying early prognostic factor [1,2,3] is crucial for guiding therapeutic decisions,including liver transplantation.Traditional static biomarkers may not fully reflect the evolving severity of liver dysfunction.
Objectives: So,this study aimed to evaluate the prognostic value of dynamic changes(delta) in arterial lactate, INR and ammonia levels over the first 72 h in ALF patients admitted to the intensive care unit(ICU).
Methods: This prospective observational study included 100 adult patients diagnosed with ALF and admitted to a tertiary ICU from january 2021 to december 2024 The mean age was 45.6 + -12.8 years; 60% male. Serum lactate, INR and Ammonia levels were collected at ICU admission(H0) and at 72 h(H72). Delta values were calculated as H72- H0. The primary endpoint was 28 day all cause mortality. Statistical analysis used Mann Whitney test to compare the different delta biomarkers between survivors and nonsurvivors. Receiver-operating charasteristic(ROC) curves were generated to assess the discriminative ability of each delta biomarker.
Results: Among 100 patients, 46(46%) died within 28 days. Nonsurvivors had significantly higher delta—lactate and delta-INR compared to survivors. ROC analysis showed: **Delta-Lactate AUC**: 0.91(95%CI: 0.85-0.97).
Delta-INR AUC: 0.87 (95% CI:0.80-0.94).
Delta-Ammonia AUC: 0.84 (95%CI:0.76-0.91).
The Mean delta values(H72-H0):
In Survivors, Delta-lactate was -0.8 mmol/L vs + 1.2 mmol/L in nonsurvivors $P < 0.001$.
In survivors, Delta-INR was -0.1 mmol/l vs + 0.6 mmol/L in nonsurvivors $P < 0.01$.
In survivors, Delta-ammonia was-10ùmol/L vs + 25ùmol/l in nonsurvivors $P < 0.01$.
We performed univariate logistic regression which clearly confirm that Delta-lactate is a strong predictor of 28-day mortality in ALF. With an odds ratio of 4.50 (95% CI:2.20-9.20, $p < 0.001$)and an AUC of 0.91,the statistical analysis demonstrate both high discriminative power and strong association with mortality.This means that for each unit increase in delta-lactate between H0 and H72, the odds of 28-day mortality increase significantly.
Conclusions: This study highlights the prognostic significance of dynamic biomarkers, specifically delta-lactate, delta-INR and delta -ammonia over the first 72 h of management in patients with acute liver failure. Dynamic changes in lactate, INR, and ammonia are strongly associated with 28-day mortality in ALF patients.Delta-lactate demonstrated the highest predictive value. This supports the hypothesis that sustained hyperlactatemia or failure to clear lactate reflects ongoing cellular hypoxia, metabolic failure,or persistent inflammation. Monitoring these biomarkers dynamically over the first 72h may offer early prognostic insight and support more individualized clinical decision -making in the management of acute liver failure. Further studies should evaluate whether integrating these dynamic variables into existing scores such as MELD or King's College Criteria could enhance their pronostic performance.

ROC curve comparing the predictive value of delta biomarkers for 28-day mortality in ALF.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**)***:816***

Introduction: Optimizing antibiotic dosing is crucial in critically ill patients, as subtherapeutic exposure is associated with increased mortality. In patients receiving extracorporeal membrane oxygenation (ECMO), antibiotic pharmacokinetics remains poorly defined. Current evidence is primarily based on ex vivo studies and case series, offering conflicting results with limited clinical applicability. Notably, drug sequestration within ECMO circuit components—particularly the membrane oxygenator—has been reported (1,2), potentially leading to reduced plasma concentrations and therapeutic failure.
Objectives: To quantify antibiotic sequestration within the ECMO membrane oxygenator and to evaluate the pharmacokinetics of meropenem, piperacillin/tazobactam, and linezolid using a noncompartmental pharmacokinetic analysis (NCA).
Methods: We conducted a prospective observational study in the intensive care unit of a tertiary university hospital. Adult patients receiving ECMO support and treated with meropenem, piperacillin/tazobactam, or linezolid were eligible for inclusion. Serial plasma samples were collected simultaneously at two points in the ECMO circuit: pre- and post-membrane oxygenator. Between 8 and 12 paired samples were obtained per patient over a complete dosing interval, under steady-state conditions. Plasma concentrations were quantified using LC-MS/MS. Differences between pre and post-membrane concentrations were calculated to assess potential drug sequestration by the ECMO circuit. Pharmacokinetic measures were derived using NCA in R (version 4.4.2), considering the mode of administration (bolus or extended infusion). The parameters calculated included: Cmax, Tmax, AUC0-24, kel, t1/2, CL and Vd, based on both pre- and post-membrane concentrations.
Results: A total of 48 meropenem plasma concentrations were analyzed from five patients (two on venoarterial (VA) ECMO and three on venovenous (VV) ECMO). In addition, 28 piperacillin/tazobactam concentrations were obtained from three patients (two on VA, one on VV), and 32 linezolid concentrations from three patients (two on VV, one on VA). The mean ± standard deviation (SD) of the difference between pre and post-membrane concentrations were: 0.50 ± 4.25 mg/L for meropenem, 1.06 ± 7.41 mg/L for piperacillin, 0.51 ± 1.00 mg/L for tazobactam, and -0.08 ± 1.08 mg/L for linezolid. The results of the NCA are presented in Table 1:

Antibiotic	Infusion time	Blood samples type¥	Cmax (mg/L)	Tmax (h)	AUC0-24 (mg · h/L)	Kel (h-1)	t1/2 (h)	CL (L/h)	Vd (L)
Meropenem	4 h	Pre-M	49,9 ± 33,1	3,44 ± 1,10	534 ± 271	0,336 ± 0,0746	2,15 ± 0,520	11,0 ± 3,90	35,0 ± 6,20
		Post-M	46,0 ± 26,9	3,46 ± 1,11	530 ± 270	0,329 ± 0,123	2,45 ± 1,25	11,2 ± 3,98	38,4 ± 7,19
Piperacillin	0,5 h	Pre-M	223 ± 107	0,525 ± 0,0118	2209 ± 1517	0,353 ± 0,211	2,39 ± 1,43	7,72 ± 4,02	30,8 ± 29,8
		Post-M	226 ± 131	0,550 ± 0,000	2187 ± 1575	0,342 ± 0,222	2,57 ± 1,67	8,02 ± 4,48	35,1 ± 35,9
	3 h*	Pre-M	101	3,15	607	0,412	1,68	26,3	64,0
		Post-M	93,9	3,18	593	0,368	1,88	27,0	73,3
Tazobactam	0,5 h	Pre-M	20,6 ± 10,0	0,525 ± 0,0118	198 ± 111	0,336 ± 0,108	2,18 ± 0,702	9,88 ± 3,74	32,9 ± 21,8
		Post-M	19,2 ± 9,12	0,550 ± 0,000	190 ± 110	0,311 ± 0,112	2,38 ± 0,855	10,5 ± 4,21	38,5 ± 27,3
	3 h*	Pre-M	10,4	3,15	64,1	0,455	1,52	31,2	68,6
		Post-M	10,1	3,18	61,7	0,353	1,96	32,4	91,8
Linezolid	1 h	Pre-M	14,9 ± 4,81	1,24 ± 0,150	152 ± 62,3	0,170 ± 0,0713	4,79 ± 2,53	9,05 ± 4,21	58,6 ± 28,0
		Post-M	14,5 ± 5,33	1,27 ± 0,150	154 ± 64,2	0,169 ± 0,0622	4,49 ± 1,59	8,92 ± 4,14	53,5 ± 16,6

All pharmacokinetic measures are expressed as mean ± SD. ¥Pre-M: pre-membrane concentrations; Post-M: post-membrane concentrations.*data from one patient

Conclusions: No significant differences were observed between pre- and post-membrane concentrations for meropenem, piperacillin/tazobactam and linezolid, suggesting minimal drug sequestration by the membrane oxygenator. Pharmacokinetic measures were similar for both pre- and post-membrane concentrations.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**)***:818***

Introduction: Central to circulatory arrest is the cessation of the brain's circulation and subsequent function thereafter leading to death. However, how the brain responds to stressors of progressive hypotension during circulatory arrest has not been described in humans despite it underpinning key concepts in the functioning of the human body. As different disease aetiologies have different locals of injury, the key question remains on whether this is associated with cerebral hemodynamics.
Objectives: We aimed to determine the relationships between cerebrovascular physiology indices in response to progressive hypotension during circulatory arrest in acute and nonacute critically ill humans.
Methods: We conducted a single center prospective observational cohort study investigating the cerebrovascular physiology of circulatory arrest following withdrawal of life-sustaining measures (WLSM) in

32 acute critically ill patients and medical assistance in dying (MAID) in 3 nonacute critically ill patients. Prior to WLSM, multimodal neuromonitoring was implemented consisting of middle and posterior cerebral artery blood velocities (MCAv, PCAv) using transcranial Doppler ultrasound and bilaterial near-infrared spectroscopy for continuous frontal lobe regional cerebral oxygen saturation (rSO2). Mean arterial pressure (MAP) was monitored via an in situ radial arterial catheter. Relationships between cerebrovascular physiologic variables and MAP were assessed visually and relationships were model fit when appropriate. Etiologic comparisons were made between post-cardiac arrest hypoxic ischemic brain injury (HIBI), sepsis, traumatic brain injury (TBI), and MAID patients.
Results: Collectively, MCAv ($P < 0.0001$) and PCAv ($P < 0.0001$) were linearly related to MAP with marked inter-individual variability of response. Reductions in MCAv and PCAv started at a lower MAP for sepsis patients compared to HIBI and TBI patients. The cerebral blood velocity slopes in MAID were less steep than acute critical illness. There was no relationship between rSO2 and MAP in any specific aetiology or across all aetiologies.
Conclusions: There may be aetiology-specific differences between HIBI, TBI, and sepsis in in the relationship between cerebral blood velocities and hypotension. Future work investigating the interplay between sedation and severity of acute critical illness is warranted to understand how different aetiologies may respond differently to clinical management (*e.g.,* vasopressors).

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***819***

Introduction: Left Ventricular Assist Devices (LVADs are increasingly used in end-stage heart failure, with critical care often forming the entry point to long-term mechanical circulatory support. While literature highlights quality of life (QoL) challenges and device-related burdens [1-2], the recent studies reveal profound emotional, existential, and identity transformations among recipients [3-7]. Patients report liminality, fear, shifting values, and changing social roles. However, little research explores how these experiences evolve through and beyond the ICU.
Objectives: To explore the lived experiences of LVAD recipients and their informal caregivers.
Methods: A qualitative study using Braun and Clarke's thematic analysis [8], informed by van Manen's hermeneutic phenomenology [9]. Twenty-one participants—12 patients and 9 caregivers—were recruited from two cardiothoracic centers in Greece. Data collection via semi-structured interviews began in May 2022 and is ongoing. Ethics approval was granted by the University of West Attica and participating hospitals.
Results (preliminary): Participants describe the ICU and early post-discharge period as liminal, marked by bodily vulnerability and identity shifts [3,5]. Caregivers mirror this, assuming ICU-like roles at home while managing fear and uncertainty [6]. Gratitude for survival coexists with reflections on dependence, time, and purpose [4,5]. Three experiential domains are emerging: a) From loss to resilience—the ICU is remembered as a turning point [3,5]; b) Carrying ICU "roles" back at home—caregivers live with prolonged vigilance and emotional burden [9]; c) Being saved, yet transformed—the device is both life-sustaining and identity-altering [6,7]. These findings deepen current understandings of liminality, value transformation, and caregiving in technologically mediated survivorship [4-7].
Conclusions: LVAD recipients and caregivers navigate complex emotional and existential landscapes that begin in the ICU and extend well beyond discharge. Patients experience a life shaped by functional limitations, fear, lifestyle changes, frustration, and what they often describe as an "up and down" journey. This trajectory requires a repertoire of adaptation strategies, hope, and continuous support from family and healthcare services. LVAD implantation introduces a new embodied experience—marked by the duality of feeling both "saved" and socially stigmatized. Along this path, many encounter a profound loss of identity and a sense of "liminality," reflecting what has been described as "biographical disruption" [7]. Understanding these lived experiences can inform more person-centered approaches to ICU care, discharge planning, and long-term psychosocial support. This study highlights the importance of attending not only to physical recovery, but also to identity, relationships, and what truly matters to patients and their families.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***821***

Introduction: Current paradigms for predicting time from withdrawal of life-sustaining measures (WLSM) to circulatory arrest are predicated on physician gestalt, cardiorespiratory dysfunction, and neurologic examination. Reliance on cardiorespiratory dysfunction may affect organ quality or disqualify heart and lung donation while physician gestalt has between-examiner variability, and the clinical exam can be

confounded by sedation or nonconvulsive status epilepticus. Alternative prediction methods without these limitations are needed.
Objectives: To assess cranial and extra-cranial measurements as predictors of length of dying duration from WLSM to circulatory arrest.
Methods: A single centre prospective observational cohort study in critically ill patients undergoing WLSM to death determination by circulatory criteria. Cranial and extra-cranial measurements were taken prior to WLSM. Cranial assessment consisted of cerebral blood velocities, jugular venous bulb saturations, and intracranial pressure (ICP) surrogates. Extra-cranial assessments consisted of respiratory and cardiovascular measurements. Times from WLSM to pulseless electrical activity were collected. Univariate predictions were based on time cutoffs of 30, 60, and 120 min.
Results: Thirty-five patients were included in the final analysis. Central venous pressures ($P = 0.04$), optic nerve sheath diameters ($P = 0.05$), and middle cerebral artery pulsatility index ($P = 0.01$) as surrogates of ICP were related to the dying duration. The area under the receiver-operator characteristic curve (AUROC) at 60 min for ICP surrogate measures was > 0.7. Middle ($P = 0.42$) and posterior ($P = 0.79$) cerebral blood velocities and jugular venous bulb oximetry ($P = 0.08$) were not related to the dying duration. The AUROC at 60 min for dead space and tidal volume were 0.79 and 0.69, respectively. For extra-cranial measurements, only dead space ($P = 0.02$) and tidal volume ($P = 0.01$) were related to the dying duration. Heart rate, cardiac output, mean arterial pressure, lactate, albumin, troponin, bilirubin, creatinine, end-tidal carbon dioxide, arterial carbon dioxide, PF ratio, and ventilation were not related to the dying duration ($P > 0.18$).
Conclusions: Brain-derived predictors were superior to extra-cranial predictors as univariate variables of the dying duration. Brain dysfunction is likely fundamental to the dying duration and may help reframe how the dying process is predicted. A prospective multicentre study is a necessary next step to determine the predictive ability of brain-specific variables for donation after circulatory determination of death.

Introduction: Current paradigms for predicting time from withdrawal of life-sustaining measures (WLSM) to circulatory arrest are predicated on physician gestalt, cardiorespiratory dysfunction, and neurologic examination. Reliance on cardiorespiratory dysfunction may affect organ quality or disqualify heart and lung donation while physician gestalt has between-examiner variability, and the clinical exam can be confounded by sedation or nonconvulsive status epilepticus. Alternative prediction methods without these limitations are needed.
Objectives: To assess blood-based neurologic biomarkers as predictors of length of dying duration from WLSM to circulatory arrest in humans.
Methods: A single centre prospective observational cohort study in critically ill patients undergoing WLSM to death determination by circulatory criteria. Blood samples from an in situ radial arterial line were obtained prior to WLSM. Serum and plasma blood samples were analyzed for biomarkers of the neurovascular unit across two analytical platforms. Specifically, glial fibrillary acidic protein (GFAP), neurofilament light chain (Nf-L), neuron-specific enolase (NSE), total tau, and ubiquitin C-terminal hydrolase L1 (UCH-L1) were quantified. Times from WLSM to pulseless electrical activity (defined as a radial pulse pressure < 5 mmHg) were collected. Univariate predictions were based on time cutoffs of 30, 60, and 120 min.
Results: Serum UCH-L1 ($P = 0.008$) and total tau ($P = 0.01$) were related to the dying duration while GFAP ($P = 0.87$) and Nf-L ($P = 0.89$) were not. Similarly, plasma UCH-L1 ($P = 0.004$) was related to the dying duration while GFAP ($P = 0.93$), Nf-L ($P = 0.84$), NSE ($P = 0.11$), and total tau ($P = 0.06$) were not. The area under the receiver-operator characteristic curves (AUROCs) for serum UCH-L1 were 0.81, 0.82, and 0.77 at 30, 60, and 120 min, respectively. The AUROCs for serum total tau were 0.78, 0.86, 0.74 at 30, 60, and 120 min, respectively. The AUROCs for plasma UCH-L1 were 0.82, 0.8, and 0.74 at 30, 60, 120 min, respectively.
Conclusions: Total tau and UCH-L1 were significant univariate predictors of the dying duration. Brain dysfunction is likely fundamental to the dying duration and may help reframe how the dying process is predicted. A prospective multicentre study is a necessary next step to determine the utility of total tau and UCH-L1 in predicting the dying duration.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***823***

Introduction: AQP4 molecules form water channels that control various cells movement and survival, immune cells migration and reactiveness to activating stimuli. Previous studies revealed the association of AQP4 rs1058427 variant single-nucleotide changes in the regulatory 3' region of the gene with unfavorable course and outcome after intracerebral hemorrhage and in patients with sepsis.
Objectives: The prospective observational uncontrolled cohort study included ICU patients diagnosed in chronic critical condition (CCC, n = 464; age 58 (IQR: 43-67), 41% women) as a consequence of cerebral catastrophes (strokes—59%, traumatic injuries -21%, anoxic injuries—6% and brain tumors- 9%, consequences of severe course of COVID-19—2%, others—3%); 192 patients were hospitalized with pneumonia on admittance, 107 patients developed nosocomial pneumonia. Mann–Whitney *U* test, t test, χ2 test with Yates' correction, Fisher's exact test, Kaplan–Meier log-rank test, ROC and logistic regression analyses were employed where appropriate. Univariate and multivariate regression analyses were used with the backward stepwise Wald method to confirm the significance. Differences were considered significant at $p < 0.05$. Statistical analysis was performed using SPSS Statistics version 27, MedCalc version 11.6 and SigmaStat version 3.5.
Methods: The prospective observational uncontrolled cohort study included ICU patients diagnosed in chronic critical condition (CCC, n = 464; age 58 (IQR: 43-67), 41% women) as a consequence of cerebral catastrophes (strokes—59%, traumatic injuries -21%, anoxic injuries—6% and brain tumors- 9%, consequences of severe course of COVID-19—2%, others—3%); 192 patients were hospitalized with pneumonia on admittance, 107 patients developed nosocomial pneumonia. Mann–Whitney *U* test, t test, χ2 test with Yates' correction, Fisher's exact test, Kaplan–Meier log-rank test, ROC and logistic regression analyses were employed where appropriate. Univariate and multivariate regression analyses were used with the backward stepwise Wald method to confirm the significance. Differences were considered

significant at $p < 0.05$. Statistical analysis was performed using SPSS Statistics version 27, MedCalc version 11.6 and SigmaStat version 3.5.
Results: Multivariate regression analysis adjusted for CIRS-G, SOFA, neutrophils, lymphocytes, gender, and age revealed that in a whole cohort Charlson comorbidity index (CCI), Glasgow coma scale (GCS) values, and NLR associated with mortality ($p < 0.001$; $p < 0.001$; $p = 0.035$, respectively). AQP4 genotyping of patients revealed that established links for neutrophil counts and mortality were significant only for carriers of AQP4 GG rs1058427 genotype (HR = 2.5 (95%CI:1.5–4.3), $n = 372$, log-rank test). In AQP4 rs1058427 T + carriers (genotypes AQP4 GT and TT), mortality was significantly associated with CCI and SOFA scale values, not NLR. Univariate regression confirmed significant link between mortality and NLR or neutrophil count only in carriers of AQP4 GG rs1058427 genotype (Bonferroni corrected $P = 0.018$ and $P = 0,045$, respectively). Lymphocyte levels on admittance provided no any predictive value in a whole cohort and in both sub cohorts differed in AQP4 rs1058427 genotypes. We suggest that single-nucleotide polymorphism of AQP4 may affect neutrophil migration to increase risk for pro-inflammatory reactions and mortality.
Conclusions: In patients in chronic critical illness, an increased neutrophil count on admittance predicts poor outcome due to a sub cohort of patients exhibiting homozygous allele G (genotype GG) of AQP4 rs1058427. We suggest that AQP4 genotyping may assist risk stratification of patients in critical illness as early as on admittance.
Fig. 1. Survival probability based on immune cells concentration and AQP4 rs1058427 genotypes (Kaplan–Meier analysis). Survival plots for groups of patients exhibiting different neutrophil-to-lymphocyte ratios (A,B,C), neutrophil count (D,E,F) and lymphocyte count (G,H,I) are shown. Patients were subdivided to groups according to their AQP4 rs1058427 genotype: GG + GT + TT (A,D,G), GG (B,E,H) and C,F,I (GT + TT)

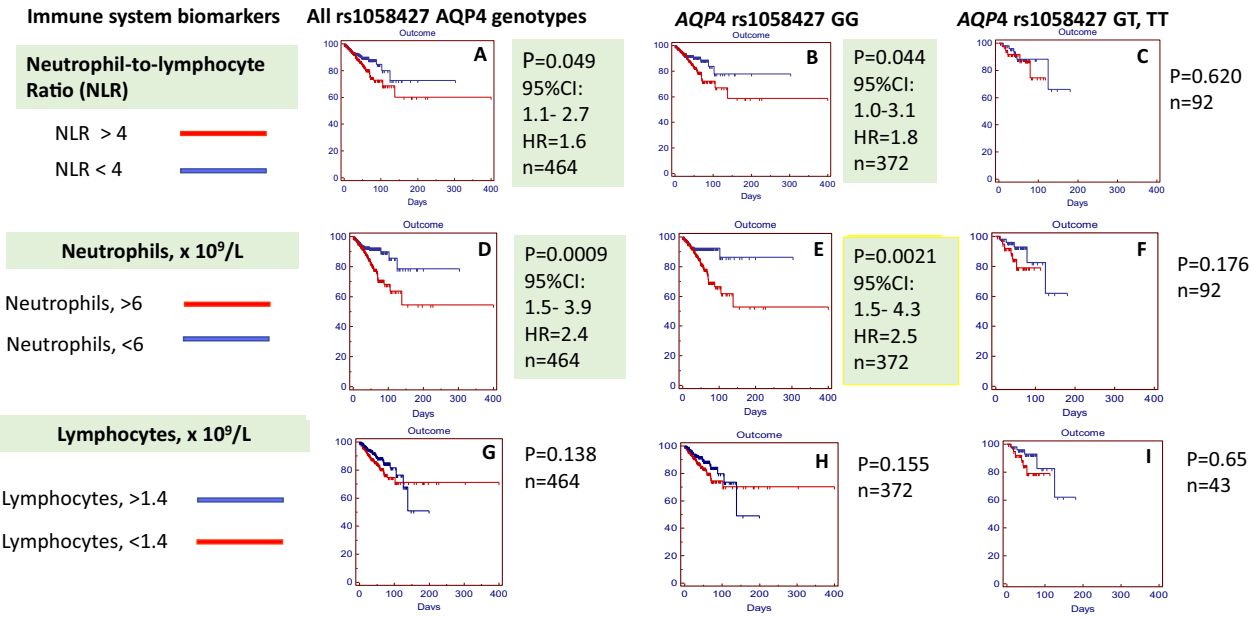
Correspondence: N. Angeloni
Intensive Care Medicine Experimental 2025 **13(Suppl 1)**:***824***.

Introduction: Specialized trauma care improves outcomes in patients with moderate and severe trauma (1,2). Transfer guidelines recommend referral to a trauma lead centre based on the physiological status and injury severity (3); however, nonclinical factors also affect transfer decisions (4, 5). Although sex-based disparities in trauma lead centre access were described in broader trauma populations (6), their extent among patients with traumatic brain injury (TBI) is poorly understood.
Objectives: To estimate the association between sex and the likelihood of transfer to a trauma lead centre of adult patients with TBI in Ontario.
Methods: We included adult patients with a first hospitalization for TBI of at least 48 h from 2009 to 2020. The main exposure was sex, and the main outcome was trauma lead centre admission. We summarized baseline and hospitalization data by sex groups and compared them with standardized differences (St.Diff). We estimated the association of sex with a trauma lead centre admission using multiple logistic regression adjusted for age, income, rural setting, injury severity score (ISS), and baseline comorbidities. We conducted a stratified analysis by age group (< 65 and ≥ 65 y/o).



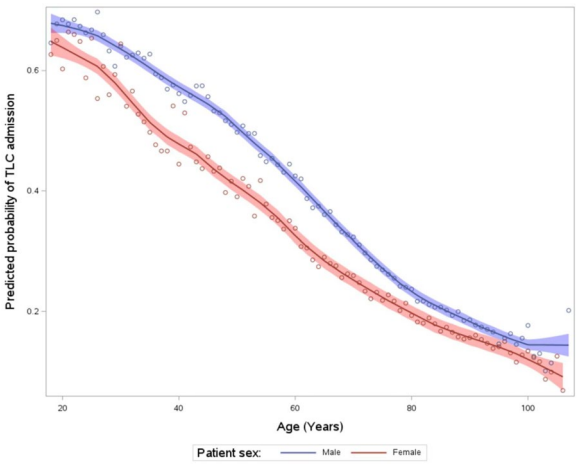


Fig.1. Survival probability based on immune cells concentration and *AQP4* rs1058427 genotypes (Kaplan-Meier analysis)

1. The study was supported by Ministry of Science and Higher Education of the Russian Federation to Federal Research and Clinical Center of Intensive Care Medicine and Rehabilitology (#075-00784-22-03 and FGWS-2025-0014 to VP). A

Results: We included 61,546 patients, 39% of whom were female. The median age was 72 years (IQR 54-83). Female patients were older (median = 78 years; IQR 63-86) compared to males (median = 68 years; IQR 49-81; St.Diff. 0.48) and were more likely to have comorbidities (84% vs. 74%; St.Diff. 0.27). Males were more likely to have severe trauma (i.e., ISS ≥ 15) (33% vs. 25%; St.Diff. 0.18) and to be admitted to the ICU (36% vs 26%; P < 0.01). The adjusted analysis showed that females had lower odds of admission to a trauma lead centre (OR 0.75; 95% CI 0.72-0.78). This disparity was more pronounced among patients ≥ 65 y/o (OR 0.72; 95% CI 0.68-0.75) compared to younger patients (OR 0.84; 95% CI 0.78-0.90).
Conclusions: Female patients with TBI were older, had more comorbidities, and had less severe injuries. Female patients were less likely to be transferred to a trauma lead centre compared to males after adjusting for age, comorbid burden, severity of injury, and socioeconomic factors.

Adjusted predicted probabilities[†] of TLC admission by age and sex. TLC: trauma lead centre.[†] Adjusted by injury severity score, rural setting, income, and comorbidities

Introduction: *Mycoplasma pneumoniae* (MP) is a usual pathogen causing acute community-acquired pneumonia. Its prevalence fell sharply during the Covid-19 pandemic. However, since November 2023, a major surge in MP infections has been observed, with severe cases requiring admission to the intensive care units. We aimed to describe the clinical characteristics, management and outcomes of critically ill patients with severe MP pneumonia.
Methods: This is a multicenter observational analysis of patients admitted with MP pneumonia in 18 French ICUs between July 2023 and September 2024. The diagnosis of infectious pneumonia was made by clinicians in charge of the patients, and the diagnosis of MP infection was made by polymerase chain reaction (PCR) or serology tests. Cases were included either prospectively or retrospectively using ICD-10 codes. Clinical data were collected by extracting information from the patients' electronic records. Statistical analysis consisted mainly of descriptive statistics: medians and interquartile ranges, means and standard deviations, or numbers and percentages. This study was approved by the French Intensive Care Society (FICS/SRLF) Ethics Committee. We present preliminary data from the first participating centers.
Results: We included 155 patients, with a median (IQR) age of 45 years (3;64), 60 (39%) females and 95 (61%) males. Only 25% (n = 39) had an underlying chronic respiratory disease and their main characteristics are presented in the table. Most patients were fit and active, as reflected by a Clinical Frailty Scale < 3 in 73% of cases. The median Sequential Organ Failure Assessment (SOFA) score at admission was 3 (IQR, 2-4), primarily driven by the respiratory component (median 2, IQR 1-3), while all other organ systems had a median score of 0 (IQR, 0-0). In 12% of patients, lower respiratory tract specimens diagnosed MP despite a negative

nasopharyngeal PCR result. Initial co-infections were identified in 23% (n = 36), and bacterial superinfections occurred in 12% of the patients (n = 19) during ICU stay. The maximal respiratory support was conventional oxygen therapy for 32% of the patients (n = 50), high-flow nasal oxygen (HFNO) for 42% of the patients (n = 67) for a median duration of 3 days (IQR, 2-5), non-invasive ventilation (NIV) in 6% (n = 10) for a median of 3 days (IQR, 2-4), and invasive mechanical ventilation for 17% (n = 27), with a median duration of 10 days (IQR, 5-20). Corticosteroids were administered to 34% of patients (n = 52). The overall prognosis was favorable, with a low in-hospital mortality rate of 2% (n = 3).

Conclusions: The post-COVID-19 *Mycoplasma pneumoniae* infection epidemic was marked by low rates of intubation and mortality. Most of the patients admitted to the intensive care unit presented with isolated respiratory failure. However, among those who required intubation, the duration of mechanical ventilation was long, with a median of 10 days.

	N=155
Demographic characteristics	
Chronic respiratory disease	39 (25%)
Chronic heart disease	36 (23%)
History of hematological cancer	20 (13%)
Diabetes mellitus	15 (10%)
History of neurological disease	7 (5%)
Chronic kidney disease	7 (5%)
ICU management and outcomes	
Invasive mechanical ventilation	27 (17%)

Intensive Care Medicine Experimental 2025 **13(Suppl 1)*:826***

Introduction: Advances in critical care have significantly improved survival rates in the initial phase of critical illness. However, this has led to the emergence of a patient population requiring prolonged intensive care unit (ICU) support due to persistent organ failure—a syndrome known as Chronic Critical Illness (CCI) (1-3). This population accounts for approximately 11% of all ICU patients but consumes up to 40% of ICU resources (2). Despite various therapeutic approaches proposed to address this growing issue, the prevalence of CCI remains high, imposing a substantial burden on patients, their families, healthcare resources, and the economy (4-8). There is a need to understand the variables contributing to good outcomes in this patient population in order to improve decision making and outcomes.

Objectives: To characterize the population of CCI patients admitted to the ICU of Hospital de Faro in 2023 and identify key prognostic factors.

Methods: We undertook a retrospective observational cohort study of all ICU patients admitted for more than 14 days in the level 3 ICU of the Hospital de Faro in 2023. We collected demographic, clinical and outcome data and compared patients who survived their ICU stays with those who did not.

Results: A total of 95 patients had ICU stays exceeding 14 days in 2023. The majority were male (73.7%) and the mean age was 59.6 ± 15.3 years. Most admissions were medical (39%) or urgent surgical (33.7%) cases. Neurocritical care (61.1%) and sepsis (25.3%) were the most common diagnoses. The average ICU stay for the cohort was 26.1 ± 13.6 days and the average duration of mechanical ventilation was 26.9 ± 13.3 days. Mortality was 31.6% at 28 days, 41.1% at 3 months and 52.6% at 6 months. Non-survivors were significantly older, had longer ICU stays, higher severity of illness scores on admission (APACHE II, SAPS II, SAPS III), and were more likely to have an admission diagnosis of sepsis (Fig. 1). Survivors were more often neurocritical care patients. Tracheostomy rates were similar between the two groups. In logistic regression age, ICU length of stay and SAPS II scores were independently associated with higher 3-month and 6-month mortality.

Conclusions: Chronic critical illness was associated with the need for prolonged ventilatory support and high mortality at 3 and 6 months. Age, illness severity scores (APACHE II, SAPS II, SAPS III) and sepsis diagnosis were independent predictors of 3-month mortality. Conversely, neurocritical care patients had higher than expected survival rates. Our findings reinforce the prognostic value of established severity scoring systems and emphasize the heavy resource utilization and poor outcomes of chronic critical illness.

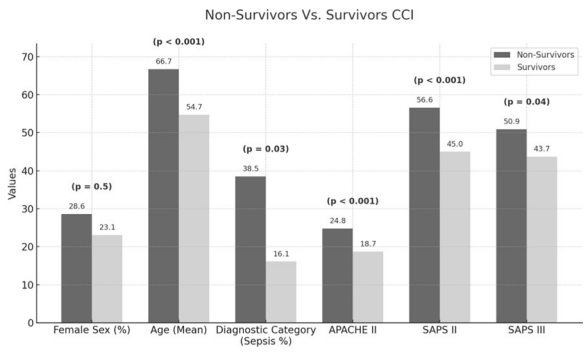

Fig. 1 (abstract 000826) Clinical and demographic variables associated with 3-month mortality in CCI patients. Nonsurvivors had higher age, sepsis prevalence, and severity scores (APACHE II, SAPS, SAPS II) as compared to survivors ($p < 0.05$)

Effects of postural change and mobilization on hemoglobin levels in patients on the ICU

T. Slijkerman[1], F. Van Steveninck[1], H. van den Oever[1], K. Kamphorst[2], J. De Kok[3]
[1]Intensive Care Unit, Deventer Hospital, Deventer, Netherlands, [2]Epidemiology, Deventer Hospital, Deventer, Netherlands, [3]Department of Clinical Chemistry, Deventer Hospital, Deventer, Netherlands

Intensive Care Medicine Experimental 2025 **13(Suppl 1)*:828***

Introduction: Anemia is frequent in ICU patients, primarily due to blood losses and reduced hemoglobin (Hb) synthesis. While posture related Hb changes have been reported, they remain unstudied in ICU patients. Hb increases upon standing have been attributed to plasma volume loss at increased hydrostatic pressure [1,2]. Effects of mobilization on Hb values have not been studied but might occur if pooled erythrocytes are redistributed with increased blood flow. An acute phase response with changes in ESR or CRP could modify these effects by altering vascular permeability and erythrocyte aggregation [3].
Objectives: To study the effects of posture and mobilization on Hb levels in ICU patients sufficiently stable to be mobilized. Secondary objectives included correlations between Hb and albumin (Alb) changes and baseline values of ESR and CRP.
Methods: A prospective, single-center uncontrolled interventional study in ICU patients aged ≥ 18 years. A priori power calculation determined that 23 patients were sufficient to detect relevant Hb changes. Major exclusion criteria included artificial ventilation, high doses of vasopressors, diuretic treatment, significant fluid shifts or transfusions within 24 h of sampling, right heart failure, bleeding and hematological disorders. Baseline arterial Hb, Alb, ESR and CRP were measured after lying supine for ≥ 6 h overnight. Hb and Alb measurements were repeated 30 min after a passive change to a sitting position in bed and again after mobilizing patients to a sitting position in a chair. Hb changes were analyzed using a linear mixed-effects model. Spearman's rank correlation was used to assess relationships between Hb change and Alb change, ESR, and CRP.
Results: 23 patients were included (median age 72 y, 57% male) with an average Hb of 6.9 (95% CI: 6.2-7.6) mmol/L in the supine position. A passive change to sitting in bed resulted in an increase of 0.2 (CI: 0.1-0.3) mmol/L, with a further increase of 0.3 (CI: 0.2-0.4) mmol/L after mobilization to a chair (both $p < 0.001$). The respective increases in Alb were 1.0 (CI: 0.5-1.4) g/L and 0.9 (CI: 0.5-1.4) g/L. There was a positive correlation between changes in Hb and changes in Alb (Spearman = 0.724, $p< 0.001$). No significant correlations were observed between ESR, or CRP and changes in Hb. The measured changes in Hb for individual patients are shown in Fig. 1.
Conclusions: Changes in the posture and mobilization were associated with Hb levels in a cohort of stable ICU patients. Measured changes in our study could affect transfusion decisions in selected patients. Concomitant changes in Alb suggest that plasma volume shifts contribute to the observed changes in Hb. As hydrostatic effects appear to equilibrate at around 30 min [4] a further increase in Hb upon mobilization may point to circulatory changes as another source of variability. These findings highlight the importance of considering both posture and immobility when interpreting Hb levels in ICU patients.

Overview of measured changes in hemoglobin (mmol/L) per individual from supine to sitting in bed, and following mobilization to a chair. Individual patients are ranked from no change to the largest total change in hemoglobin observed.

Intensive Care Medicine Experimental 2025 **13(Suppl 1)*:829***

Introduction: *Candida auris* is a multidrug-resistant yeast that is being increasingly reported worldwide.
Objectives: To describe the epidemiology of *Candida auris* candidemia, identify its predictive factors and evaluate its prognostic impact.
Methods: Retrospective study conducted in the intensive care units (ICUs) of two tertiary hospitals. All adult patients with candidemia admitted between 01.01.2022 and 31.03.2024 were included. Two groups were compared: *Candida auris* candidemia (CA) and non-candida auris (NCA) candidemia groups.

Results: During the study period, 51 patients developed candidemia including 27 (52.9%) patients with *Candida auris*. The mean age of all included patients was 64.9 ± 17.2 years. Mean SAPSII was 60.9 ± 20.1. there was no significant difference between both groups in terms of invasive venous lines requirement, urinary catheters insertion, and parenteral nutrition administration as risk factors for candidemia. However, the invasive venous access was left in situ for significantly longer time in (CA) group patients at the candidemia onset (21 [12-43.8] versus 9 [6-15] days; ***p* = 0.007**). Moreover, patients with *Candida auris* candidemia had significantly higher rate of colonisation with carbapenem-resistant Enterobacteriales (CRE) (51.9 vs 20.8%; ***p* = 0.022**). All patients received at least one broad spectrum antibiotic during the three months preceding candidemia. However, *Candida auris* candidemia was more frequently associated with previous exposure to ceftazidime–avibactam (40.7% vs 8.3%; $p = 0.008$) and/or tigecycline (44.4% vs 12.5%; $p = 0.012$). Similarly, previous exposure to antifungals was significantly higher in (CA) group (74.1% Vs 33.3%; $p = 0.004$). All *Candida auris* isolates were resistant to fluconazole and sensitive to echinocandins and amphotericin B. In multivariate analysis, only previous exposure to antifungals was identified as an independent factor predicting *Candida auris* candidemia (OR = 6.5 CI95% [1.7-25.3]; ***p* = 0.007**).
Candidemia was associated with higher rate of septic shock (83.3% vs 40.7%; ***p* = 0.002**), and higher requirement of mechanical ventilation (95.8% vs 63%; ***p* = 0.004**) in patients with *non-Candida auris* fungemia. The 28-day mortality was 66.7%. There was no significant difference between (CA) and (NCA) groups in terms of 28-day mortality (OR = 0.3 95% CI [0.1-1.1]; $p = 0.08$).
Conclusions: *Candida auris* became the dominant isolate in our units during the study period. Exposure to broad spectrum antibiotics and antifungals, in addition to colonization with CRE represent the main risk factors for *Candida auris* fungemia. However, the associated 28-day mortality rate was not different in comparison to candidemia caused by other species.

Microcirculation assessment with hyperspectral imaging as innovative measure for nociception monitoring—results from an exploratory prospective study on awake volunteers

HT. Hölzer[1], D. Herrschuh[1], MA. Weigand[1], J. Larmann[2]
[1]Department of Anaesthesiology, Heidelberg University, Medical Faculty Heidelberg, Heidelberg, Germany; [2]Department of Anaesthesiology, RWTH Aachen University, Medical Faculty, Aachen, Germany
Correspondence: H.T. Hölzer
Intensive Care Medicine Experimental 2025* 13(Suppl 1):*830

Introduction: Nociception monitoring remains a relevant challenge for patients in intensive care and during surgery. Awake patients can rate nociceptive stimuli on a numeric rating scale (NRS), which not feasible for deeply sedated patients. Nevertheless, nociception monitoring is crucial, as nociception leads to an activation of the autonomic nervous system (ANS), which has potential negative influence on outcome [1]. At the same time, ANS activation results in changes of microcirculation. Microcirculation can be measured with hyperspectral imaging. Within 20 s a hyperspectral image can be recorded without contact and the use of ionizing radiation. Based on light absorption and reflection tissue parameters are calculated [2].
Objectives: The aim is to explore whether nociception monitoring via hyperspectral imaging of the palm is feasible.
Methods: We included 20 healthy awake volunteers of the Medical Faculty Heidelberg (ethics: S-482/2024, registry: DRKS00034934). A blood pressure cuff which was inflated with 50 mmHg above systolic blood pressure for five minutes was used as a tourniquet on the left leg. The resulting ischaemic pain was rated by the participants on NRS from 0-10 every 30 s. At the same time, hyperspectral images of the right palm were recorded with the MDR certified TIVITA® 2.0 camera (Diaspective Vision GmbH, Germany). Tissue oxygen saturation (O2), near infrared perfusion index (NIR), and tissue haemoglobin index (Hb) were calculated and compared with ten images before stimulation. Normally distributed mean parameters were analysed with a paired t-test.
Results: The volunteers were between 18 and 40 years old, 55% were female, and gave their informed consent. Overall, 199 images were recorded before and 198 during stimulation, of which 104 were rated as painful (NRS > 3) by 16 participants. NRS ratings increased over time starting with a mean of 3.13 (SD = 2.68) and ending with 5.73 (SD = 1.44). Baseline range was 49-75% for tissue O2, 45-67 for NIR, and 18-39 for tissue Hb. During pain a decrease of mean tissue O2 (– 0.41%, SD = 2.23) and an increase of NIR (+ 0.41, SD = 2.07) and tissue Hb (+ 1,6, SD = 3.96) were observed. Similar effects were observed while the stimulation was rated NRS < 3 (Fig. 1). The change was especially noticeable in six participants who rated the beginning of the stimulation painful with a mean tissue O2 -2.83% (SD = 4.07, p = 0.149), NIR – 1.67 (SD = 1.63, p = 0.055), and tissue Hb + 4.67 (SD = 3.93, $p = 0.034$) in the first image (Fig. 2). After an initial decrease, NIR usually went back to the baseline within 90 s.
Conclusions: During nociception small changes in microcirculation occur in the palm which can be measured via hyperspectral imaging. Further studies should evaluate, whether these changes are similar for different body regions and whether they are still detectable during catecholamine infusion in critical patients. NIR and tissue O2 might be indicators for the onset of nociception while tissue Hb stays on a higher level throughout stimulation.

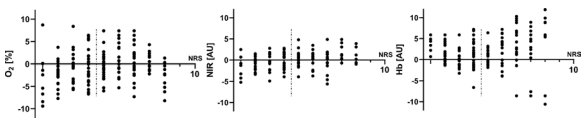

Fig. 1 (abstract 000830) Hyperspectral tissue parameters during stimulation. In comparison to the baseline, tissue oxygen saturation (O2 in percent) decreases and near infrared perfusion index (NIR in arbitrary units) as well as tissue haemoglobin index (Hb in arbitrary units) increase during painful stimulation (NRS > 3, dotted line) ($n = 16$)

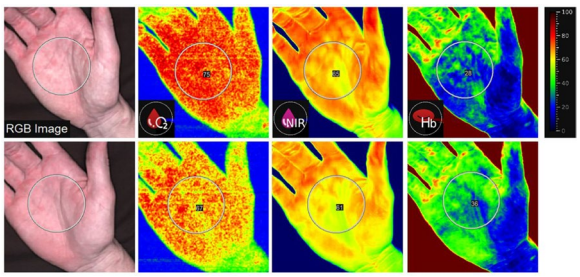

Fig. 2 (abstract 000830) Change of microcirculation in hyperspectral images. In the upper row, the last baseline measurement of one participant is depicted with colour coded images for the tissue parameters from left to right oxygen saturation (O2 in percent), near infrared perfusion index (NIR in arbitrary units) and haemoglobin index (Hb in arbitrary units). In the lower row, changes of the microcirculation after the start of the painful stimulation (NRS = 6) can be observed. Tissue parameters are calculated for a circular region of interest

Introduction: Unilateral pulmonary artery ligation induces local injury. Mechanisms involved remain mostly unknown and could include regional hypocapnia, worsening mechanics increasing stress, and hypoperfusion [1,2].
Objectives: We conducted a large observational experimental study in 46 pigs undergoing unilateral ligation of the left pulmonary artery and different ventilation strategies, to identify pathophysiological mechanisms and protective factors correlated to lung injury.
Methods: Sedated, paralized and mechanically ventilated healthy pigs underwent left pulmonary artery ligation. Animals were treated with different levels of PEEP (1-5 cmH2O), respiratory rate (15-25 b/min), and tidal volume (Vt, 6-15 ml/kg), and were kept at various arterial pCO2 levels (obtained by low Vt, instrumental dead space or inhaled 5% FiCO2), in the supine or prone position. Physiological (all animals) and EIT ventilation and perfusion data (n = 34) were collected and analyzed at the end of the experiment (24 or 48 h) and the validated [1] lung injury histological score (HS) was assessed after euthanasia.
Results: The left lung with pulmonary artery ligation developed lung injury with median HS of 7 [5;9] and large variability (range 2-16). Lower left lung HS correlated with increasing arterial pCO_2 levels (Fig. 1A), and with higher blood flow reaching the left lung from the bronchial artery (Fig. 1B). We also confirmed that bronchial blood flow was positively correlated to PaCO2 (Fig. 1C) [3]. Left HS was correlated with higher lung stress, as assessed by higher plateau pressure and mechanical power (Fig. 1D-E), likely caused by worsening respiratory system compliance (Fig. 1F). Interestingly, regional index of wasted ventilation (left side Vt, minute ventilation, dead space fraction and ventilatory ratio) were not correlated with left lung HS ($p > 0.05$), questioning the pathological role of alveolar hypocapnia. Adjustment for treatment strategies (PEEP, body position, Vt, respiratory rate, duration) did not alter the abovementioned correlations.
Conclusions: In our large animal model of unilateral pulmonary artery ligation on controlled ventilation, regional hypoperfusion seems to play a key role for the development of injury. Higher arterial pCO2 protects the lung also by increasing regional blood flow, while impaired respiratory mechanics and higher inspiratory stress could be early signs of injury (but also potential triggers of a pathologic vicious circle).

PaCO2 showed negative association with histological score (HS) (**A**) and blood flow in the left lung (**B**). Blood flow and PaCO2 were positively correlated (**C**). Higher left HS was correlated with increased plateau pressure (**D**), mechanical power (**E**), and decreased total compliance (**F**). Rho and *p* values for Pearson correlations are reported in the graphs. LL = left lung, RS = respiratory system

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***833***

Introduction: Cardiac surgery-associated acute kidney injury (CSA-AKI) is a major complication associated with a high mortality. Its early prediction using biomarkers has become increasingly popular in the recent years. Human liver-type fatty acid-binding protein (l-FABP) is a biomarker which is expressed in proximal tubule cells, amoung others. If a form of tubulointerstitial damage occurs, tubule cells perish and l-FABP is thereby excreted in the urine. It has gained a good predictive and prognostic value in kidney diseases during the last years.
Objectives: Our aim was to investigate if l-FABP can predict as well as diagnose acute kidney injury timely and reliably.
Methods: In this prospective cohort study, we analysed 63 patients who underwent elective cardiac surgery on cardiopulmonary bypass at the Medical University of Vienna.Urine samples were collected at the beginning of the operation, 30 min after start of CPB, at the end of surgery and on postoperative day (POD) 1.Quantitative measurement of l-FABP was performed by an enzyme-linked immunosorbent assay (ELISA) with a 96-well plate human l-FABP-ELISA (R&D-Systems, Minnesota, USA). Patients were grouped in two groups: patients without postoperative CSA-AKI and with CSA-AKI, according to KDIGO-criteria.
Results: We report 63 patients (25 female), with a mean age of 67.1 ± 11.6 years. In 12.7% (*n* = 8) CABG, in 57.1% (n = 36) a valve, in 28.6% (n = 18) a combined procedure and in one case (1.6%) a Bentall was performed. According to the KDIGO-criteria (5), 19 patients (30.2%) of the patients suffered from CSA-AKI, none of them needed renal replacement therapy.
Urinary l-FABP levels increased continuously from start of surgery started until the end of surgery (baseline, 2444 ± 3637 pg/ml; 30 min after initiation of CPB, 3012 ± 4385 pg/ml; end of surgery, 8775 ± 7803 pg/ml) and decreased again on POD1 (6660 ± 7661 pg/

ml). At the end of surgery urinary l-FABP levels were significantly different between non-CSA-AKI and CSA-AKI patients (7827 pg/ml vs. 10918 pg/ml, $p = 0.046$).
Conclusions: Urinary l-FABP has the possibility to predict CSA-AKI at the end of surgery. Furthermore, we found an increase in l-FABP-levels in both, non-CSA-AKI and CSA-AKI patients as sign of subclinical renal impairment in every patient.

l-FABP concentration in patients without AKI and with AKI.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**)***:835***

Introduction: Antimicrobial resistance (AMR) and healthcare-associated infections are growing global threats for public health. High levels of multidrug-resistant organisms (MDROs) is a concerning issue in Hellenic health system especially due to and their frequent transmission to newly admitted patients. ICU patients often acquire intestinal colonization by different MDROs which is associated with increased risk for bloodstream infections (BSI) caused by the same colonizing organism.
Objectives: Aim of the study was to record local epidemiology of intestinal colonization in our cohort of ICU patients, establish the most prevalent strains, assess the rate of subsequent BSIs caused by the same colonizing strain and evaluate BSI resolution.
Methods: A retrospective single cohort study was conducted from 01 January to 31 [32]. Age, sex, APACHE II, SOFA, Charlson Comorbidity Index (CCI) and active COVID19 infection were recorded on admission day. Patients with positive rectal swab on admission as well as those with ICU length of stay (I-LOS) shorter than 72 h were excluded per study protocol. BSI by the same colonizing rectal strain (swab monitored once weekly) during their ICU stay were recorded. Resolution of BSI positivity, I-LOS and survival were also recorded. Linear regression tested associations between variables. Chi-square test examined association between categorical variables and Cramer's V measured their association.
Results: Rectal colonization data are presented in Fig. 1. Among 55 new rectal carriers with median age 75 years, 33 (60%) were men and 30 (55%) were admitted with active COVID19 infection. Mean APACHE_II was 24.48 (± 6.9), SOFA 7.98 (± 2.76), CCI 5.57 (± 2.44) and LOS 29.91 days (± 10). 14 patients (25.45%) developed BSI (11 of which were COVID19 positive), after a mean time of 10 days. 11 patients recovered from BSI successfully (50% mortality vs 40% of the overall mortality). As shown in the Flowchart (Fig. 1), the most common rectal colonizer was Klebsiella pneumoniae (Kp) with metallo-b-lactamase (MBL) enzyme, followed equally by Acinetobacter MBL and Kp_KPC. The presence of BSI was not associated with increased mortality in comparison with patients with no BSI and neither was COVID19 infection itself. The presence of COVID 19 infection was moderately associated with BSI appearance (Cramer's V effect size = 0.26, p=0.05).
Conclusions: In our cohort of patients MBL enzymes were the main enzymes of intestinal colonizing strains. Therefore these patients are at increased risk for BSI from difficult to treat bacteria. We found that COVID19 infection, with its concomitant immunosuppressive and antibiotic therapy, must have contributed to this. In this ongoing work we aim to better understand the mechanisms that contribute to this rapid dissemination of MDROs. The knowledge of AMR status, microbe's virulence and host's specific risk factors may help establish preventive measures, assess risk stratification and finally reduce the risk of ICU-acquired infections.

Introduction: Veno-venous extracorporeal membrane oxygenation (VV-ECMO) is a potentially life-saving intervention for patients with refractory respiratory failure with an increasing use in the recent years. Currently, the only absolute contraindication is futility, but relative contraindications include the duration of mechanical ventilation prior to ECMO—which is often cited as not more than 7 to 10 days (1-4). This was one of the main exclusion criteria during COVID-19 pandemic, potentially denying patients a life-saving intervention (5). The recent studies have questioned the strict application of these cutoffs, with some suggesting no clear relationship between pre-ECMO ventilation duration and mortality (6-8). Other factors, such as pre-ECMO infections, may play a more significant role and act as confounding factor in this association. As prolonged mechanical ventilation increases the risk of infection(9), and ECMO is sometimes initiated due to complications of such infections, it is possible that coinfection, rather than ventilation duration per se, is the primary determinant of outcomes.
Objectives: To evaluate the impact of pre-ECMO mechanical ventilation duration and coinfections on mortality in COVID-19 patients receiving VV-ECMO.
Methods: A retrospective study was conducted including the adult COVID-19 patients with respiratory ECMO support from the ELSO registry data, from January 2020 to May 2022. Data collected included days of mechanical ventilation, pre-ECMO assessment, complications, coinfections at ECMO initiation and outcomes. We excluded patients with cardiac arrest. The relationship between mechanical ventilation duration, coinfection and mortality was studied with a causal mediation analysis. Survival was evaluated using Kaplan–Meier survival function.
Results: 12803 patients were analyzed. Hospital mortality was 44.8% in patients without coinfection and 52.3% in those with coinfection. There was no significant association between duration of mechanical ventilation prior to ECMO and mortality (OR 1.00; 95% CI 0.99-1.01; P = 0.517). However, the presence of coinfection at the time of ECMO initiation was significantly associated with increased mortality (OR 1.35; 95% CI 1.26-1.44; $P < 0.001$). In addition, longer mechanical ventilation was significantly associated with a higher risk of coinfection (OR 1.04; 95% CI 1.03-1.05; $P < 0.001$). When examining the simultaneous effects of both variables on mortality, days of mechanical ventilation were not associated with mortality (OR 1.00; 95% CI 1.00-1.01; $P = 0.884$), whereas coinfection remained significantly associated with increased mortality (OR 1.37; 95% CI 1.26-1.47; $P < 0.001$).
Conclusions: Mortality was unrelated to pre-ECMO ventilation duration but significantly associated with coinfection at ECMO initiation.

Intensive Care Medicine Experimental ***2025*** **13**(**Suppl 1**):***838***

Introduction: Delirium is an acute confusional state, associated with significant functional and cognitive impairment [1,2] and is linked to increased mortality, morbidity, treatment costs and long term cognitive decline and mental ill health [3]. If risk is determined, effective preventative measures may help improve patient outcomes. The PRE-DELIRIC model is the most widely used day of ICU admission delirium prediction tool [4,5]. Up to 80% of mechanically ventilated patients in ICU develop delirium [6], however the impact of mode of ventilation on efficacy of the PRE-DELIRIC model has not been evaluated.
Objectives: Determine how mode of ventilation impacts the performance of the PRE-DELIRIC model.
Methods: We retrospectively analysed data from patients admitted to a teaching hospital mixed ICU between April 2023 and December 2024. Patients were excluded if the 10 data parameters of the PRE-DELIRIC tool were not available or no delirium assessments, using the CAM-ICU, were documented during the ICU stay. Patients were grouped according to mode of ventilation and PRE-DELIRIC scores were calculated. AUROC values were used to evaluate the predictive power of PRE-DELIRIC scores in each group of patients.
Results: Of the 3256 patients admitted into the hospital GICU from April 2023-December 2024, 1254 (38.5%) were included in the analysis. The AUROC of the PRE-DELIRIC model for the total cohort was 0.766 (95% CI 0.739-0.793), suggesting good predictive power. The following characteristics table shows the AUROC values according to highest mode of ventilation patients received:

Table 1 (abstract 000838) xxxx

Characteristics Table	All Patients (*n*=1254)	Invasive Ventilation (*n*=516)	Non-Invasive Ventilation (*n*=174)	No Ventilation (*n*=564)
Sex, male (%)	723 (57.7)	328 (63.6)	92 (52.9)	303 (53.7)
Age (years), mean ± SD	70.0, ±17.3	59.5, ±17.1	64.4, ±13.5	61.3, ±18.6
APACHE-II score, mean ± SD	17.0, ±4.8	17.1, ±4.8	19.0, ±4.4	16.2, ±4.8
Sedative Use (%)	575 (45.9)	503 (97.5)	26 (15.0)	46 (8.2)
Metabolic Acidosis (%)	330 (26.3)	161 (31.2)	31 (17.8)	138 (24.5)
Unplanned/Urgent Admission (%)	1110 (88.6)	458 (88.6)	167 (96.0)	485 (86.0)
Coma: Any(%)	284 (22.6)	282 (54.7)	0 (0)	2 (0.4)
- Drug-Induced (% of *n*)	- 137 (10.9)	- 136 (26.4)	- 0 (0)	1 (0.2)
- Misc. (% of *n*)	- 26 (2.1)	- 26 (5.0)	- 0 (0)	0 (0)
- Mixed (% of *n*)	- 121 (9.6)	- 120 (23.3)	- 0 (0)	1 (0.2)
Admission Category:				
- Surgery (%)	- 308 (24.6)	- 134 (26.0)	- 19 (10.9)	155 (27.5)
- Medical (%)	- 813 (64.8)	- 302 (58.5)	- 144 (82.8)	367 (65.1)
- Trauma (%)	- 131 (10.4)	- 78 (15.1)	- 11 (6.3)	42 (7.4)
- Neurology (%)	- 2 (0.2)	- (0.4)	- 0 (0)	0 (0)
Infection (%)	927 (73.9)	420 (81.4)	136 (78.2)	371 (65.8)
AUROC (95% CI)	**0.766 (0.739-0.793)**	**0.628 (0.579-0.676)**	**0.780 (0.693-0.866)**	**0.670 (0.615-0.724)**

Conclusions: Overall, the PRE-DELIRIC model demonstrates a good predictive value of developing delirium in our ICU patients. The performance of the PRE-DELIRIC tool was better in patients receiving non-invasive ventilation compared to those receiving invasive ventilation or no ventilation.

Prehospital management of acute heart failure by EMS 03: clinical characteristics and outcomes: an 8-month observational study

H. Bradai, R. Mbarek[1], G. Sassi[1], N. Chebbi[1], N. Chebili[1]
[1]EMS 03, UNIVERSITY HOSPITAL SAHLOUL, Sousse, Tunisia, Sousse, Tunisia
Correspondence: H. Bradai

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***839***

Introduction: Heart failure (HF) is a global health concern, affecting approximately 26 million people according to the European Society of Cardiology (ESC). Its prevalence continues to rise due to population aging and improved cardiovascular disease management. HF remains a major challenge in prehospital medicine.
Objectives: This study aimed to (1) describe epidemiological and clinical characteristics of HF patients transported by EMS 03's mobile intensive care unit (SMUR) over eight months, and (2) analyze therapeutic approaches and medium-term outcomes.
Methods: A longitudinal, exhaustive study of all HF cases managed by EMS 03 at Sahloul University Hospital (Sousse, Tunisia) from October 1, 2023, to May 31, 2024. Data included sociodemographics, clinical features, treatments, and outcomes. Survival analysis was performed using the Kaplan–Meier method.
Results: Among 120 enrolled patients: Demographics: Mean age 69.6 ± 10.2 years, male predominance (62.5%). Comorbidities: Hypertension (60%), diabetes (50%), chronic HF (45.8%). Clinical Presentation: Dyspnea (92.5%), respiratory distress (94.1%), tachypnea (66.6%), accessory muscle use (59.2%). Auscultation: Crackles (86.4%), wheezing (10%). Mean BP: 150.04/83.6 mmHg. ECG repolarization abnormalities (46.7%). Management: CPAP (69.2%), diuretics (84.2%), nitrates (41.7%), antithrombotics (33.3%), antihypertensives (15.8%). Outcomes: Decompensation triggers: ACS (36.5%), infection (25%), hypertensive crisis (21.7%). Initial improvement: 79.2% at 24h, 94.1% at 7 days (5.9% unfavorable). Oxygen dependence persisted in 12.2%. 30-day survival: 96%. Median survival: 24 h (no significant subgroup differences).
Conclusions: Our findings demonstrate the effectiveness of prehospital HF management strategies in this cohort. Multicenter studies are needed to validate these results and optimize protocols.

The effectiveness of FOUR Score versus GCS scale in predicting mortality and morbidity in traumatic brain injured patients in intensive care: a systematic review

M. Dos Santos[1], LC. Stayt[2]
[1]Neuro ICU, Oxford University Hospitals Foundation Trust, Oxford, United Kingdom; [2]Oxford Brookes, Oxford Brookes University, Oxford, United Kingdom
Correspondence: M. Dos Santos

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***840***

Introduction: Traumatic brain injuries (TBI) is one of the leading causes of death and disability worldwide. In Intensive Care, the Glasgow Coma Scale (GCS) is widely used to assess severity of brain injury. An alternative tool is the Full Outline of UnResponsiveness (FOUR) score which assesses stages of locked-in syndrome and brain herniation.
Objectives: To evaluate the effectiveness of both assessment tools in predicting mortality and morbidity in TBI patients in ICU. Is the FOUR score more effective in predicting mortality and morbidity in critical ill patients with TBI in ICU compared to GCS?
Methods: Systematic review guided by the Joanna Briggs Institute (JBI) Manual for Evidence Synthesis (2021). A comprehensive database search was conducted for the period January 2005—September 2023. Searches repeated in February 2025. Primary research comparing FOUR with GCS, published in English, including adults aged 16 and over and patients with TBIs in ICU were included. Studies were appraised using JBI critical appraisal tools. Data were narratively synthesised.
Results: Eleven studies were included. No study reported significant statistical differences between GCS and FOUR score in predicting mortality. Area under the curve and receiving operating characteristic curve values for both tools were rated good to excellent (Range 0.80-0.96) in predicting mortality. Morbidity was only reported in 6/11 studies. Both assessment tools perform similarly in predicting mortality and morbidity. There was a great variability in which and how morbidity outcomes were assessed.

Conclusions: Further research to determine the additional clinical benefits of FOUR assessment in this population is recommended. The development of core morbidity outcome measures in patients with TBI is required to evaluate if these tools effectively predict morbidity. Effective prognostication may assist healthcare providers in managing resources as well as providing patients and families with realistic expectations of long-term recovery.

ADELPHA: association between delirium and the presence of alpha band

A. Amaro Harpigny[1], M. Carretero Rodrigo[2], C. Chamorro Jambrina[1], JA. Galiano Gordillo[3], I. Tendero Herraiz[1], P. Enciso Paniagua.[1]

Intensive Care Medicine Experimental 2025 13(**Suppl 1**):***841***

Introduction: ADELPHA: Association between delirium and the presence of alpha band
Objectives: Delirium (DEL) is a common complication in critically ill patients who are mechanically ventilated and under sedation. Having predictive and/or predisposing data for DEL occurrence could lead to the implementation of measures in order to minimize or prevent its development. The presence of alpha-band EEG (8-12 Hz) activity in the spectral density matrix (SDM) during general anesthesia monitoring has been associated with lower incidence of postoperative DEL; however, this has been poorly studied in critically ill patients
Methods: The ADELPHA study (Delirium/Alpha Band Association) is a prospective, observational, single-center study analyzing frontal/temporal EEG data collected through unilateral/bilateral BIS® monitoring. Mechanically ventilated patients under deep sedation (RASS − 4, − 5) with GABAergic sedatives (midazolam and/or propofol) throughout the entire period of deep sedation were included. The SDM of each patient, exported daily from the monitor in PDF format, was analyzed by two investigators and visually classified into two groups based on the absence or presence of alpha- band activity. The latter group was further subclassified into three categories based on the color intensity of the alpha- band: high (bright red), medium (sustained yellow), and low (yellow traces). Upon sedation withdrawal, the presence and duration of DEL were assessed
Results: 58 patients were included in the study. The incidence of DEL was 25/39 (64%) in the alpha band group vs. 17/19 (89%) in the non-alpha band group, ($p = 0.042$). Median DEL duration was 1 day in the alpha band group vs. 4 days in the non-alpha band group ($p = 0.113$). Among the different subgroups of the alpha- band, a higher incidence and longer duration of DEL were observed in the low-intensity alpha-band group compared to the other groups ($p = 0.040$ and $p = 0.002$, respectively).
Conclusions: The absence of the alpha- band or its presence with low intensity in the SDM of EEG processed at the bedside is associated with a higher likelihood of DEL development and its longer duration in a group of critically ill patients undergoing deep sedation with GABAergic drugs.

Intensive Care Medicine Experimental 2025 13(**Suppl 1**):***842***

Introduction: To study mortality in the ICU, in-hospital mortality, and mortality at 6 months (6 M), as well as functional dependence (modified Rankin scale at 6 M), in patients diagnosed with acute ischemic stroke with ASPECTS ≤ 7 on computed tomography and treated with mechanical thrombectomy (MT) versus patients with ASPECT > 7
Methods: Retrospective study (January 2015-May 2024). The study includes all patients who underwent MT and were admitted to the ICU of a tertiary university hospital. Collected variables: age, gender, risk factors (hypertension, diabetes, dyslipidemia, smoking/alcohol consumption, atrial fibrillation, antiplatelet/anticoagulant therapy), Rankin score at admission, NIHSS at diagnosis, time from symptom onset to hospital admission and symptom-to-recanalization time, IV fibrinolysis, ICU and hospital length of stay, and ICU, in-hospital, and 6-month mortality. Functional dependence was defined as a Rankin score > 3 at 6 months. Quantitative variables: mean ± SD, median (IQR 25-75). Qualitative variables: absolute value (%). Statistical analysis: chi-square, Fisher's test, Wilcoxon test, and logistic regression as appropriate. Statistical significance: $p < 0.05$
Results: A total of 395 patients were included, of which 120 (30.4%) had ASPECTS ≤ 7.When comparing ASPECTS ≤ 7 vs. ASPECTS > 7, no differences were found in: age (69 ± 14 vs. 72 ± 13 years), male gender

[57 (48%) vs. 135 (50%)], risk factors, Rankin at admission [0 (0-1) vs. 0 (0-1)], time from symptoms to hospital (3 ± 3 vs. 3 ± 3 h), and time from symptoms to recanalization [5 ± 2 (30% wake-up stroke) vs. 5 ± 2 h (20% wake-up stroke)], IV fibrinolysis [30 (25%) vs. 95 (35%)], and hospital length of stay [12 (6-23.5) vs. 11 (7-19.5) days].Differences were found in: NIHSS at diagnosis (18 ± 5 vs. 15 ± 6 points) and ICU stay [1 (1-4.25) vs. 1 (1-2) days]. ICU mortality: 22 (18.3%) vs. 22 (8%); in-hospital mortality: 39 (32.5%) vs. 49 (17.8%); and 6-month mortality: 48 (40%) vs. 58 (21%). Rankin > 3 at 6 months: 85 (70.8%) vs. 123 (44.7%).After adjusting for NIHSS, ASPECTS ≤ 7 was independently associated with: ICU mortality [OR 2.22 (1.15-4.30)], in-hospital mortality [OR 1.71 (1.02-2.86)], 6-month mortality [OR 1.85 (1.13-3.04)], and Rankin > 3 at 6 months [OR 2.95 (1.19-7.54)].

Conclusions: A careful evaluation of patients with ASPECTS ≤ 7 who are being considered for MT is essential. The use of complementary tests such as perfusion CT in the decision-making algorithm may help in better selection of patients who are most likely to benefit from mechanical thrombectomy, minimizing the associated risks.

Intensive Care Medicine Experimental 2025* 13(Suppl 1):*843

Introduction: As second-line vasopressors become increasingly used, non-catecholaminergic agents have gained attention for their distinct organ-specific hemodynamic profiles. Although both agents effectively reduce catecholamine requirements (1), some evidence suggests that angiotensin II (Ang-II) may be associated with increased pulmonary vascular resistance (2), while arginine vasopressin (AVP) appears to exert minimal pulmonary vasoconstrictive effects (3), which could be more favorable to right ventricular (RV) function (4).

Objectives: To evaluate the effects of AVP versus Ang-II on RV function when used as second-line vasopressors in patients with refractory shock.

Methods: Prospective ongoing registry (SEVERE registry, B4062024000091) including all adult patients (≥ 18 years) admitted to the ICU for refractory vasodilatory shock and treated with a second-line vasopressor (AVP or Ang-II). Patients were eligible for analysis if a complete transthoracic echocardiographic assessment was available at baseline (prior to vasopressor initiation) and at 3, 6, and 24 h following administration. The echocardiographic and hemodynamics parameters of interest and their variation in time were analyzed using Fisher's exact test, Mann–Whitney or linear mixed-effects model, as appropriate.

Results: A total of 19 patients were included between May 2024 and April 2025, 9 received AVP and 10 Ang-II. Baseline characteristics in the two groups were comparable, as shown in Table 1.At baseline, RV function assessed by TAPSE, RVS' and RV strain were significantly different in the two groups, showing lower values in patients treated with AVP compared to Ang-II ($p < 0.05$ for all comparison—Table 2). The AVP group showed a significantly greater improvement over time in TAPSE and RVS compared to the Ang-II group, with a significant group-by-time interaction ($p = 0.03$ and $p = 0.02$, respectively), as also depicted in Fig. 1. No significant differences between groups were observed for RV strain and TAPSE/PAPs ratio.

Conclusions: In vasodilatory shock, AVP was associated with greater improvement in RV function compared to Ang-II.

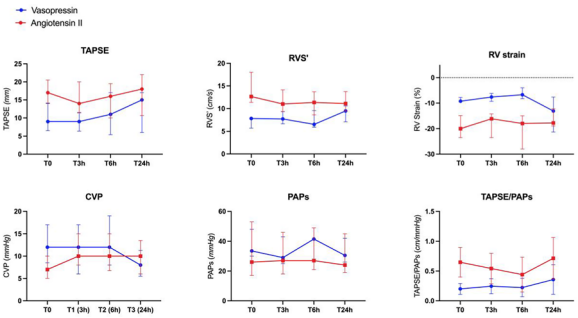

Fig. 1 (abstract 000843) Time course of right ventricular function parameters in patients treated with AVP or Ang-II: evolution of RV parameters over time (T0 = baseline, 3 h, 6 h, 24 h) in patients receiving AVP (blue) or Ang-II (red) as second-line vasopressor therapy

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***844***

Introduction: Landiolol is a highly β1-selective, ultra-short-acting beta-blocker. This study aimed to analyze the cardiovascular effects and safety profile of landiolol in ICU patients.
Methods: This retrospective, observational study included patients admitted to medical or surgical ICUs in our university hospital who received landiolol. Cardiovascular parameters, including heart rate (HR), systolic, diastolic, and mean blood pressure, vasopressor catecholamine doses, and blood lactate levels, were extracted at baseline, H1, H2, H6, and H24. The primary endpoint was a composite safety outcome, defined as a decrease in mean arterial pressure (MAP) below 64 mmHg, bradycardia (HR < 50 bpm), or an increase in vasopressor catecholamine dose of more than 50%.
Results: Between January 2021 and February 2023, 73 patients treated with landiolol were identified, with a median age of 67 years; 64.3% were male. The mean norepinephrine dose at landiolol initiation was 0.30 µg/kg/min [95% CI 0.15-0.45]. The primary indications for landiolol treatment were atrial fibrillation (87.7%), sinus tachycardia associated with septic shock (8.2%), sinus tachycardia with postoperative vasoplegic shock (1.4%), and atrial flutter (2.7%). The median duration of landiolol treatment was 2 days [0.89-4.88], with a mean landiolol dose of 7.05 µg/kg/min [95% CI 6.30-7.80] over the first 24 h. The primary safety endpoint was met in 9.6%, 4.1%, 6.8%, and 2.7% of patients at H1, H2, H6, and H24, respectively. HR decreased from 156 bpm at baseline to 113 bpm at H6 ($p < 0.0001$) and 103 bpm at H24 ($p < 0.0001$). MAP and vasopressor doses remained stable over time. HR below 110 bpm was achieved in 45.2% of patients at H6 and in 61.6% of patients at H24. Conversion to sinus rhythm at H24 was observed in 35 of 66 patients (53%) initially in atrial fibrillation. ICU mortality was 37% (27/73).
Conclusions: In our experience, landiolol appears to be a safe option for treating supraventricular tachyarrhythmia in ICU patients. Careful dose titration to target HR, as recommended by atrial fibrillation guidelines, can be achieved with relatively low doses of landiolol, with minimal impact on blood pressure and stable vasopressor requirements over time.

Evolution of heart rate (bpm) during the first 24 h of landiolol administration.

Is mechanical power normalization the key to its association with mortality in mechanically ventilated critically ill patients?

S. Manrique[1], J. Berrueta[1], N. Murillo Moreno[2], LE. Andrade[1], L. claverias[1], A. Rodriguez[1], M. Samper[1], O. Plans-Galván[1], M. Magret[1], M. Bodi Saera.[1]

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):845

Introduction: Higher mechanical power (MP) has been associated with increased ICU mortality in mechanically ventilated critically ill patients in several studies. However, the lung damage caused by the energy delivered to the lungs may vary depending on lung size. Some studies suggest that normalizing MP by ideal body weight (IBW) or by pulmonary compliance (C) could be a better predictor of mortality.

Objectives: To assess which method of measuring MP shows the strongest association with mortality in mechanically ventilated critically ill patients

Methods: This was a retrospective, single-center observational study conducted in the mixed ICU of Hospital Universitari Joan XXIII in Tarragona. We included patients > 18 years of age admitted to the ICU (April 2022–August 2024) who received invasive mechanical ventilation (IMV) for more than 24 h. Median absolute MP (MPa) over the first 14 days of admission was calculated using the formula: *MP = 0.098 × Vt × RR × (Peak Pressure—Driving Pressure / 2)*, with data automatically recorded every 2 min from the clinical information system while patients were on volume-controlled ventilation. MP normalized by ideal body weight (MPibw) was obtained by dividing MPa by IBW, and MP normalized by compliance (MPc) by dividing MPa by the median compliance over the first 14 days. Univariate and multivariate analyses (adjusted for variables associated with mortality in the univariate analysis) were performed to identify which MP measure was most strongly associated with 14-day ICU mortality.

Results: A total of 491 patients were included. 66% were male, with a median age of 62 years (52-72), a median SOFA score of 5 (3-7), APACHE II of 17 (12-23), and Charlson Index of 3 (1-5). 94% were urgent admissions, and 63% were admitted for medical reasons, 24% due to respiratory conditions. Median MPc during the first 14 days was the only MP metric significantly associated with ICU mortality at day 14, both in the univariate analysis (Table 1) and the multivariate analysis (OR 3.98 [1.28-12.19], AUC 0.76) (Fig. 1). When MPc was categorized into quartiles, only the highest quartile (0.41-1.25 J x min-1 × ml-1 × cmH_2O) remained significantly associated with mortality (OR 2.27 [1.03-5.17], AUC 0.76) (Fig. 2).

Conclusions: MPc seems the only MP measure significantly associated with mortality in mechanically ventilated critically ill patients. These results suggest that normalizing MP by pulmonary compliance may improve its predictive value for mortality.

Table 1 (abstract 000845) Univariate analysis for mortality

Variable	Total population (N= 491)	Survived in the ICU (N=405)	Died in the ICU (N=86)	P values

Diaphragmatic ultrasound as a predictive tool for weaning success in ICU: insights on excursion and thickening fraction

S. Bekkaoui[1], H. Berrichi[2], H. Bkiyar[3], B. Housni.[4]
[1]service d'anesthésie réanimation oujda, Faculty of Medicine and Pharmacy of Oujda, Oujda, Morocco; [2]Anesthésie et réanimation, المركز الاستشفائي الجامعي محمد السادس, Oujda, Morocco; [3]Service anesthesie reanimation, المركز الاستشفائي الجامعي محمد السادس, Oujda, Morocco; [4]Intensive care and anesthesiology, المركز الاستشفائي الجامعي محمد السادس, Oujda, Morocco
Correspondence: S. Bekkaoui

Introduction: Weaning failure from mechanical ventilation is a major challenge in intensive care units (ICUs), often leading to prolonged ICU stays, increased morbidity, and higher mortality. Diaphragmatic dysfunction (DD) is a key contributor to extubation failure, but traditional diagnostic tools are invasive and impractical in critically ill patients [1-3]. Diaphragmatic ultrasound (DU) has emerged as a non-invasive, bedside method to assess diaphragmatic function and predict weaning outcomes [4,5].
Objectives: To evaluate the prognostic accuracy of diaphragmatic excursion (DE) and thickening fraction (TF) in predicting extubation success, and to identify clinical risk factors associated with weaning failure.
Methods: We conducted a prospective cohort study over six months in the ICU of Mohammed VI University Hospital. Eighty adult patients intubated > 48 h and undergoing their first weaning attempt were enrolled. Diaphragmatic excursion (M-mode, subcostal approach) and thickening fraction (M-mode, zone of apposition) were measured during spontaneous breathing trials. Extubation failure was defined as reintubation within 48 h due to respiratory or hemodynamic deterioration. Risk factors and clinical characteristics were analyzed, with multivariate assessment of outcomes.
Results: Among the 80 patients (mean age 58.2 ± 17.3 years, 61.2% male), the extubation failure rate was 40% ($n = 32$). Diaphragmatic dysfunction was present in 21.3% ($n = 17$) of patients, and it was significantly more frequent in the failure group (70.6% vs. 38.1%, $p = 0.03$).DE showed excellent predictive performance for extubation failure, with an area under the curve (AUC) of 0.972, sensitivity of 92.1%, specificity of 88.2%, and an optimal cutoff value of < 10 mm. TF was also predictive (AUC = 0.808), but less accurate than DE.Patients who failed extubation had significantly higher rates of shock (75% vs. 43.8%, $p = 0.017$), organ failure (81.3% vs. 40.6%, $p = 0.0003$), and were more likely to have received aminoglycosides (65.6% vs. 25%, $p = 0.001$) or corticosteroids (59.4% vs. 35.9%, $p = 0.043$). Smoking was also strongly associated with extubation failure (68.8% vs. 18.8%, $p < 0.0001$).In-hospital mortality was significantly higher among patients who failed extubation (79.4% vs. 4.7%, $p < 0.001$), underlining the prognostic importance of successful weaning.
Conclusions: Diaphragmatic excursion, as assessed by ultrasound, is a robust and highly reproducible predictor of extubation outcomes. Compared to thickening fraction, it demonstrates superior diagnostic performance and bedside feasibility 6. Routine incorporation of DU into weaning protocols could enable early identification of high-risk patients, individualize extubation strategies, and ultimately improve outcomes [3-5]. These findings support further multicenter validation and integration of DU into standardized weaning algorithms in the ICU.

ROC Curves Comparing Diaphragmatic Excursion and Mean Thickening Fraction for Predicting Extubation Failure

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**)***:847***

Introduction: The presence of the alpha- band EEG (8-12 Hz) in the spectral density matrix (SDM) monitoring during general anesthesia has been associated with a lower incidence of postoperative delirium (DEL). During anesthesia or prolonged sedation, patients often experience variations in the SDM with periods of persistence or loss of the alpha- band. This phenomenon may have implications in DEL development.
Methods: Sub-analysisof the alpha-band patients of the ADELPHA study (Delirium/Alpha Band Association). ADELPHA is a prospective, observational, single-center study that analyzes frontal/temporal EEG data collected through unilateral/bilateral BIS® monitoring from mechanically ventilated patients throughout the entire period of deep sedation (RASS -4, -5) with GABAergic drugs (midazolam and/or propofol) The SDM of each patient, exported daily from the monitor in PDF format, was analyzed by two investigators and visually classified into two groups based on the absence or presence of frontal/temporal alpha- band activity. The latter group was further subclassified into two categories based on the daily evolution of the alpha band: persistence throughout the entire sedation period or loss over time. Other analyzed data included demographic information, sedative doses, opioids, alpha2-agonists, and antipsychotics. Upon withdrawal of sedation, the presence and duration of delirium were assessed.
Results: Fifty-eight patients were included in the ADELPHA study of which 39were classified into the group with alpha band presence, with 25 maintaining it throughout the sedation period analyzed, and 14 losing it. The incidence of DEL was 14 (56%) in the group with persistent alpha band activity vs. 11 (79%) in the group with alpha band loss, ($p = 0.159$). The median duration of DEL was 1 day in the first group vs. 7 days in the group with alpha band loss ($p = 0.013$). The group with persistent alpha band activity required lower doses of alpha2-agonists (dexmedetomidine 6.873 vs. 12.750 mcg, $p = 0.155$), antipsychotics (haloperidol 0 vs. 13 mg, $p = 0.086$), and opioids (morphine equivalent dose 2.160 vs. 9.597 mg, $p = 0.009$).
Conclusions: Patients who exhibit the alpha band and maintain it throughout the majority of the deep sedation period tend to show a non-significant trend towards a lower incidence of DEL, a significant

reduction in its duration, and a trend towards requiring lower doses of antipsychotics and alpha2-agonists, as well as a significant reduction in opioid doses

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**)***:849***

Introduction: Anemia, defined by the WHO as hemoglobin (Hb) levels < 13 g/dL in adult males and < 12 g/dL in adult females, is a highly prevalent comorbidity in heart failure (HF), affecting 4-35% of patients. Its severity correlates with poorer outcomes, including reduced survival, impaired quality of life, and increased hospital readmissions. The etiology is multifactorial (iron deficiency, hemodilution, inflammation, erythropoietin deficiency, medication effects, or bone marrow dysfunction). The optimal Hb target in HF remains undefined.
Objectives: To evaluate the prognostic impact of Hb levels in patients managed by prehospital emergency teams for acute decompensated HF
Methods: A 10-year retrospective study (2011-2021) was conducted in the EMS 03 region (Sousse, Monastir, Kairouan, Mahdia), including adults (> 18 years) with acute HF managed by mobile intensive care units. HF diagnosis was based on clinical, biochemical, and echocardiographic criteria
Results: Among 1,980 patients (mean age 69 ± 11 years; sex ratio 1:1):Comorbidities: Hypertension (63%), diabetes (51%), chronic HF (32%), atrial fibrillation (25%), CAD (24%).Baseline therapy: Diuretics (11%), beta-blockers (5%), nitrates (0.3%). Clinical severity: Killip class 3-4 dyspnea (56%), orthopnea (26.2%), NYHA ≥ 3 (16.4%). Persistent ST-elevation ACS (1.8%). Hb levels: Mean Hb 10.9 ± 1.7 g/dL; hematocrit 34 ± 7.6%. Outcomes:6-month mortality: 27.6% (Hb < 9 g/dL) vs. 20.7% (Hb ≥ 12 g/dL; p = 0.002). 12-month mortality: 32.6% (Hb < 9 g/dL) vs. 25.3% (Hb ≥ 12 g/dL; p < 0.001). No significant effect on readmissions or composite endpoints (mortality + readmission).
Conclusions: Hb levels independently predict mortality in acute HF. Our study confirms higher mortality with Hb < 12 g/dL.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**)***:850***

Introduction: Antibiotic resistance is a well recognised threat to public health as well as to ICU patients. In light of ongoing Russian aggression against Ukraine this problem is gaining actuality. Up to 35% of patients after combat injuries develop infection (Tribble et al., 2011). Previous reports from the war in Afghanistan and Iraq point to the prevalence of multidrug-resistant (MDR) isolates from wounds at 25% (Weintrob et al., 2010). However, Ukrainian data from 2014 to 2022 shows a significant increase of MDR up to 80% (Kovalchuk et al., 2016).
Objectives: To estimate actual resistance levels of wound isolates and evaluate its temporal dynamics.
Methods: We conducted a retrospective cohort single center study of patients admitted with combat injuries to Role 4 hospital during study period (Feb 2022—Mar 2024). Inclusion criteria among others were having combat-related injury, admission in < 30 days since date of trauma, wound culture result availability. Exclusion criteria were having injury not directly related to battlefield (e.g., traffic accidents), continuing hospital treatment on cut-off date (Mar 14th 2024), lack of demographic and/or other data. Analysis was performed using R and MS Excel software.
Results: Of 1593 treated military patients 448 patients were included and 1169 wound cultures were performed in the cohort with 1812 results/isolates obtained. The most common isolates were K.pneumoniae (23,23%, 95% CI 21,29%—25,18%), A. baumannii (21,80%, 95% CI 19,90%—23,70%) and P.aeruginosa (13,30%, 95% CI 11,74%—14,86%). The results of antibiotic resistance levels and their trends based on linear regression are summarized in the table below:

Table 1 (abstract 000850) Antibiotic resistance levels and temporal dynamics for most common wound isolates

Isolate	Resistance level	Prevalence of resistance levels, %	k	r2	p
K.pneumoniae	non-MDR	0,24%	0,05	0,06	0,56
	MDR	46,04%	– 2,1	0,08	0,49
	XDR	51,80%	2,21	0,08	0,49
	PDR	1,92%	– 0,16	0,03	0,68
A.baumannii	non-MDR	1,03%	0,31	0,19	0,24
	MDR*	64,60%	9,12	0,76	0,002
	XDR*	33,59%	– 9,42	0,77	0,002
	PDR	0,78%	– 0,01	0,001	0,92
P.aeruginosa	non-MDR*	6,36%	4,98	0,69	0,011
	MDR	30,51%	– 2,93	0,12	0,403
	XDR	58,47%	– 1,09	0,02	0,748
	PDR	4,66%	– 0,95	0,1	0,448

Non-MDR—nonmultidrug resistant, MDR—multidrug resistant, XDR—extensively drug resistant, PDR—pandrug resistant.

* Statistically significant trend

Conclusions: Over a 2-year study period there were no significant trends in *K. pneumoniae* resistance levels. *A. baumannii* exhibited a trend toward decrease in XDR isolates with increase in MDR cases. *P. aeruginosa* have a tendency to increase in more susceptible strains. Such high levels of antimicrobial resistance necessitates extensive surveillance and immediate intervention to tackle the spread of resistant gram-negative isolates.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**)***:852***

Introduction: As life expectancy increases, a growing number of patients aged ≥ 85 years are being admitted to intensive care units (ICUs). This age group presents unique challenges due to increased frailty, frequent comorbidities, and atypical presentations of acute illness. Understanding reasons for ICU admission and ICU outcomes in this population are key to optimize care strategies and guiding resource allocation.
Objectives: To characterize the reasons for ICU admission and outcomes amongst patients aged ≥ 85 years in a Portuguese polyvalent ICU.
Methods: We conducted a single-center retrospective observational cohort study of patients admitted to the level 3 and level 2 polyvalent ICUs in a Portuguese hospital in 2023 and 2024. Demographic and clinical data were extracted from the electronic medical record.
Results: Out of 1,760 patients admitted to level 2 and level 3 polyvalent intensive and intermediate care units (ICUs) in a Portuguese hospital between 2023 and 2024, 102 unique patients (5.8%) were aged ≥ 85 years. The mean age was 87.7 years (median: 87 years). The median ICU length of stay was 3 days (interquartile range [IQR]: 1-5 days), with a maximum stay of 22 days. The most frequent locations prior to ICU admission were the operating theatre (23.5%) and the emergency department (22.6%). Postoperative peritonitis (9.8%) and septic shock secondary to pyelonephritis (7.8%) were the leading admission diagnoses, followed by cardiac arrest (5.9%), gastrointestinal hemorrhage (4.9%), and pneumonia (2.9%).The median SAPS II score was 24 (IQR: 18-50), with a mean of 36.9 (range: 18-109). When analyzed by outcome, nonsurvivors ($n = 25$; 24.5%) had a significantly higher mean SAPS II score (54.9) as compared to survivors ($n = 77$; 75.5%), who had a mean score of 30.3 ($p = 0.0003$). At ICU discharge, 75.5% of patients had clinically improved, 24.5% had died. No patients were discharged with unchanged or worsened clinical status in this adjusted cohort.
Conclusions: A substantial proportion of very elderly ICU patients were admitted from high-acuity settings, particularly the operating theatre and emergency department, reflecting the predominance of acute surgical and emergent conditions in this age group. Postoperative peritonitis and urosepsis were key contributors to ICU admission. Despite advanced age, three-quarters of patients demonstrated clinical improvement at discharge, especially those with lower SAPS II scores. The significantly higher SAPS II scores among nonsurvivors emphasize its value in prognostication and triage. These findings support individualized decision-making and suggest that age alone should not preclude ICU admission in this population.

Initial subjective responses by study subjects enrolled in a pilot trial evaluating the effects of a diet high in fermented foods in patients with post-ICU syndrome

B. Harris[1], Z. Ahmed[1], L. Karnatovskaia[1]
[1]Division of pulmonary and critical care, Mayo Clinic, Rochester, United States of America
Correspondence: L. Karnatovskaia
Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**)***:855***

Introduction: Survivors of critical illness frequently develop post-intensive care syndrome (PICS). Critical illness and associated therapies disrupt the gut microbiome, leading to loss of gut microbiome diversity or dysbiosis, which may contribute to the development of PICS. High fermented food diet increased gut microbiome diversity in healthy adults. Whether using a similar approach may be feasible in patients with PICS has not been investigated.
Objectives: We report initial response to high fermented food diet intervention among patients with PICS.
Methods: We conducted a single center, prospective, 1:1 randomized trial evaluating incorporation of a high fermented food diet among critical illness survivors at a tertiary medical center. We included adults with at least one PICS-related impairment who were able to document food intake on a smart phone application and come in for in-person assessments. We excluded those with significant cognitive impairment, inability to tolerate oral foods, non-English speaking, or having an active contraindications to a diet high in fermented foods including immunosuppression. Intervention patients received introductory education on the gut microbiome and explanation of what probiotic fermented foods are. Patients were instructed to start with a serving daily, increase to 6 + servings a day over 4 weeks, and continue

6 + servings daily for additional 12 weeks. They were instructed to document all fermented food intake in the diet app. We contacted patients by phone weekly to review any symptoms or challenges with the diet. Responses were thematically categorized by the authors. The study was approved by the institutional review board and registered on clinicaltrials.gov (NCT06020703).
Results: Of the 52 patients enrolled, 25 were randomized to the intervention. 11 intervention and 4 control patients withdrew from the study due to challenges with stool sample collection, diet app use, or ability to find/afford probiotic fermented foods. Intervention patients reported positive gastrointestinal symptoms (less reflux, better bowel movements) in 10 of 15 (67%); better neurocognitive symptoms (higher energy levels and improved concentration) in 9 of 15 (60%); and improved psychiatric symptoms (better mood, less depressive symptoms) in 6 of 15 (40%). Negative themes included mild gastrointestinal symptoms upon starting the diet (bloating, constipation, early satiety) in 14 of 15 patients (93%) that subsequently resolved; difficulties with the diet (cost, flavor, and availability) in 3 of 15 (20%), and tracking fermented foods in the application in 3 of 15 (20%).
Conclusions: Patients with PICS appear to tolerate high fermented food diet overall, with majority reporting improved gastrointestinal and neurocognitive symptoms during the study. Socioeconomic factors appear to represent a major challenge to using this approach.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***856***

Introduction: Carbon monoxide (CO) poisoning is a life-threatening emergency with underrecognized cardiovascular complications. This case series investigates the association between CO intoxication and toxic myocarditis, analyzing clinical, biological, and outcome data.
Objectives: Characterize the clinical spectrum of toxic myocarditis in patients with acute carbon monoxide (CO) poisoning, focusing on electrocardiographic (ECG) abnormalities, troponin elevation, and echocardiographic findings.
Methods: Retrospective study of 13 patients admitted for CO poisoning (confirmed by elevated carboxyhemoglobin) with suspected myocarditis (troponin elevation + ECG abnormalities). Data included demographics, hemodynamics, ECG findings, troponin levels, management (normobaric/hyperbaric oxygen therapy), and outcomes.
Results: 1. Demographic and Clinical CharacteristicsThe study included 13 patients (median age: 50 years, range: 15-80) with 77% male predominance. The majority presented with neurological symptoms (headache, altered consciousness), while 46% (6/13) reported chest pain, suggesting cardiac involvement. Notably, one elderly patient (80 years) exhibited severe hemodynamic instability (HR 150 bpm, troponin 1915 ng/L), whereas a 15-year-old female had milder elevation (troponin 450 ng/L) without chest pain. 2. Respiratory and Hemodynamic Status. Respiratory failure requiring ventilatory support occurred in 31% (4/13), including one patient with SpO_2 83% on admission (improving to 99% with 15L O_2).Hypotension (SBP < 100 mmHg) was observed in 23% (3/13), all of whom required vasopressor support. 3. Cardiac Abnormalities. Electrocardiographic (ECG) Findings:100% (13/13) showed abnormalities:ST-segment elevation in lead aVR (23%, 3/13), a marker of global ischemia.Diffuse ST depression (54%, 7/13), often associated with troponin elevation.T-wave inversions (15%, 2/13) in anterolateral leads.Troponin Elevation:Median peak troponin: 840 ng/L (range: 94-25,000).The highest troponin (25,000 ng/L) occurred in a 19-year-old male with ECG showing aVR ST-elevation and diffuse depression, suggesting severe myocardial injury.4. Management and Outcomes. All patients received high-flow oxygen (normobaric or hyperbaric). 85% (11/13) were referred for hyperbaric oxygen therapy (HBO); two cases were deferred due to instability. No fatalities occurred; all patients achieved hemodynamic and neurological stabilization within 72 h
Conclusions: Toxic myocarditis is a severe complication of CO poisoning, warranting systematic screening (ECG, troponin) and prompt management. HBO remains a therapeutic cornerstone, but patient selection requires individualized assessment.

Introduction: Epigenetic clocks use DNA methylation markers to measure biological or "epigenetic" age. Some are designed to predict chronological age while others are designed to predict clinically significant outcomes, such as health status or long-term mortality. Studies have demonstrated associations between epigenetic age and ICU survivorship, disease-specific outcomes, and unplanned readmissions (Sharma-Oates et al. 2024; Binnie et. al 2020). We evaluated ten epigenetic clocks and their predictive value for ICU mortality and ICU-free-days.
Methods: We analyzed whole blood samples from 144 critically ill patients admitted to 4 Canadian ICUs participating in the DYNAMICS trial (NCT01355042). The population was oversampled for non-survivors. Using the *dnaMethyAge* R-package (Wang et al. 2023), we calculated epigenetic age on the day of ICU admission using 10 different epigenetic clocks. In addition, for each clock we calculated epigenetic "age acceleration", meaning the difference between an individual's epigenetic and chronological ages. Our primary outcome was ICU mortality; our secondary outcome was days alive and out of the ICU at day 28 (ICU-free days).
Results: Epigenetic age demonstrated stronger associations with mortality than chronological age and APACHE-II score. PhenoAge showed the strongest correlation between epigenetic age and mortality with PhenoAge acceleration demonstrating an even stronger association (see Table 1). Nine clocks predicted increased epigenetic ages for non-survivors relative to survivors, with PhenoAge demonstrating the largest effect (mean difference = 11.5 years, Cohen's d = 0.77), as shown in Fig. 1. Cross-validated logistic regression performance is shown in Fig. 2, with PhenoAge showing an area-under-curve of 0.72, with good

PPV (0.73), NPV (0.71), and specificity (0.90). For ICU-free-days, eight clocks outperformed chronological age and APACHE-II score, with PhenoAge acceleration (r = -0.38, p < 0.001, CI = [-0.54, -0.22]) and Mortality Risk (Zhang 2017) acceleration (r = -0.31, p < 0.001, CI = [-0.48, -0.15]) showing the strongest associations.

Table 1 (abstract 000857) Spearman Correlation between Epigenetic Age, Age Acceleration, and Mortality

	Epigenetic Age			Epigenetic Age Acceleration		
Clock	Correlation	p	95% CI	Correlation	p	95% CI
PhenoAge	0.308	<0.001	0.15,0.45	0.384	<0.001	0.23,0.52
Multitissue Estimator	0.222	0.010	0.05,0.38	0.273	0.001	0.11,0.42
DNAmTL	-0.286	0.001	-0.43,-0.12	-0.270	0.002	-0.4,-0.11
Mortality Risk	0.274	0.001	0.11,0.42	0.246	0.004	0.08,0.40
Hannum 2013	0.207	0.017	0.04,0.36	0.238	0.006	0.07,0.39
Skin & Blood Clock	0.223	0.010	0.06,0.38	0.216	0.012	0.05,0.37
DunedinPACE	0.229	0.008	0.06,0.38	0.210	0.015	0.04,0.37
Zhang 2019	0.204	0.018	0.04,0.36	0.181	0.036	0.010.34
PC GrimAge	NA	NA	NA	0.151	0.082	-0.02,0.31
APACHE II	0.131	0.132	-0.0,0.30	NA	NA	NA
Chronological Age	0.131	0.133	-0.04,0.29	NA	NA	NA
epiTOC2	-0.032	0.716	-0.20,0.14	-0.059	0.501	-0.23,0.11

Conclusions: Epigenetic clocks, particularly PhenoAge, consistently outperformed chronological age and APACHE-II score in predicting mortality and length of stay amongst critically-ill patients admitted to ICU.

Intensive Care Medicine Experimental* 2025 13(Suppl 1):*859

Introduction: The ICU is an environment where large volumes of clinical data, essential for clinical care management and research, are generated. Traditionally, these data are collected manually, despite being entered and stored in electronic health records (EHR). The growth of data science has driven automatic methods of information collection. This study compares automatic and manual extraction, focusing on data accuracy and quality.
Objectives: Three main objectives: (1) to evaluate the concordance between historical records entered through a traditional method (manual paper recording followed by transcription into a database) and a new database obtained through automated data mining; (2) to create the necessary tools for extracting information; and (3) to conduct a statistical analysis of discrepancies and patterns in the clinical data, with the goal of identifying significant relationships between variables and gaining a deeper understanding of the differences between both methods.
Methods: Information was extracted from certain items recorded in the EHR of a general registry of patients admitted to the ICU of a Spanish hospital. The selected items refer to specific techniques used in the ICU, such as MV, tracheostomy, urinary catheter, PN, CVC, use of norepinephrine, use of continuous NMB, CRRT, arterial catheter, and a general item, sex. These variables are recorded in 100% of patients in the old database and are automatically recorded in the EHR, assuming lack of errors in their registration.
Results: As shown in Table 1, the concordance percentages vary between 86.9% and 97.6%, with kappa indices between 0.5 and 97.1%. It is particularly noteworthy to have found gender differences in 1.4% of the patients Kappa 97.1% but not zero, as expected.

Table 1. Concordance results

	Count	% of Concordance	95.0% lower CL	95.0% upper CL	Standard Error	Kappa Index (%)
VM	4258	88,8	87,9	89,7	0,5	67,9
VMNI	4448	92,8	92,0	93,5	0,4	70,2
Confirm I	4278	89,3	88,4	90,1	0,4	1,6
Preventive I	4165	86,9	85,9	87,8	0,5	0,5
Tracheostomy	4454	92,9	92,2	93,6	0,4	34,2
Urinary C	4342	90,6	89,7	91,4	0,4	78,9
Parenteral	4608	96,1	95,6	96,7	0,3	71,6
CVC	4393	91,7	90,8	92,4	0,4	83,3
Peripheral CVC	4678	97,6	97,1	98,0	0,2	3
Noradrenaline	4321	90,2	89,3	91,0	0,4	80
NMB	4793	98,5	98,1	98,8	0,2	75,4
CRRT	4566	95,3	94,6	95,8	0,3	23
Sex	4727	98,6	98,3	98,9	0,2	97,1
AC	4374	91,3	90,4	92,0	0,4	82,5

CRRT: Continuous Renal Replacement Techniques; AC: Arterial Catheter; NMB: Neuromuscular Block; I: Isolation; CVC: central venous catheter.

Conclusions: The results obtained demonstrate that it is possible to extract information that previously consumed significant time from professionals. It shows that manual recording is prone to human error, even generating discrepancies in patient gender. Moreover, it is evident that information positively included in the EHR can be collected reliably. There is also a percentage of cases where information collected in the old database is not present in the EHR, which may correspond to documentation errors. This study has served to enrich the use of our EHR program, coding certain procedures more precisely and enhancing storage of information not previously present. This serves as a starting point to continue improving our information management with real possibilities for clinical management, and research advancement.

***Intensive Care Medicine Experimental* 2025 13(Suppl 1):860**

Introduction: ICUs form a major healthcare expense [1], potentially leading to differences in ICU profiles based on national income and health expenditure.

Objectives: This study aimed to provide an overview of ICU profiles according to the World Bank Classification.
Methods: A scoping review was conducted following a PRISMA-based approach (Fig. 1). In addition, a secondary analysis of the 2018 DecubICUs study (NCT03270345) [2] was performed to assess patient demographics (i.e. age, sex, ICU mortality rate, and ICU length of stay). The search (2010-2019) combined terms related to intensive care and geographic regions. Outcomes considered were nationwide bed capacity, level of care, median number of beds, ICU bed-to-hospital bed ratio, bed occupancy, staffing, organizational format, and visitation policy. Countries were classified according to the World Bank Classification based on the reports' year of data collection: High-Income Countries (HIC), Upper-Middle-Income Countries (UMIC), Lower-Middle-Income Countries (LMIC), or Low-Income Countries (LIC).
Results: A total of 7,287 records were screened, with 120 reports included, covering 81 countries (43 HIC, 18 UMIC, 13 LMIC, and 7 LIC). Search results are depicted in Fig. 1. The DecubICUs data included 90 countries (44 HIC, 25 UMIC, 19 LMIC, and 2 LIC). The number of ICU beds per 100,000 inhabitants varied from 0.1 to 1.1 in LIC, 0.3-15.0 in LMIC, 3.2-25.0 in UMIC, and 2.7-29.8 in HIC. The number of beds per ICU varied from 4.0 to 9.0 in LIC, 5.0-16.0 in LMIC, 7.0-18.0 in UMIC, and 6.0-22.0 in HIC. The proportion of 'closed' ICUs ranged from 20.0 to 42.0% in LIC, 25.8%-39.2% in LMIC, 14.8%-87.0% in UMIC, and 9.5-89.0% in HIC. Median patient age in years (interquartile range, IQR) increased with income: 40.3 (5.5) in LIC, 53.0 (11.0) in LMIC, 64.0 (6.3) in UMIC, and 64.0 (6.0) in HIC. The median ICU mortality percentage (IQR) decreased with income: 32.5 (35.0) in LIC, 28.3 (21.3) in LMIC, 23.1 (19.7) in UMIC, and 12.7 (9.0) in HIC. Other considered aspects of ICU profiles showed substantial variability without a clear pattern or were lacking.
Conclusions: The bed capacity was substantially higher in countries with higher income (Fig. 2). Gaps in ICU profiles were further illustrated by differences in the levels of care, number of beds and the percentage of 'closed' units (Fig. 3). Despite older patients in countries with a higher income, mortality rates were lower. Heterogeneous reporting methods and definitions, and the scarcity of data from lower-income regions made a systematic international comparison impossible. This stresses the necessity of standardized databases to record ICU profiles and their changes in time, particularly in lower-income countries.

Frailty assessed by patients ≥ 80 years and their next of kin

LT. Sandøy[1], IN. Knudsen[1], GE. Eide[2], K. Harris[2], GL. Schwarz[1]
[1]Department of Anaesthesia and Intensive Care, Haukeland University Hospital, Bergen, Norway; [2]Department of Health and Caring Sciences, University of Applied Sciences, Bergen, Norway

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***861***

Introduction: In 2050, the number of people aged 80 years and older (≥ 80 yrs) will more than double worldwide, placing immense pressure on healthcare systems (1). Research shows that frailty is a stronger predictor of vulnerability and rehabilitation potential than age itself, particularly for patients ≥ 80 yrs who are admitted to an intensive

care unit (ICU) (2). In intensive care research and practice, the Clinical Frailty Scale (CFS) has gained increasing popularity. It is recommended to rate frailty on the CFS based on the patients' stauts 14 days prior to acute illness (3). The frailty assessment of critically ill older adults is often restricted to statements of their next of kin acting as the older patient's proxy. These lay CFS assessments are shown to correspond well to those made by health care professionals (4, 5). In contrast, the correlation between proxy's CFS assessment and the older patients self-evaluation has not been explored yet.

Objectives: To examine the agreement between self-assessment and proxy assessment of frailty on the CFS among potential ICU candidates ≥ 80 yrs.

Methods: This study is part of a survey investigating the thoughts and preferences of a purposive sample of older Norwegian adults and their next of kin regarding intensive care treatment in hypothetical scenarios of acute critical illness (6). Only outpatients ≥ 80 yrs, regarded potential ICU candidates in the Norwegian health care context, were approached. The survey participants identified their next of kin who would likely act as proxy in an event of critical illness. These outpatient–proxy pairs independently assessed the older adult's fitness/frailty using a validated Norwegian translation of the Clinical Frailty Scale (CFS) (3). We analyzed the agreement using quadratic weighted kappa and intraclass correlation coefficients (ICC).

Results: This substudy included 140 pairs. The participants ≥ 80 yrs had a mean age of 85.5 (3.95 SD) yrs, and the genders were equally represented (50% female). Among the proxy respondents, the mean age was 68.8 (13.2 SD) and the proportion of females was 75%. The study participants ≥ 80 yrs rated themselves as slightly fitter on the CFS than their proxies (mean 2.93 vs. 3.06). Overall, the agreement between the frailty ratings of the participants ≥ 80 yrs and their proxies was good, with a Quadratic Weighted Kappa of 0.75 (95% CI: 0.58 to 0.92) and an ICC of 0.86 (95% CI: 0.8 to 0.9). Patients' CFS scores and proxies corresponded in 68 cases (52%). In another 46 cases (35%), the difference was ± 1. Only 17 pairs (13%) disagreed on the older participant's frailty by ≥ 2 points on the CFS, see Fig. 1. In 9 of the pairs data were missing from either proxy or the patient ≥ 80 yrs.

Conclusions: The agreement between CFS self-assessment and proxy assessment was good among potential Norwegian ICU candidates ≥ 80 yrs with low to intermediate frailty. Older adults living independently could effectively score their own CFS. Therefore, the CFS self-assessment of older adults may be used to inform communication about treatment goals in cases of acute critical illness and in advance care planning. Further studies on CFS self-assessment among the adults ≥ 80 yrs living with higher degrees of frailty are needed.

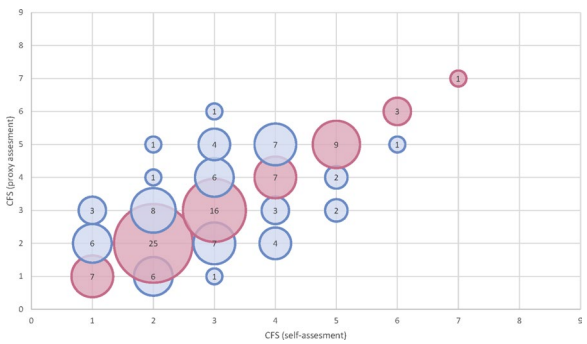

Fig. 1 (abstract 000861) Older (≥ 80 yrs) adults' frailty as rated by themselves and their next of kin on the Clinical Frailty Scale (CFS). Red circles indicate perfect agreement. The area of the circles corresponds to the number of entries

Intensive Care Medicine Experimental 2025 **13(Suppl 1)*:862***

Introduction: Anabolic agents such as nandrolone have been proposed aspotential adjuncts in the management of chronic critically ill patients to mitigate catabolicstates, promote faster recovery times and improve long-term outcomes.

Objectives: To outline baseline characteristics, clinical parameters and outcomes of chronic critically ill patients treated with nandrolone during their ICU stays in a polyvalent intensive care unit (ICU) in Portugal.

Methods: We conducted a single-centre, retrospective cohort study of 26 chronic critically ill ICU patients who received nandrolone during their ICU stay at the discretion of the medical team. Data collected included demographics, admission diagnosis, ICU length of stay, clinical severity scores, duration of ventilatory support, antibiotic therapy and outcomes. The results were compared with a cohort of 84 chronic critically ill patients from the same ICU who did not receive nandrolone.

Results: Amongst 26 patients who received nandrolone, the average age was 63.0 (± 13.3) years and the percentage female was 34.6%. The majority had an admission diagnosis of sepsis (65.4%) (Fig. 1) and the average APACHE II score on admission 20.6 (± 11.7). The average duration of mechanical ventilation was 26.7 (± 13.3) days and the average length of ICU stay was 29.5 (± 11.7) days. Mortality was 19.2% at ICU discharge and 23.1% at 6 months. When compared with chronic critically ill patients from the same ICU who did not receive nandrolone, the nandrolone group had a higher prevalence of sepsis (65.38% vs. 25%, $p < 0.001$), longer ICU admissions (26.5 vs. 20.0 days, $p = 0.016$), and more days of mechanical ventilation (26.4 vs. 21.0 days, $p = 0.028$). At ICU discharge, 19.2% of patients who received Nandrolone and 26.2% of those who did not were deceased, which was not statistically significantly ($p = 0.471$). At 6 months, a nonsignificant trend toward better survival was noted in the nandrolone group (76.9% vs 58.3%, $p = 0.087$).

Conclusions: Nandrolone use in critically ill patients is associated with highseverity of illness, prolonged ventilatory support and prolonged ICU stays. Inspite of these poor prognostic signs, mortality at 6 months was not increasedrelative to other chronic critically ill patients. Further randomized controlledstudies are warranted to define the therapeutic role of nandrolone in chronicalcritical illness care, identify appropriate patient populations, and clarify optimaldosing and timing of administration.

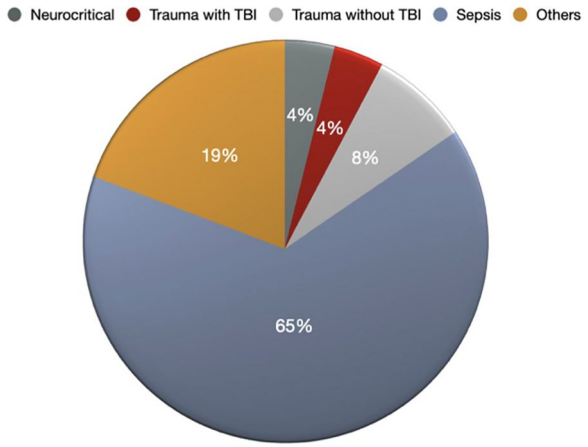

Fig. 1 (abstract 000862) Admission diagnosis category of nandrolone patients (%)

Introduction: Noninvasive ventilation (NIV) has become a cornerstone in the treatment of acute respiratory failure (ARF). However, it often poses a barrier to adequate nutritional intake (1). As a result, patients receiving NIV are at increased risk of malnutrition, yet data and recommendations regarding nutritional adequacy and management in this population remain limited.
Objectives: The primary objective was to quantify calorie and protein intake and adequacy—defined as intake relative to target—in patients undergoing NIV across different levels of care.
Methods: This preliminary analysis from a prospective observational study was conducted in adult patients who started NIV within 24 h of admission for ARF and received oral nutrition in the intensive care unit (ICU), intermediate care units, and cardiology/internal medicine wards of a tertiary university hospital in Italy between December 23, 2024, and February 2, 2025. Caloric and protein intake were assessed by a hospital dietitian using a daily food diary collected for five days from NIV initiation. Daily nutritional targets were calculated according to ESPEN guidelines (2,3): 25 kcal/kg and 1.3 g/kg of protein, following a stepwise approach—25% of the target on day 1, 50% on day 2, and 70% from day 3 to day 5.
Results: This preliminary analysis included 24 patients, 2 in the ICU, 10 in intermediate care units, 12 in ordinary wards. Eighteen (75%) were males, with a median age of 76 years [IQR 69-84], admitted mainly for pulmonary edema (29%), pneumonia (21%), obstructive disease exacerbation (25%), or multiple diagnoses (13%). The median Nutritional Risk Screening (NRS) 2002 score was 2 [IQR 1-3], and the median calf circumference was 34 cm [IQR 32-37.5]. NIV was initiated in pressure support mode in 13 patients (54%), with a median NIV duration of 20 h [IQR 12-23] on day 1. Thirteen patients remained on NIV by day 4. On day 1, six patients were fasting, primarily due to NIV dependency. Caloric intake increased from a median of 5.6 kcal/kg [IQR 0.3-10.0] on day 1 to 14.3 kcal/kg [IQR 9.5-21.2] on day 5, with a maximum median daily intake of 1050.0 kcal [IQR 575.0-1287.5]. Caloric adequacy was highest on day 2 (median 97% [IQR 69-133]) and reached 82% [IQR 54-121] on day 5. Median protein intake ranged from 0.2 g/kg [IQR 0.0-0.4] on day 1 to a maximum of 0.6 g/kg [IQR 0.4-0.8] on day 4, corresponding to a total daily consumption of 42.0 g [IQR 28.3-55.0]. Median protein adequacy over the five-day period was 67% [IQR 23-107]. Most of the meals (210/280, 75%) were ordered by health care assistances. Caloric intake was higher in the intermediate care and wards compared to ICU patients, though differences were not statistically significant.

Conclusions: Nutritional intake among patients on NIV was inadequate, particularly regarding protein consumption, despite the early initiation of oral feeding. Additional data are required to define optimal nutritional strategies for this population.

Introduction: High flow nasal oxygen therapy (HFNC) is an important method for the treatment of mild to moderate hypoxic respiratory failure, which can significantly reduce the 28-day all-cause mortality of critically ill patients. However, the rate of HFNC treatment failure and mortality from failure remain high, mainly due to the difficulty in identifying early HFNC treatment failure, which delays the time of mechanical ventilation. VOX index can be used as one of the evaluation tools for the efficacy of HFNC, and the change of tidal volume is more sensitive to respiratory rate, which can well reflect the early increase of respiratory drive, timely identify the early risk to upgrade respiratory support, and improve patient prognosis or treatment outcome. Therefore, the aim of this study is to find the factors that predict the failure of nasal high-flow humidified oxygen therapy equipment (HFNC) through a new VOX30 index, so as to achieve patient safety oxygen therapy in time.
Methods: 1. The differential pressure flow sensor was designed based on the preliminary work of the project, and Vox30 Index was automatically calculated and generated according to the captured tidal volume data to realize the dynamic and real-time evaluation of the safety of HFNC oxygen therapy process. 2. After the equipment is calibrated, the capacity is compared with the standard ATS respiratory waveform. 3. Patients with respiratory failure using HFNC who are willing to participate in this study will be recruited for preliminary clinical testing, and the correlation and consistency analysis will be conducted between the treatment results of HFNC (i.e., intubation or respiratory treatment degradation and discharge) and the Vox30 index obtained by the device for accurate verification in the next step.
Results: 1. In terms of capacity detection, after using the standard 3L calibration barrel for 10 times of fast and slow testing, the error between the measured value and the standard value was controlled within ± 8%, which was within the acceptable error range. 2. The respiratory simulator is used to simulate the standard ATS waveform for testing, and the results show that the detection value of the device is highly consistent with the standard waveform value, and the sensitivity is high. 3. In terms of clinical consistency, we conducted clinical tests on 22 subjects, and the final results showed that the prognosis of the subjects was consistent with the detection data and changing trend of the device, with a strong correlation. The conformance boundary map shows that most of the test data falls within the conformance boundary.
Conclusions: This device has high precision and consistency, accurate numerical collection and calculation, and high consistency with clinical prognosis. The VOX30 index obtained by its monitoring can be used as a factor to predict the success of HFNC oxygen therapy in patients with respiratory failure, and this device can be used for clinical popularization.

The device of vox30 index

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***865***

Introduction: Ventilator-associated pneumonia (VAP) remains one of the most prevalent and preventable healthcare-associated infections in intensive care units (ICUs), contributing significantly to morbidity, mortality, and hospital costs. Promoting a culture of safety and prevention is critical, and training intensive care residents in the use of management tools is a strategic approach to address these challenges. This project integrated educational strategies with quality improvement tools to reduce VAP incidence through the structured involvement of residents and the multidisciplinary team.

Objectives: The primary objective was to reduce the incidence of VAP in the ICUs of a tertiary hospital in São Paulo, Brazil. Secondary objectives included implementing an electronic prevention bundle, promoting continuous education, fostering a culture of prevention, analyzing the microbiological profile of pathogens, and applying the PDCA (Plan, Do, Check, Act) cycle to assess and refine interventions.
Methods: This prospective, interventional study was conducted from June 2024 Mars 2025 in the ICUs of a terciary hospital ins a Middle income country. All patients on mechanical ventilation for over 48 h were included. Root cause analysis identified factors contributing to increased VAP incidence. Subsequently, a PDCA cycle was implemented. A digital bundle incorporating key VAP risk factors was developed and integrated into the electronic medical record. Periodic training sessions were conducted with the care team, focusing on VAP prevention and bundle adherence. Resident physicians were actively involved in leading the implementation and audit processes.
Results: Before the intervention, VAP incidence ranged from 7.41 to 13.2 cases per 1000 ventilator days. Following implementation, the rate decreased to 0-9.54 cases per 1000 ventilator days, reflecting a 38.46% reduction—exceeding the initial 15% target. The ventilator utilization rate remained unchanged. Of the 9000 bundle forms expected, 3447 (38%) were completed, indicating moderate adherence. Bundle use also highlighted the need for additional protocols, such as sedation management for early weaning and delirium prevention.
Conclusions: The project demonstrated that training intensive care residents in quality improvement methodologies and management tools—specifically the PDCA cycle—can significantly impact clinical outcomes such as VAP incidence. The initiative emphasized the importance of education, continuous auditing, and team engagement. Despite partial adherence to the bundle, the substantial reduction in VAP highlights the potential of integrating structured management tools into resident education for sustainable improvements in ICU safety culture and infection prevention.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***866***

Introduction: The Resistance Zero (RZ) program is being implemented in Intensive Care Units (ICU) in Spain with the aim of reducing the selection and/or dissemination of multidrug-resistant bacteria (MDR-B).
Objectives: To evaluate the current situation and evolution over time of risk factors (RF) and MDR-B colonization in patients admitted to our ICU.
Methods: Observational, descriptive, retrospective study of RF and colonization of patients admitted to our ICU in 3 study periods: period 1 (P1) 1/5/2018-28/2/2020, period 2 (P2) 1/11/2021-31/3/2023 and period 3 (P3) year 2024. All patients admitted to the ICU are evaluated for: RF of being MDR-B carriers, according to the RZ program. In case of presenting any RF, oropharyngeal (OP) and rectal exudates are taken for screening for MDR-B. It is a 12-bed multipurpose ICU.
Results: In P1, 912 patients were admitted to our ICU, 701 in P2 and 548 in P3, of whom 147 (16.12%), 146 (20.8%) and 116 (21.7%) had RF, respectively. The most frequent RF in all periods was previous hospitalization [108 (73.47%), 111 (76.02%) and 81 (69.83%)] in P1, P2 and P3 respectively, followed by previous antibiotherapy [91 (61.9%), 65 (44.52%) and 67 (57.76%)]. They were institutionalized 12 (8.16%), 9 (6.16%) and 16 (13.79%), and had had previous MDR-B colonization 13 (8.84%), 14 (9.6%) and 14 (12.07%) in P1, P2 and P3 respectively. MDR-B colonized patients were 30/114 (26.32%) in P1, 32/108 (29.62%) in P2 and 24/110 (21.8%) in P3. Rectal colonization (RC) was 25/114 (21.93%), 27/108 (25%) and 19/110 (17.27%), and OP colonization 8/114 (7%), 12/108 (11.11%) and 12/110 (10.9%), respectively. As for RC, 17/25 (68%) in P1, 26/27 (96.3%) in P2 and 12/19 (63.16%) in P3 were colonized by Gram-negative bacillus (GNB), of which 12/17 (70.6%), 13/26 (50%) and 7/12 (58.33%), respectively had extended-spectrum beta-lactamase (ESBL). In P2 there are 7/26 (26.9%) carriers of KPC and 2/26 (7.7%) of metallobetalactamases (MBL), with 1 case of each in P1 and none in P3. They were colonized by more than one MDR-B 3/17 (17.6%) in P1, 5/26 (19.23%) in P2 and 2/12 (16.66%) in P3. Gram-positive (GP) isolates in RC were methicillin-resistant staphylococcus aureus (MRSA) in 4/8 (50%) in P1, 3/3 (100%) in P2 and 5/9 (55.55%) in P3, and vancomycin-resistant enterococcus faecium (VRE) 4/8 (50%) in P1 and 4/9 (44.4%) in P3. Regarding OP colonization, MDR-B were GP 5/8 (62.5%) in P1, 3/12 (25%) in P2 and 5/12 (41.66%) in P3, being all MRSA. They carried GNB 3/8 (37.5%), 10/12 (83.33%) and 8/12 (66.66%), respectively.
Conclusions: In P3, 21.7% of the patients admitted to our ICU had RF, of which 21.8% were colonized by MDR-B, predominantly RC by GNB, with more than half being ESBL. Over time, there was a progressive increase in RF, the most frequent in all periods being previous hospitalization, followed by previous antibiotherapy, with an increase in previous colonization by MDR-B to 12.07% in P3. As for patients colonized by MDR-B, there was an increase in P2 with a decrease in P3 to lower levels than in the two previous periods. Carbapenemase-producing GNB such as KPC and MBL appeared in P2, which did not appear in P3. The GP isolated in RC were MRSA and VRE. OP colonization remained stable in P3 (10.9%), with a predominance of GP in P1 and P3, all of them MRSA.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***867***

Introduction: Emergent endotracheal intubation is commonly performed in the emergency department (ED) for critically ill patients. Post-intubation care involves complex care processes, and complications frequently occur especially in these patients with reduced physiological reserves. Few studies have demonstrated the positive effects of post-intubation interventions such as lower mortality. We implemented a bundle checklist comprising of 10 post-intubation interventions in November 2022 to improve the quality of care in the post-intubation period in the ED.

Objectives: 1. To assess the effect of a post-intubation bundle checklist on the identification and correction of malpositioned endotracheal tubes (ETT) and gastric tubes (GT)
2. To evaluate the association between post-intubation care bundle checklist and intensive care unit (ICU) length of stay (LOS) and mortality
Methods: We conducted a retrospective observational study of all patients intubated in the ED of an acute district hospital with an annual attendance of 100,000. We included all patients aged 21 and older who were admitted to the ICU. Patients who died in the ED or were transferred to another facility during their stay were excluded. Data were collected during the 12-month period before and after implementation.
Results: A total of 394 patients met the inclusion criteria and 26 were excluded. There were 151 patients before and 243 after the implementation. The mean age of the groups before and after were 61.2 ± 15.4 (75.5% males) and 60.1 ± 16.2 years (66.3% males), while the mean Sequential Organ Failure Assessment (SOFA) scores were 8.2 ± 3.4 and 8.9 ± 4.0, respectively. Overall compliance with completing ≥ 8 interventions was 53% (n = 129/243). The proportion of malpositioned ETT and GT that were identified and corrected improved in the post-implementation period [12/29 (41.4%) vs 29/40 (72.5%)]. Clinical outcomes were adjusted for age, sex and SOFA scores. Patients in the post-implementation period had lower odds of ICU mortality than those in the pre-implementation period [adjusted odds ratio (OR) 0.686, 95% CI 0.325, 1.449, p = 0.324]. Quantile regression analysis showed that post-implementation was associated with reduced median ICU LOS of survivors by 13.2 days (95% CI 9.8, 16.6, p < 0.001). Those who received ≥ 8 interventions in the post-implementation cohort had lower odds of ICU mortality than those with < 8 (adjusted OR 0.856, 95% CI 0.491, 1.495; p = 0.585). This was also associated with a 1.8 day reduction in median ICU LOS (95% CI 0.4, 3.3; p = 0.012).
Conclusions: The implementation of a bundle checklist resulted in moderate improvement in compliance with post-intubation care practices. It demonstrates a potential correlation with increased recognition and correction of tube malposition, as well as a reduction in ICU mortality and a shorter ICU LOS. The study also suggests that greater adherence to the complete bundle may result in more substantial benefits.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***869***

Introduction: Maintaining fluid homeostasis is an integral part of caring for critically ill patients. When a critically ill patient has excess fluid in their body, it is associated with organ failure, higher morbidity and mortality. There are multiple shortcomings to the conventional techniques for monitoring changes in fluid status. Subcutaneous edema formation may result from positive cumulative fluid balance, which can be measured objectively with ultrasonography (USG).
Objectives: Ultrasonographic quantification of subcutaneous edema in ICU patients at day-1,3, and 7 of their ICU stay, assessemet of its prognostic utility in predicting 28-day mortality, and correlation with cumulative fluid balance (CFB).
Methods: This study was conducted in AIIMS New Delhi from November 2023 to March 2025. Patients admitted in ICU within 72 h of hospitalization were included in this study after meeting the predefined inclusion-exclusion criteria. Ultrasonography was performed at 12 defined regions, and ultrasonographic subcutaneous edema (USE) scored between 0 and 4 as per the FLUID protocol1. The total CFB, USE score at day-1, 3, 7, along with the change in the USE scores at day3 (day3-day1), and day7 (day7-day1) were calculated. Data analysed using SPSS software version 29.0.
Results: 100 patients (30 surgical, 35 medical, 35 polytrauma) were included in this study. The median age was 30 years (IQR: 23-50), 28-days mortality was 40%. The median CFB at day1,3 and 7 were + 1250 ml (Range: -800 ml to + 4750 ml), + 1800 ml (-1350 ml to + 3750 ml), and + 2800 ml (+ 80 ml to + 4595 ml), respectively.
The total USE score and CFB at day1 did not correlate with each other and the 28-day mortality. The change in USE score at day3 and 7 weakly correlated with CFB at day3 (r = 0.28, p = 0.03) and CFB at day7 (r = 0.34, p = 0.038), respectively. The 28-day mortality exhibited moderate correlation with the change in USE score at day3 (r = 0.58, p = 0.005), but weak correlation with CFB at day3 (r = 0.32, p = 0.03). Likewise, 28-day mortality had a strong correlation with change in USE score at day7 (r = 0.72, p = 0.001), but moderate correlation with CFB at day7 (r = 0.58, p = 0.001). A decreasing trend in the USE score by day3 and day7 showed very high correlation with 28 days ICU mortality (r = 0.84, p = 0.0001). Receiver-operator curve which was plotted for the same showed an area under the curve of 0.90 (CI:0.88-0.92, p = 0.0001). A decrease in USE score by 6 or more showed sensitivity of 100% and specificity of 80% respectively.
Conclusions: The ultrasonographic subcutaneous edema score performed better in predicting the 28-day mortality in ICU patients and had a limited correlation with cumulative fluid balance. One novel and more precise method for determining the cumulative fluid status of ICU patients is subcutaneous ultrasonography.

Iluustration of subcutanious edema assesment regions with USE score.

Introduction: Carotid Doppler ultrasound Flow (CADFlow) may be a promising tool for non-invasive hemodynamic monitoring. Carotid corrected flow time (ccFT) measured by CADFlow has been used as an accurate surrogate measure of stroke volume (SV) in critically ill patients.
Objectives: We aimed to use ccFT to predict the short-term clinical efficacy in patients after cardiac surgery.
Methods: This is a single-central, prospective, observational pilot study. Logistic analysis was used to determine whether ccFT could predict the duration of mechanical ventilation (MV) and length of intensive care unit (ICU) stay in patients after cardiac surgery. The predictive value of ccFT was determined using area under receiver operating characteristic (AUROC) curve.
Results: In total 43 patients were included, the multivariate logistic regression analysis revealed that ccFT is an independent risk factor for the length of ICU stay [OR = − 0.502 (95% confidence interval (CI) − 1.73-− 0.524), $P = 0.001$] and duration of MV [OR = − 0.334 (95% CI (− 0.829 to − 0.048), $P = 0.029$]. The AUROC for ccFT to predict the length of ICU stay and duration of MV ≥ 24 h was 0.844 [95% CI (0.726-0.961), $P < 0.001$] and 0.796 [95% CI (0.651-0.942), $P = 0.002$], the optimal cut-off value was 314.5 ms and 309 ms, separately.
Conclusions: We found that ccFT is a protective factor for short-term clinically efficacy in patients after cardiac surgeries, and the longer the ccFT (i.e., the higher the cardiac output), the shorter the duration of MV and ICU LOS. Continuous monitoring with CADFlow may be a potential bedside methodology to assess the hemodynamic status of critically ill patients.

Carotid corrected flow time (ccFT) measured by the wearable carotid Doppler ultrasound flow.

The area under the ROC for ccFT to predict the length of ICU stay ≥ 24 h.

The area under the ROC for ccFT to predict the duration of MV ≥ 24 h.

Intensive Care Medicine Experimental 2025* 13(Suppl 1):*874

Introduction: Non-invasive respiratory support, including non-invasive positive pressure ventilation (NIPPV) and high-flow oxygen therapy (HFOT), have become standard for managing several acute cardiopulmonary diseases (1). However, it is challenging to deliver optimum nutritional support to patients receiving prolonged courses of NIPPV or HFOT, and there is little evidence to guide decision-making in this regard (2).

Objectives: To determine the rates of enteral nutrition in patients receiving NIPPV and HFOT.

Methods: This multicentre retrospective cohort at 2 tertiary care hospitals in Hamilton, Canada examined enteral nutrition and non-invasive respiratory support. Patients greater than 18 years of age, admitted to the ICU, and receiving enteral nutrition (EN) for 48 h were included in this preliminary report. These results are from the subgroup of patients who received at least 48 consecutive hours of NIPPV or HFOT between Jan 1, 2023, and Dec 31, 2023. A chart review was conducted to abstract data on demographics, admission characteristics, comorbidities, and enteral intake. Data on respiratory support and nutrition from the first 30 days of the ICU admission were exported directly from the electronic medical record. The proportion of days in which patients received enteral nutrition while receiving HFOT and NIPPV was compared using the Independent T-test and Chi-square tests where appropriate.

Results: A total of 37 patients (9 female, mean age 66.1 years) received at least 48 h of consecutive NIPPV or HFOT; 17 (45.9%) received HFOT, 19 (51.3%) received both NIPPV and HFOT, and 1 patient (2.7%) received only NIPPV. In the first 30 days of their ICU admission, patients received EN on 52.5% (95%CI 40.0-65.5%) of days on HFOT, while those on NIPPV only received this on 23.0% (95%CI 5.4-40.0%; p = 0.017) (Table 1). NIPPV compared with HFOT was associated with more days of NPO prescription (NIPPV (51.4% [95%CI 30.1-72.6] vs HFOT 38.2% [95%CI 25.0-51.4%]). Fewer days of tube feeds were associated with NIPPV (15.5% [95%CI 0.29-30.7] vs HFOT (31.4 [95%CI 18.6-44.7]) although neither difference reached statistical significance (Table 1). Furthermore, only 65.2% (95%CI 44.1-82.3%) of patients admitted on HFOT or NIPPV reached 80% of their predicted nutritional requirement during their admission.

Table 1 (abstract 000874) Nutritional support of patients on non-invasive respiratory support

	High Flow Oxygen Therapy (95% CI) (*N* = 36)	**Non-invasive Positive Pressure Ventilation (95% CI) (*N* = 20)**	***p* value ***
Percent days prescribed NPO (%)	38.2(25.0-51.4)	51.4(30.1-72.6)	0.28
Percent days receiving Tube Feeds** (%)	31.4(18.6-44.1)	15.5(0.2-30.7)	0.10
Percent days receiving Enteral Nutrition*** (%)	52.5(40.0-65.5)	23.0(5.4-40.0)	**0.017**

*Significant differences calculated via Independent *t*-test

**Tube feeds—EN delivered via gastric or jejunal tubes

***Enteral Nutrition—Includes both oral nutrition and tube feeds

Conclusions: Providing enteral nutritional support for those on non-invasive respiratory support is challenging. This study shows that many patients on prolonged courses of both NIPPV and HFOT are underfed, with those on NIPPV at higher risk of receiving no nutrition. Further study is needed to evaluate the most appropriate method for nutritional support in this population, given the increasing use of non-invasive respiratory support in critically ill patients.

Introduction: Patient–ventilator asynchrony (PVA) refers to the phenomenon where the patient's ventilatory demands are mismatched with the support provided by the ventilator. The aim of these studies is to explore the potential value of long duration PVA monitoring with an automatic system in ventilated critically ill patients at risk of ventilator-induced lung injury.
Methods: A retrospective analysis was conducted on patients admitted to the ICUs in four tertiary hospitals from January to November 2023, who were connected to a mechanical ventilation remote monitoring system and had a Pmean over 10 cmH2O within 24 h of mechanical ventilation. Six types of PVA, including double triggering, ineffective triggering, reverse triggering, flow starvation, premature cycling, and delayed cycling, were counted using a rule-based automated PVA recognizing algorithm. The total patient–ventilator asynchrony index was defined as the total number of asynchrony cycles / total respiratory cycles × 100%. Spearman correlation analysis was used to explore the respiratory factors associated with PVA, and Logistic regression analysis was used to assess the impact of total asynchrony index on prolonged mechanical ventilation.
Results: A total of 254 patients were included during the study period, with a median age of 65 years, APACHE II score of 17 (13, 24), primarily due to pulmonary infection and cardiac surgery, Pmean of 11.9 (10.9, 13.7) cmH2O, PaO2/FiO2 ratio of 208 (139, 275) mmHg, and total asynchrony index of 14 (7, 28) %. The overall 28-day mortality rate was 26.8%, and the ventilator-free days within 28 days was 12 (0, 22) days. Lower PaO2/FiO2 ratio and faster respiratory rate were associated with higher asynchrony index. After adjusting for confounding factors, higher asynchrony index was independently associated with mechanical ventilation for more than 7 days or death [per 1% increase of total asynchrony index, OR 1.03 (1.00-1.05, $p = 0.034$)].
Conclusions: PVA is common in patients with elevated Pmean and is associated with longer duration of mechanical ventilation.

Flow resistance in two cleared heat and moisture exchangers compared with a novel humidification system

M. Moylan[1]
[1]Biostatistics and Epidemiology, Auckland University of Technology, Auckland, New Zealand
Correspondence: M. Moylan

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**)***:876***

Introduction: Heat and moisture exchangers (HMEs) are devices commonly used in respiratory care to warm and humidify inhaled air while reclaiming heat and moisture from exhaled air. One issue with these devices is the potential increase in resistance when the HME becomes saturated and work of breathing is increased.
Objectives: Our aim was to characterise how HMEs affect airflow resistance under different breathing conditions and humidity levels with a novel humidification device (RespirAq™ Active Humidifier (RAH) System) which operates as simply as the HME and performs similarly to a heated humidifier (HH).
Methods: One hundred and eight benchtop tests were conducted using a set-up to simulate human respiratory conditions compliant with ISO 9360-1.
Results: The two HMEs (HME-1 Covidien DAR™ and HME-2 ICU Medical Portex®) showed a significant pressure drop in both dry (0.7-3.0 cmH20) and saturated (0.7-4.1 cmH20) air and at all three flow rates (30, 60 and 90 L/min) compared with the RAH System (0.1-1.0 cmH20, $p < 0.05$). See Fig. 1.
Conclusions: The RAH System offers a simple, effective alternative to traditional HMEs. While HMEs can increase breathing resistance with flow rates and when saturated. These results show that the RAH system's breathing work is significantly lower than that of both of the HMEs tested. Furthermore, no significant difference was seen in dry and saturated conditions on pressure drop with the RAH System.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**)***:879***

Introduction: In-hospital cardiac arrest remains a significant clinical challenge, with survival outcomes closely tied to the efficiency of resuscitation and post-resuscitation care. The "ABC code" at ABC Medical Center is a rapid response protocol activated for patients with no pulse and no respiration, attended by trained critical care personnel.
Objectives: To determine the survival rate following in-hospital CPR in patients attended by the Critical Care Team under ABC Code activation. Secondary objectives included analyzing factors associated with return of spontaneous circulation (ROSC), long-term survival, and site of code activation.
Methods: We conducted a retrospective, observational study at ABC Medical Center (Santa Fe campus) from January 2022 to September 2024. We included all patients attended by the Critical Care Team following adequate ABC Code activation. The data were extracted from institutional logs, electronic medical records, and post-discharge follow-up calls. Exclusion criteria were mock drills and cases handled by other services. Statistical analysis included descriptive statistics and chi-square tests ($p < 0.05$ was considered significant).
Results: Out of 70 ABC Code activations, 17 (24.2%) were confirmed as true cardiac arrests. Median patient age was 75 years old (IQR 58-83), with 58.8% male. ROSC was achieved in 76.5% ($n = 13$), predominantly within 1–3 cycles of CPR (64.7%). A statistically significant association was found between fewer CPR cycles and higher ROSC rates ($p = 0.008$). Among those admitted to the ICU post-ROSC, 84.6% survived hospitalization and 76.9% remained alive at 6-month follow-up. Of the 11 patients discharged, 90.9% were alive at > 6 months. (See Table 1 and Fig. 1).

CPR cycles	ROSC	No ROSC	*p* value
1-3 cycles	11 (64.7%)	0	0.008
4-6 cycles	1 (5.9%)	1 (5.9%)	
> 6 cycles	1 (5.9%)	2 (11.8%)	

Conclusions: High ROSC and survival rates were observed in patients managed by the Critical Care Team following ABC Code activation. Early, high-quality resuscitation and organized post-cardiac arrest care were likely contributing factors. The results highlight the importance of structured response systems and point to opportunities for improving code activation criteria.

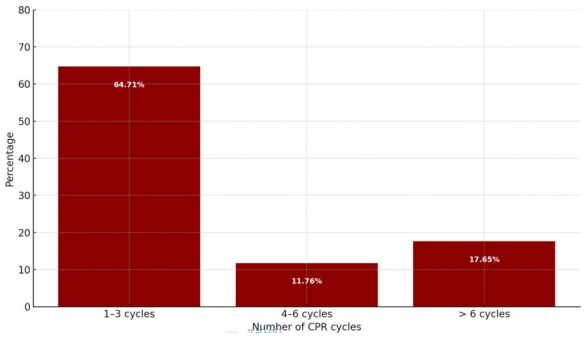

Fig. 1 (abstract 000879) Relationship between CPR cycles and ROSC outcome

Bench test comparison of absolute humidity in cleared humidification devices and a novel humidification system

M. Moylan[1]
[1]Biomedical Sciences, Auckland University of Technology, Auckland, New Zealand
Correspondence: M. Moylan
Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**)***:880***

Introduction: Humidification during mechanical ventilation is crucial for preventing airway complications such as hypothermia, epithelial damage, and obstruction. A novel system (RespirAq™ Active Humidifier (RAH) System) offers a new approach to humidification, utilising a rapid-switching fabric technology to capture and return moisture, eliminating the need for an external water source.
Objectives: This bench test aimed to compare the absolute humidity (AH) delivered by the RAH System with a cleared heat and moisture exchanger (Covidien DAR™) and a cleared heated humidifier (F&P MR850).
Methods: Thirty bench tests simulating human respiratory conditions were conducted.
Results: Mean AH was 32.2 ± 2.1 mg/L—HME, 39.4 ± 2.4 mg/L—HH, and 39.1 ± 1.1 mg/L—RAH System. A significant difference was observed between HME and both the HH and RAH System. No significant difference was found between HH and RAH System. The RAH System's AH showed no significant difference as compared to AH data from a clinical trial conducted during invasive ventilation therapy (38.8 ± 1.8 mg/L $n = 23$). See Fig. 1.
Conclusions: The RAH System performed comparably to the HH device when delivering AH, suggesting it can provide adequate humidification without a water bolus. This has the potential to mitigate the risk of aerosolising bacteria/viruses without compromising therapeutic efficacy. Eliminating a water source addresses a key infection control concern in respiratory care.

Glucose variability in the early stage is associated with acute kidney injury of traumatic brain injury patients

L. Wang[1], X. Ou[1], Y. Kang[1]
[1]Department of Critical Care Medicine, West China Hospital of Sichuan University, Chengdu, China
Correspondence: L. Wang
Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**)***:883***

Introduction: Traumatic brain injury (TBI), the leading cause of disability in adults under 35, poses major healthcare and economic burdens [1]. In 2019, 27.16 million TBI cases occurred globally (incidence: 346/100,000) [2]. Acute kidney injury (AKI) has been demonstrated to be prevalent following traumatic brain injury (TBI) and is associated with poorer prognosis in TBI patients [3]. Hyperglycemia and glucose variability (GV) are associated with AKI development in populations undergoing COVID-19, cardiac surgery and liver transplantation, however, their role in TBI-associated AKI remains unexplored [4-6]. Therefore, this study selected patients with AKI secondary to TBI from the MIMIC-III database as the research subjects. The SD and CV of blood glucose levels intermittently measured on the first day after admission were analyzed to examine the relationship between blood glucose levels, glucose variability, and the occurrence of AKI after TBI.
Objectives: This study investigates associations between glycemic fluctuations and AKI pathogenesis, aiming to address critical knowledge gaps and refine risk stratification for TBI-related renal complications.
Methods: 1544 TBI patients from the Medical Information Mart for Intensive Care-III were enrolled (Fig. 1). The main exposure factor of this study was the glucose variability during the first day after admission reflected by the standard deviation (SD) and coefficient of variation (CV) of intermittently measured glucose levels. The primary outcome was the AKI during hospitalizations confirmed based on the KDIGO criteria. The unadjusted and adjusted association between glucose variability and AKI after TBI were visually showed as Fig. 2 using the RCS method. The area under the ROC curve (AUC) value of SD of glucose and CV of glucose for predicting AKI was 0.655 and 0.644, respectively(Fig. 2).
Results: 1544 TBI patients were selected from the MIMIC-III with the AKI incidence of 30.2%. AKI patients had higher level of glucose average ($p < 0.001$), glucose SD ($p < 0.001$), glucose CV ($p < 0.001$), 30-day mortality ($p < 0.001$) than non-AKI patients. The stepwise multivariate logistic regression showed SD of glucose ($p < 0.001$) and CV of glucose ($p < 0.001$) were both significantly related with the AKI after TBI. The area under the ROC curve of SD and CV for predicting AKI was 0.655 and 0.644, respectively.
Conclusions: Increased glucose variability is positively associated with the AKI after TBI. The glucose variability should be alleviated when managing TBI patients especially those with high risks of AKI.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***885***

Introduction: Inappropriate antimicrobial therapy is associated with increased morbidity and mortality in patients with sepsis. However, in critically ill populations, outcomes are influenced by multiple factors, including the severity of the clinical presentation, particularly the presence of septic shock.
Objectives: We aimed to assess the incidence of appropriate empirical antimicrobial treatment in ICU patients with microbiologically confirmed infection and its impact on 28-day mortality rates, both with and without septic shock.
Methods: We conducted a sub analysis of the DIANA study database, including adult ICU patients who received empirical antimicrobial therapy for a microbiologically confirmed bacterial infection. Antimicrobial treatment was deemed appropriate if the patient received at least one agent with documented in vitro activity against the identified culprit pathogen. Patients were categorized based on the clinical diagnosis of septic shock (using Sepsis 3.0 criteria). Statistical analyses included comparisons of demographic and clinical characteristics, and impact on mortality using Kaplan–Meier 28-day survival analysis and multivariable logistic regression.
Results: A total of 857 patients from 152 ICUs in 28 countries were studied. Empirical antimicrobial therapy was appropriate in 88% (753/857) of patients. Septic shock was present in 29%(222/753) and 13.5% (14/104) of patients receiving appropriate therapy and inappropriate therapy, respectively. Patients with appropriate antimicrobial empirical therapy had significantly more days free of vasopressor, ventilator and renal support (p = 0.001), significantly shorter ICU lengths of stay ($p \leq$ 0.001) and lower mortality rates (17.5% vs. 30.8%) at 28 days. Kaplan–Meier survival analysis showed different survival profiles between these two groups (log-rank test p = 0.004) (Fig. 1). In the multivariable logistic regression model assessing 28-day mortality, appropriate antimicrobial therapy was independently associated with a significantly lower odds of death (odds ratio of 0.52 (95% CI 0.38-0.89), p = 0.011). However, in patients with septic shock, survival was not significantly different (p = 0.13) (Fig. 2).
Conclusions: Appropriate empirical antimicrobial therapy was independently associated with improved 28-day survival in ICU patients; this could not be demonstrated in the subgroup of patients with septic shock.

Intensive Care Medicine Experimental 2025* 13(Suppl 1):*886

Introduction: Lymphopenia has consistently emerged as a hallmark immunological signature in critically ill patients with COVID-19, often associated with worse clinical outcomes. While multiple studies have reported its correlation with disease severity, the independent contribution of lymphocyte depletion to mortality remains insufficiently defined. As we move toward more precise immunophenotyping in critical illness, understanding whether lymphopenia functions as a driver or merely a marker of disease burden is key. Clarifying its prognostic value is not only relevant for patient-level risk stratification but also for better understanding immune dysfunction in sepsis.
Objectives: We aimed to assess the incidence of lymphopenia in a large dataset of hospitalised COVID-19 patients and its independent impact on overall patients' survival.
Methods: We conducted a secondary post hoc analysis of the prospectively collected, standardised, global ISARIC dataset, including all adult patients admitted to the hospital due to confirmed COVID19. Patients were analysed according to the occurrence of lymphopenia, defined as an absolute serum count of lymphocytes < 1000/µL in the first 48 h of Hospital admission. Demographic and clinical characteristics were assessed between groups along with Kaplan–Meier survival curve analysis and Cox regression modeling.
Results: Overall, 231,933 patients from more than 60 countries and 1500 centres worldwide were included. 131,235 patients (56.6%) presented lymphopenia. Patients with lymphopenia were older and more frequently male ($p < 0.001$). They required more multiorgan support, including vasopressor, mechanical ventilation or renal replacement therapy, and a longer ICU stay ($p < 0.001$ on all comparisons). Kaplan–Meier survival curve analysis demonstrated significantly higher mortality over time in the lymphopenia group (log-rank test $p < 0.001$) (Fig. 1). Cox regression model results revealed that lymphopenia was independently associated with an increased hazard of 28-day mortality. Each 1,000 cells/µL increase in lymphocyte count was associated with a 25% reduction in the hazard of death (HR = 0.75; 95% CI 0.74-0.76; p < 0.001) (Fig. 2).
Conclusions: In this large, multinational cohort of hospitalised COVID-19 patients, lymphopenia was common and independently associated with worse clinical outcomes. These findings reinforce that lymphocyte count is a robust, accessible biomarker for risk stratification, that needs to be considered in COVID-19 viral sepsis syndrome.

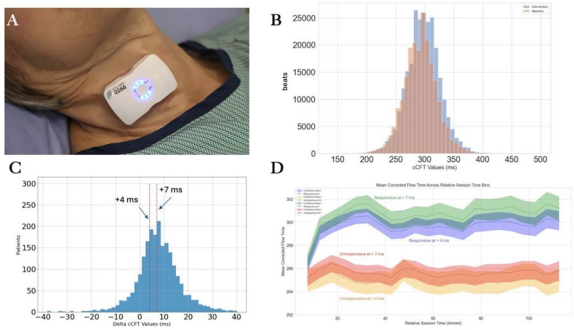
Evaluating the change and time-to-peak corrected carotid artery flow time during a preload challenge in over 2000 septic emergency department patients



S. Atwi[1], M. Hebscher[1], JE. Kenny[2], J. Eibl[3], SM. Ko[4], J. Nunnally[4], K. Ugale[4], J. Bond[4], K. Haycock[4]
[1]Engineering, Flosonics Medical Toronto, ON. Canada, Toronto, Canada; [2]Clinical Research, Health Sciences North Research Institute Walford Site, Greater Sudbury, Canada; [3]Physiology, Northern Ontario School of Medicine, Sudbury, Canada; [4]Emergency, Riverside University Health System Medical Center, Moreno Valley, United States of America
Correspondence: K. Haycock
Intensive Care Medicine Experimental 2025* 13(Suppl 1):*888

Introduction: Change in the corrected flow time of the common carotid artery (ccFTΔ) during preload augmentation is used as a surrogate for stroke volume change (SVΔ). With this, preload responsiveness (PR) is inferred; PR is an important measure in early sepsis care to avoid physiologically ineffective intravenous (IV) fluid. A wireless, wearable Doppler ultrasound that continuously measures ccFT is used in a large, academic, county-owned, government-funded emergency department (ED) as a part of a sepsis resuscitation algorithm. This is a descriptive analysis of this growing dataset.
Objectives: 1.) Describe the median ccFTD as a measure of PR for over 2000 septic ED patients. 2.) Describe the time to peak ccFTD as a measure of PR in the same dataset. 3.) Compare the rate of change of PR in patients with multiple sessions
Methods: This is a retrospective cohort study comprising over 2000 sepsis patients in whom severe sepsis was identified in a large, publicly funded, academic ED in southern California. This dataset includes patients evaluated between September 2023 to March 2025; for this analysis, no patient health information is linked to the Doppler assessments. All patients in the ED or general medical floor in whom changes in vital signs or laboratory values triggered a Best Practice Alert (BPA) in the electronic medical record and are then identified to have severe sepsis are seen by a dedicated nursing-led rapid response team or sepsis emergency response team (SERT). The SERT RN employs bedside ultrasound and a wireless, wearable 4 MHz, continuous wave, Doppler ultrasound (Flosonics Medical, Sudbury, Canada) to assess fluid responsiveness. All patients receive a preload challenge (PC) as either a rapid fluid challenge of 100 mL/min over 2-3 min or Trendelenburg positioning from 20 degrees head up to 10-20 degrees head below the horizontal for at least 90 s; PC type is decided by the treating clinician. To determine PR, carotid Doppler spectrograms are analyzed for ccFTΔ, calculated as the difference between cardiac cycles averaged during 'assessment' (i.e., RFC or head-down) and before assessment (i.e., 'baseline'). Baseline windows are selected based on a minimum

of 15 cardiac cycles, low coefficient of variation, and high density of cardiac cycles. Assessment windows are selected based on a minimum of 20 cardiac cycles, low coefficient of variation, high density of cardiac cycles, and the largest change with baseline. Time-to-peak was assessed by calculating the time-elapsed, binning across 5 s intervals, and calculating the maximum ccFT across time. The start and end times of the peak was compared between ccFTΔ ≥ 7 ms and ccFTΔ ≥ 4 ms cohorts using a Student's *t* test.

Results: A PC with the wearable Doppler ultrasound was attempted in 2292 patients. Of these, an adequate ccFTΔ was completed in 2171 patients. In total, 466,042 cardiac cycles are included. For the first PC, the mean baseline ccFT for all patients was 295 ms (± 29 ms) and the mean ccFT for the intervention was 300 ms (± 29 ms) ($p < 0.01$). The median ccFTΔ was 7.5 ms. 53.4% of patients had a ccFTΔ ≥ 7 ms, while 69.8% had a ccFTΔ ≥ 4 ms. For patients identified as PR based upon either a 4 ms or 7 ms ccFTΔ threshold, the time-to-peak ccFTΔ was 30-40 s, with no difference in start and end times between cohorts ($p > 0.05$). The average number of assessments per patient was 1.6, where 1093 had more than 1 assessment completed. Comparing only the first to last assessment, 23.0% and 20.5% of patients change from PR to preload unresponsive (PUR) based upon 7 ms and 4 ms ccFTΔ thresholds. 19.7% and 18.2% change from PUR to PR based upon 7 ms and 4 ms ccFTΔ thresholds.

Conclusions: This study comprises nearly 500,000 carotid Doppler cardiac cycles obtained from over 2000 ED patients with severe sepsis. In these patients, 53% and 70% are judged to be preload responsive on their first assessment based upon 7 ms and 4 ms ccFTΔ thresholds, respectively. The time-to-peak ccFT is in the first 30-40 s of intervention for all patients, consistent with passive leg raise data and esophageal Doppler data. It is more common to change from preload responsive to unresponsive between first and last assessment than vice versa.

A The wireless, wearable Doppler on a healthy volunteer. **B** The total number of beats and ccFT value in baseline (orange) and intervention (blue). **C** The distribution of ccFTΔ across all first assessments **D** The temporal ccFT change in responders versus non-responders based upon a ccFT change threshold of +7 ms (green – responder; red – non-responder) and + 4 ms (blue – responder; yellow – non-responder).

Evaluation of family satisfaction in under-age visits to adult patients in the humanized intensive care unit: a focus on safety and well-being

R. Botello Maraver[1], J. Aguirre Sánchez[2], AMD. Braulia[3], J. Franco[4], E. Rocha[5]
[1]Medicina Crítica, ABC Medical Center, Ciudad de México, Mexico; [2]Intensive care unit, The American British Cowdray Medical Center, Mexico City, Mexico; [3]MEDICINA CRITICA, ABC Medical Center, Ciudad de México, Mexico; [4]Medicina Critica, ABC Observatory Medical Center, Ciudad de México, Mexico; [5]Intensive Care Unit, Centro Medico ABC, Mexico City, Mexico

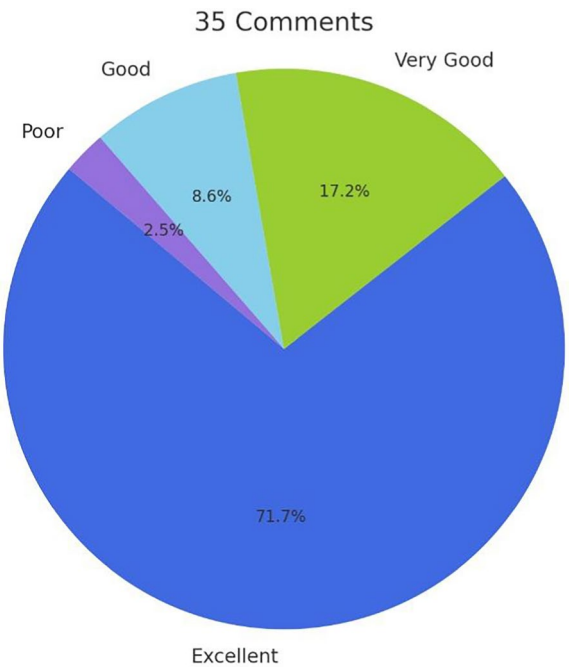
Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***891***

Introduction: Intensive Care Units (ICUs) have significantly evolved since their inception, not exclusively in terms of technology and medical management but also in their approach to humanizing care. Traditionally, intensive care has focused on biomedical aspects, overlooking the emotional and psychological well-being of patients and their families. However, the current trend towards more holistic and integrated care has led to the incorporation of strategies that prioritize the dignity and values of individuals. One key area in this effort has been the inclusion of under-age in visits to hospitalized adult family members. This practice aims to improve the patient's experience and the satisfaction of their families subsequently, promoting an environment of safety, well-being, and empathy during a time of high vulnerability. Specific studies that evaluate family satisfaction regarding the inclusion of under-age in adult ICUs are limited; however, some studies have addressed this topic as part of their assessments and have measured overall satisfaction with flexible visiting policies, including those who are under-aged.



Objectives: To evaluate the level of satisfaction of family members accompanying under-age during visits to adult patients in the ICU, aiming to improve service quality and ensure that the environment remains humanized, centered on emotional well-being and the safety of minors.

Methods: This is a prospective observational cross-sectional study that assessed family satisfaction regarding minor visits to adult patients in the Humanized Intensive Care Unit at ABC Medical Center, Santa Fe campus, from February 2023 to February 2024, involving 224 under-aged admissions. Subsequently, surveys were sent to the emails provided through public attention at ABC Medical Center, Santa Fe campus, to evaluate the visiting experience. A total of thirty-five survey responses were received. For statistical analysis, Excel was used for qualitative, dichotomous, or ordinal variables, which were presented in frequencies and proportions.

Results: 71.4% (25 patients) rated the experience as excellent, 17.1% (6) as "very good", 8.6% (3) indicated a "good experience", and 2.9% (1) considered the experience poor. 88.6% (31) of respondents reported that they were provided with sufficient information about the rules and procedures; 8.6% (3) indicated that they received information "to

some extent," which presents an opportunity for further improvement in the consistency and clarity of information even though 2.9% (1) stated that they did not receive clear information. 85.7% (30) of family members expressed that the ICU staff was fully prepared to assist during the minor visits, 11.4% (4) felt that the staff was "somewhat prepared," and 2.9% (1) responded that they were not adequately prepared. 85.7% (30) of family members reported feeling completely safe and comfortable entering the ICU with underage, 11.4% (4) felt "somewhat safe," and 2.9% (1) responded that they did not feel safe. 85.7% (30) of respondents believe that adequate measures were implemented to ensure the safety and well-being of minors during the visit, 11.4% (4) think those measures were "somewhat sufficient," and 2.9% (1) did not consider that the measures were adequate.

Conclusions: The results obtained in this research demonstrate that the implementation of under-aged visits in the humanized ICU has had a positive impact on both patients and their families. A significant percentage of family members reported important levels of satisfaction. However, it is advisable to improve how information is communicated and reinforce the sense of security for family members.

General experience of under aged visits

Vasoactive–ventilation–renal index and its association with the requirement for continuous renal replacement therapy in patients with septic shock

FG. Delgado Mejia[1], J. Garduño-López[1], MA. Amezcua-Gutiérrez[1], GA. José Carlos[1], SP. Avila Villalobos[1], FJ. Ramírez Almaraz[1], HA. Velez Davila[1], FP. Hernandez Bielma[1], JA. Intensive Care Medicine Experimental 2025 **13(Suppl 1)*:892***

Introduction: Sepsis is defined as life-threatening organ dysfunction resulting from a dysregulated host response to infection (1). Many studies, focused on intensive care units (ICUs), report a high incidence of patients diagnosed with sepsis (2,3). The optimal timing of initiation of continuous renal replacement therapy (CRRT) in patients with acute kidney injury (AKI) in the ICU remains undefined. Currently, several predictors of severity exist in patients with septic shock; however, they fail to predict the optimal timing of CRRT initiation. The Vasoactive–Ventilatory–Renal (VVR) score is an index of disease severity that incorporates validated markers of cardiovascular, pulmonary, and renal function. Miletic et al. found the VVR score to be most promising for accurately predicting outcomes after cardiac surgery (4); however, there are no widely validated studies for patients with septic shock.

Objectives: To evaluate the association of the VVR index with the requirement for CRRT in patients with septic shock and AKI.

Methods: Diagnostic capacity was assessed using the area under the ROC curve (AUC), and the association between VVR and CRRT was determined using the chi-square test, with continuity correction.

Results: Of the 35 patients diagnosed with septic shock, 9 (25.7%) received CRRT, of whom 6 (66.6%) died. The overall mortality rate was 31.4% (Tables 1 and 2). The VVR index result was obtained for patients who met the inclusion criteria. ROC analysis was performed with an area under the curve (AUC) of 0.637, indicating moderate discriminatory capacity. The optimal cutoff point, determined using the Youden index, was 39.5 points, with a sensitivity of 66% and a specificity of 72% (Fig. 1). Furthermore, a significant correlation between the VVR and its association with CRRT was demonstrated using the chi-square test with continuity correction ($p < 0.040$) and the Spearman correlation test ($p < 0.015$).

Conclusions: A VVR index greater than 39.5 showed moderate discriminatory ability to predict the need for CRRT, in addition to demonstrating a statistically significant association with its requirement. These findings suggest that the VVR could be a useful parameter in predicting the initiation of CRRT in patients with septic shock.

Table 1 (abstract 000892) Demographic characteristics and comorbidities

Characteristics	Total, n=35
Sex (%)	
Male	14 (40)
Female	21 (60)
Average age in years	50
Comorbidities (%)	
High blood pressure	11 (31.4)
Diabetes	11 (31.4)
COPD	2 (5.7)
Heart disease	2 (5.7)
Liver disease	1 (2.8)
Scales (average) points	
SOFA	13.89
APACHE II	22.29
SAPS II	36.94

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**)***:893***

Introduction: Low cardiac output syndrome (LCOS) is a condition characterized by insufficient cardiac output to meet metabolic oxygen demands.1 Common after cardiac surgery, it is linked to increased morbidity, mortality, ICU stay, and hospital resource use. Definitions vary, causing wide-ranging incidence reports (1.5%-91%), especially in low-resource settings.2
At our institution, LCOS is defined by cardiac index < 2 L/min/m^2, need for inotropes > 30 min, lactate ≥ 2 mmol/L, or use of ventricular assist devices. No reliable predictive model exists, but known risk factors include female sex, prior cardiac surgery, coronary artery bypass graft, left ventricular systolic dysfunction, urgent surgery, and peripheral artery disease.3
Objectives: To identify LCOS-associated risk factors and evaluate its frequency and mortality in our center.
Methods: A retrospective cohort (Mar 2022–Jan 2025) included ICU patients postcardiac surgery diagnosed with LCOS per international and institutional criteria (cardiac index < 2 L/min/m^2, inotropic support for more than 30 min, or use of ventricular assist devices in the context of hypoperfusion). Clinical history, surgery details, and treatments were collected. Bivariate and multivariable analyses identified associations.
Results: Among 868 patients, 117 developed LCOS. Mean age was 53.3 ± 14.3 years; mortality was 18.3%. Of these, 47.9% had acute kidney injury, 17.9% liver failure, and 24.8% atrial fibrillation. Risk factors included previous cardiac surgery (p < 0.003), higher EUROscore (p < 0.018), NYHA class III-IV (p < 0.03), and hypothyroidism (p < 0.03). Longer bypass time (p < 0.001) and aortic cross-clamp time (p < 0.01) were significant intraoperative predictors, especially in aortic valve replacement.

Table 1 (abstract 000893) Characteristics of patients with and without LCOS

Variable	Without LCOS (n = 712)	LCOS (n = 117)
Age (years)	54.1 ± 14.4	53.3 ± 14.3
In-hospital mortality	4.7%	18.3%
SOFA 24 h	4.57 ± 2.44	6.50 ± 3.02
SOFA 72 h	3.38 ± 2.25	4.87 ± 3.04
Hepatic failure	7.6%	17.9%
Postoperative atrial fibrillation	13.7%	24.8%
Acute kidney injury	27.0%	47.9%

Conclusions: Despite its clinical relevance, there remains no universally accepted definition of LCOS, resulting in substantial heterogeneity regarding its reported incidence, therapeutic approaches, and prognostic implications. In our cohort, it was associated with a 4.5-fold higher in-hospital mortality risk. No significant associations were found with diabetes, pulmonary or chronic kidney disease; hypertension showed a non-significant trend. Higher body weight appeared protective, possibly due to greater physiological reserve. Most common therapy was dual inotropes (47.8%), followed by dobutamine (29.91%) and levosimendan (12.82%), with no mortality difference by treatment type.

Ventriculo-arterial coupling after vasopressin administration in septic shock patients

K. Mantzarlis[1], V. Vazgiourakis[1], A. Valsamaki[1], ME. Papadonta[1], D. Makris[1]
[1]Intensive Care, Larissa General University Hospital, Larissa, Greece

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***895***

Introduction: Vasopressin presents pleiotropic effects on septic shock patients. According to survival sepsis campaign (SSC) guidelines it can be added as a second line vasopressor agent early after the initiation of noradrenaline [1]. At the same time, proper ventriculo-arterial (V–A) coupling results in optimal cardiac output. V–A coupling is defined by the relationship between the elastances of the left ventricle (Ees) and the arterial circuit (Ea) [2]. Decoupling is often in septic shock patients leading to hemodynamic deterioration, and it may be further affected by medications that can alter cardiac contractility or arterial load [3].
Objectives: To define the effect of vasopressin on V–A coupling and other hemodynamic variables in septic shock patients, examining the feasibility of the measurement
Methods: In a prospective, observational study V–A coupling and other hemodynamic variables were measured before and after the initiation of vasopressin. The addition of vasopressin as second line vasopressor was at physician's discretion, and the administration rate was at the standard dose of 0.04 unit/min. Ees was measured by echocardiography using the single-beat method as described by Chen et al. [4]. Ea was calculated as 0.9 × (systolic arterial pressure/stroke volume). The V–A coupling was calculated as the Ea/Ees ratio. Univariate analysis was performed to determine statistically significant changes between the several variables before and after the initiation of vasopressin.
Results: Seven patients were included in the study. V–A coupling was mildly abnormal in concordance with previous studies describing V–A de-coupling in septic shock [3]. After vasopressin initiation V–A coupling was improved but not significantly significant [mean (mean S.E.) 1.5 (0.2) vs 1.1 (0.02) before and after vasopressin use respectively, $p = .10$, 95% confidence interval (CI), − 0.1 to 0.8]. The improvement was due to a trend for increased Ees [1.5 (0.2) vs 2.2 (0.3), $p = .066$, 95% CI − 1.5 to 0.06]. Ea was not statistically different [2.3 (0.2) vs 2.4 (0.3), $p = .789$, 95% CI, − 0.8 to 0.6]. All other hemodynamic variables did not present statistical differences.
Conclusions: The addition of vasopressin as a second line vasopressor in septic shock patients prevented prevented them from further V–A uncoupling with a trend for improvement.

Table 1 (abstract 000895) Baseline characteristics

Intensive Care Medicine Experimental 2025* 13(Suppl 1):*898

Introduction: Spirituality is a fundamental aspect of life that can influence the process of health and illness. In intensive care medicine, spiritual care (SC) has been recognized as an essential component of patient-centered care; however, its systematic implementation is a challenge for ICU's healthcare professionals (HP), due to barriers such as a lack of training and limited selt-awareness of one's own spirituality.

Objectives: To assess the spirituality of ICU's healthcare professionals in Chile.

Methods: We present the initial results of a national study aimed to assess the spirituality of HP working with adult critical care patients in Chile. All HP with at least three months of experience in an ICU were invited to participated, answering 3 evaluation instruments: the Spirituality Questionnaire (SQ), a survey about learning needs in spirituality and SC and a personal information survey. These instruments were widely distributed online with the assistance of the Sociedad Chilena de Medicina Intensiva. The SQ is specific to HP and has been validated in Chile. It consists of 4 components: self-awareness, spiritual beliefs, spiritual practices and spiritual needs, assessed through 29 items using a Likert scale; the maximum score is 116 (higher level of spirituality) and minimum 29. At the end of the SQ, the participants could answer 2 questions about barriers and facilitators for SC implementation at the ICU. The results are described using mean ± standard deviation (SD) and percentages, and compared with Student's *t* test and chi-square. The study was approved by the institutional review board of Pontificia Universidad Católica de Chile.

Results: From February to May 2025,130 participants were included. The majority were single young females that worked directly in patient's care (78.9%). Most HP had postgraduate studies in critical care (70%), and almost a half have worked in ICU for more than 5 years (45,4%). More than a half of the participants practice a religion, mostly Catholicism (70,8%). Table 1 shows the characteristics of the participants.

In the spirituality evaluation, the mean score in the SQ was 87.1 ± 25.7. Previous training in spiritual care and work directly in patient's care were significantly associated with a higher level of spirituality (*p* value 0.045 and 0.002, respectively). No other characteristics of the participants were associated with the level of spirituality, including their religiosity. For each of the SQ components, the results were: self-awareness 33.9 ± 6.28 (maximum score 40), spiritual beliefs 12.57 ± 3.2 (maximum score 16), spiritual practices 17.09 ± 5.3 (maximum score 24), spiritual needs 29.92 ± 5.83 (maximum score 36). The work overload, the lack of protected time, and have a limited self-awareness of one's own spirituality were detected as important barriers for SC implementation at the ICU. Having a developed spirituality and work in an institution that supports spirituality (institutions that had specialized units for spiritual and religious assistance) were identified as facilitators for SC implementation.

Although only a quarter of the participants had previous training in spirituality and SC, 82.3% were interested in participating in a SC training program for critical care professionals. Most prefer a telematic and asynchronous modality (54,2%), that includes topics like spirituality in health and pain and suffering.

Table 1 (abstract 000898) Characteristics of the participants

Characteristic	Mean/frequency	SD/percentage
Age (years)	39	8.8
Women	81	62%
Practice any religion	72	55%
Civil status single	65	50%
Profession nurse	55	42%
Profession physicians	42	32%

Conclusions: In this initial analysis of a national study that assesses the spirituality of ICU's healthcare profesionales, the previous training in spiritual care and work directly in patient's care were associated with a higher spirituality.

Intensive Care Medicine Experimental 2025* 13(Suppl 1):*899

Introduction: Intraoperative hypotension (IOH) is a significant risk factor for postoperative organ dysfunction, particularly postoperative acute kidney injury (PO-AKI) [1]. However, whether implementation of a quality indicator (QI) could effectively decrease rates of IOH and thereby AKI in clinical routine care has not been assessed.
Objectives: To evaluate the association of a hypotension QI on the incidence of IOH and PO-AKI.
Methods: A hypotension QI was implemented as part of a standard operating procedure (SOP) at Charité—Universitätsmedizin Berlin, Campus Benjamin Franklin, a tertiary care center, on Jan 1st, 2021. The QI was defined as ≥ 90% of documented intraoperative mean arterial pressure (MAP) measurements ≥ 60 mmHg. We retrospectively analyzed electronic healthcare records of patients aged ≥ 18 years undergoing non-cardiac surgery from 2019 to 2025. Exclusion criteria included an ASA status ≥ 5 and cardiac or gynecological procedures. PO-AKI was identified based on KDIGO criteria within the first three postoperative days [2]. To assess the effect of the QI, interrupted-time-series analyses (ITSA) were performed, comparing the period before and after the QI's introduction into routine clinical practice. The primary outcome was QI fulfillment. The secondary outcome was PO-AKI. In addition to ITSA, multivariable regression was used to assess the association of QI fulfillment with PO-AKI, after adjusting for age, sex, ASA status, Elixhauser index, procedure duration, baseline creatinine, general anesthesia, surgical service, use of vasopressors, blood products, and propofol. The Ethics Committee approved the protocol (EA4/239/19).
Results: A total of 73,437 patients were included in the ITSA, while 54,290 were included in the adjusted analysis following the complete case approach. The median age was 65 years [51-76], 36,651 (43%) were female, and median Elixhauser index was 4 [0-11]. Upon QI implementation, ITSA revealed a significant immediate increase in QI fulfillment (2.8%, 95%CI 1.3-4.2, $p < 0.001$), with a significantly increased improvement per week post-implementation (0.04% per week, 95%CI 0.03-0.04, $p < 0.001$; Fig. 1a). ITSA of PO-AKI demonstrated a significant decrease post-implementation (0.004% per week, 95%CI 0.001%-0.007%, p = 0.043), whereas pre-implementation rates of PO-AKI were stable (Fig. 1b). Fulfillment of the QI was associated with a decreased risk of PO-AKI (adjOR 0.69, 95%CI 0.62-0.77, p < 0.001). Median intraoperative MAP was stable over time, however, postinduction hypotension is reduced after QI implementation (Fig. 2).
Conclusions: To our knowledge, this is the first study to demonstrate the effectiveness of a QI for IOH implemented in clinical routine, which was associated to significantly reduced rates of IOH and AKI. These findings highlight the potential of standardized QIs in preventing IOH and improving patient outcomes. In addition, these results may point towards a direct pathophysiological link between IOH and PO-AKI.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***900***

Introduction: Nutrition is essential for life under all conditions. Previous studies have shown an association between adverse outcomes and inadequate nutritional support in elderly critically ill patients. However, there are conflicting results on nutrition of the elderly.
Objectives: We aimed to evaluate the effects of daily calorie and protein administration on the number of ventilator-free days and changes in muscle thickness in elderly critically ill patients.
Methods: After ethical committee approval, data of 101 patients who were admitted to the ICU between October 15, 2023, and December 1, 2024, were prospectively collected. Patients aged 65 years and older who were expected to require mechanical ventilation for more than 7 days and had no contraindications to enteral nutrition therapy were included. Dimensions of the quadriceps muscle in the right leg were measured by ultrasonography at admission and monitored weekly. Correlation analysis was performed between clinical variables and laboratory variables using the Spearman's test.
Results: Median age was 74, and 61.4% of patients were men. The most common comorbidity was hypertension. Mean APACHE II was 26.6, median SOFA 8, CCI 7 and mNUTRIC was 7. A significant, weak, positive correlation was found between the number of ventilator-free days and daily median calorie intake (rs = + 0.201, $p = 0.044$). In addition, nonsignificant, weak, positive correlations were found between the number of ventilator-free days and daily median calorie per body weight (kcal/kg), daily median protein intake, and daily median protein per body weight (g/kg) values ($p = 0.14$, $p = 0.073$, $p = 0.16$). A significant, weak, positive correlation was found between changes in muscle thickness and median daily calorie and protein intake ($p = 0.003$, $p = 0.007$). A significant, moderate, positive correlation was found between changes in muscle thickness and daily median kcal/kg and gr/kg protein values ($p < 0.001$, $p < 0.001$). Daily median calorie, protein, kcal/kg, and gr/kg protein values were higher in survivors ($p = 0.004$, $p = 0.005$, $p = 0.016$, $p = 0.031$). In univariate logistic regression analysis, we found that patients with a daily average kcal/kg ≤ 17.5 had a significantly higher risk of mortality (OR = 0.43, $p = 0.043$). However, in multivariate analysis, this relationship was not found (OR = 0.91, $p = 0.87$).
Conclusions: We found nutrition therapy positively contributed to changes in muscle thickness and 60-day mortality, although its contribution to the number of ventilator-free days was limited. Further studies may be planned regarding different compositions of nutrition.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):903

Introduction: Intensive care unit (ICU) patient monitors generate alarms to alert healthcare providers about potentially life-threatening events. Patient monitoring involves integrating disparate sources of information, including auditory alarms, visual alarms, and multisensory cues from the patient. Object-based visual displays depicting patient vital signs through shapes and symbols, like the rate of a contracting heart, have been shown to aid in integrating information about a patient's current state [1].
Objectives: In previous work we developed a visual display, depicted in Fig. 1, that represented physiologic data about heart rate, blood pressure, and blood oxygen saturation as a ring whose color saturation and symmetry changed according to the severity of these vital signs (e.g., a saturated red, asymmetric ring indicated high blood pressure). In the present modification, shown in Fig. 2, we added visual icons such as rhythmically contracting symbols (i.e. large, quick contractions for high heart rate) and a color legend. In an experiment, we tested the modified display against the original version. We predicted the display innovations would aid the integration of patient emergency information, reducing response time and increasing accuracy compared with the original display.
Methods: Participants (n = 20) identified patient emergencies while performing a distracting task. Displays were presented in a simulated clinical environment via the HTC VIVE Pro Eye virtual reality headset, which recorded participant response time and accuracy. Each participant performed four blocks of monitoring, with a different display configuration for each block. In the first two configurations, each display was presented independently in the participant's central visual field in random order. Next, both displays were presented bilaterally in the participant's peripheral visual field, with the relative position of the displays randomized between blocks.
Results: An one-way ANOVA using display configuration as the factor and accuracy as the dependent variable revealed that participants performed better on the emergency identification task when two displays were presented bilaterally than when one display was presented centrally ($F(3,38) = 10.85$, $p < 0.001$, $\eta^2p = 0.36$). An one-way ANOVA did not reveal differences in reaction time across the different display configurations. These results are represented in Fig. 3.
Conclusions: Future work will examine whether the patient monitoring benefits of having two displays are due to the bilateral presentation of information or the simultaneous presentation of the original and modified displays. By demonstrating significant differences between participants' performance while viewing the original and modified display in distinct visual configurations, this study informs future work to examine whether the patient monitoring benefits of having two displays are due to the bilateral presentation of information or the simultaneous presentation of the original and modified displays.

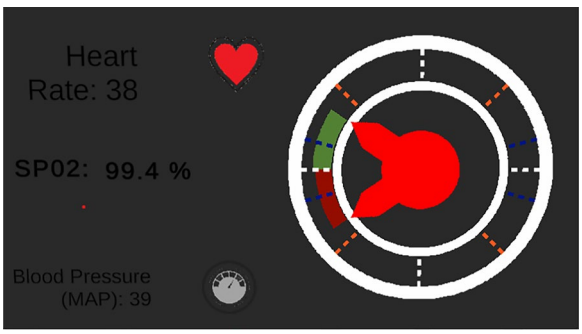

Fig. 1 (abstract 000903) Original object-based visual display

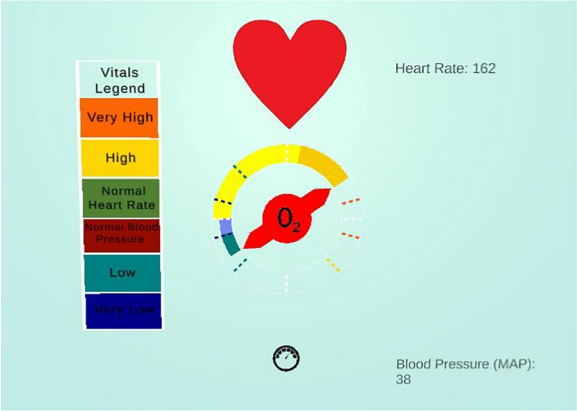

Fig. 2 (abstract 000904) Modified object-based visual display*

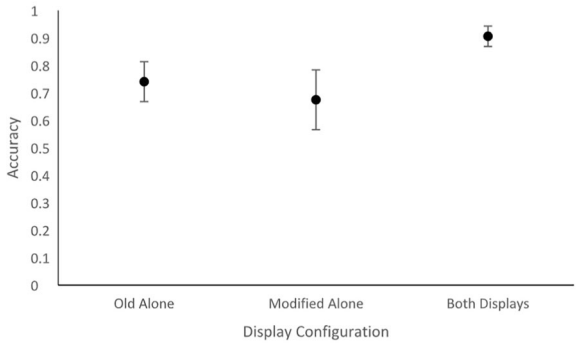

Fig. 3(abstract 000905) Effect of display configuration on accuracy. An one-way ANOVA test showed a significant increase in accuracy when participants viewed both displays while identifying simulated patient emergencies ($p < 0.001$)

Intensive Care Medicine Experimental 2025 **13(Suppl 1)*:906***

Introduction: Psychiatric disorders are common, affecting up to 30% of patients in primary care settings (1). Individuals with mental health disorders have worse physical health than the general population and excess healthcare resource consumption is a problem in this population (2,3). However, this patient collective is neglected and marginalized in somatic medicine: despite the high prevalence of psychiatric diseases, data on epidemiology among critically ill patients and impact on ICU outcome are scarce.

Objectives: The purpose of this study was to find out whether pre-existing psychiatric disorders (PPD) are associated with negative outcomes in critically ill patients.

Methods: This is a retrospective case–control study aiming to compare patients with PPD with the general population admitted to the Intensive Care Unit (ICU) of the Kantonsspital Graubünden in Chur, Switzerland over 10 years. Reviewing our clinical information systems, we collected demographic data, data on primary diagnosis, comorbidities, therapeutic and outcome data. Primary outcomes were ICU and 28-days mortality, length of stay on the ICU and re-admission within 24 h and 1 year. We also analysed the need of mechanical ventilation and vasopressor in both groups. Univariate and multivariate regression analyses were performed. Data are expressed as mean (SD), Median (interquartile range) or n (%).

Results: 11'262 adult patients were included in the study. 2150 (19%) had documented PPD. These patients were admitted from healthcare facilities more often (1.7% vs 0.4% $p < 0.01$), 35% had an affective disorder (mainly depression) and 55% were substance dependent. Patients with PPD were younger (59 ± 16 vs. 64 ± 15 y, $p < 0.01$) and more patients were female (37% vs 30.6%, $p < 0.01$) as compared with patients without PPD. SAPS score did not differe between the two groups. Outcome data are summarized in Table 1. More patients with PPD were in need of mechanical ventilation and vasopressor therapy and they stayed longer in the ICU. Re-admission rates were higher in this group. Within the PPD population, male sex was associated with higher re-admission rates within 24 h (3% vs 1.5% $p < 0.01$) and after 1 year (21% vs 17% $p < 0.01$) compared to female sex. Pre-existing respiratory disease was more common in PPD patients (9.4% vs 6.4% $p < 0.01$). Multivariate regression analysis showed that psychiatric disease was independently associated with lower ICU mortality [OR 0.48 (CI 0.4-0.65), $p < 0.001$] and 28-day mortality [OR 0.65 (CI 0.5-0.8), $p < 0.001$] but with higher risk of re-admission within 24 h and within one year [(OR 1.6 (CI 1.3-1.9) $p < 0.01$]. Age and male sex were independently associated with mortality at 28 days: [(OR 1.02 (CI 1.01-1.02) $p < 0.01$] and [(OR 1.27 (CI 1.07-1.5) $p < 0.01$], respectively.

Conclusions: Our data confirm a high prevalence of PPD (19%) among critically ill patients. Despite higher use of health care resources, PPD is not associated with increased mortality. Patients with PPD are more likely to have a complicated clinical course. In particular, male sex had a higher rate of re-admission over time. Our results might be attributed to vulnerability of this population, but also to lack of awareness among health care professionals. High re-admission rates and sex differences emphasize the need of tailored concepts for this population at risk.

Table 1 (abstract 000906) Outcomes according to presence of psychiatric disorder; data expressed as median (interquartile range) and n (%)

	psychiatric	Non psychiatric	P value
Length of stay (hours)	31 (19-71)	23 (17-44)	< 0.001
ICU mortality	85 (4)	681 (8)	< 0.001
28 days mortality	183 (9)	1156 (13)	< 0.001
Need of mechanical ventilation	819 (38)	2602 (29)	< 0.001
Need of vasopressors	912 (42)	3412 (38)	< 0.001
Re-admission after 24 h	53 (2.5)	129 (1.5)	< 0.01
Re-admission within 1 year	414 (19)	1220 (13)	< 0.001

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***911***

Introduction: Norepinephrine has been recommended as the first-line vasopressor for management of septic shock [1]. In clinical practice, various vasopressors are being used and norepinephrine equivalence (NEE) doses of vasopressin, phenylephrine and epinephrine are proposed as 0.04 units/min, 1 mcg/kg/min and 0.1 mcg/kg/min respectively, when compared to norepinephrine dose of 0.1 mcg/kg/min [2,3]. However, there is no prospective study to prove the same.
Objectives: To evaluate the NEE doses of vasopressin, phenylephrine and epinephrine in septic shock patients, against the norepinephrine dose of 0.1 mcg/kg/min.
Methods: After ethical approval, this prospective study included septic shock patients on mechanical ventilation receiving norepinephrine at least 0.1 mcg/kg/min for a minimum of six hours, with no dose alteration in the last 2 h before the study was conducted. Patients were excluded if presence of other forms of shock concurrently, arrhythmias, ventilator asynchrony, ongoing fluid resuscitation, diuretics or hemodialysis at the time of study.
The studied drugs were prepared as follow: vasopressin, 20 units in 20 ml of saline, with a concentration of 1 U/ml which delivered drug at 0.04 U/min when run at 2.4 ml/hr; phenylephrine, dose was calculated as body weight × 0.15 drug (in mg) in 25 ml preparation, which delivered 0.1 mcg/kg/min when infused at 1 ml/hr; epinephrine dose was calculated as body weight × 0.03 drug (in mg) in 50 ml preparation; 1 ml/hr of this infusion delivered drug at the rate of 0.01 mcg/kg/min. The transducer was zeroed to the atmospheric pressure at the level of the heart and baseline invasive mean arterial pressure (MAP) were recorded. Studied vasopressor was connected and norepinephrine infusion was reduced over 5-10 min by 0.1 mcg/kg/min with simultaneous titration of the studied vasopressor to achieve the similar baseline MAP. Two readings were recorded 5 min apart and mean of the studied drug was calculated. After withdrawing the first studied drug, the process was repeated for the other studied drugs, with a gap of 2 h.
Results: During the study period (Jul 2024 to Feb 2025) 23 patients were included with median age 36 years (IQR 31-48.5) of which 60.8% were males, Charlson comorbidity index 0 (IQR 0,0.5). On the study day, the median SOFA score was 15 (IQR 12-17) and patients were receiving median norepinephrine dose of 0.22 mcg/kg/min (IQR 0.155-0.275). The NEE dose of vasopressin found to be 0.039 units/min (IQR 0.032-0.042) as against to proposed 0.04 units/min (p = 0.441) (Fig. 1); phenylephrine 0.83 mcg/kg/min (IQR 0.31-0.96) as against to proposed 1 mcg/kg/min (p = 0.001) (Fig. 2); and epinephrine 0.09 mcg/kg/min (IQR 0.043-0.12) as against to proposed 0.1 mcg/kg/min (p = 0.60) (Fig. 3).
Conclusions: In septic shock patients, the NEE dose of phenylephrine was significantly lower than the proposed dose; however, the NEE doses of vasopressin and epinephrine were found similar to the proposed doses.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**)***:912***

Introduction: Cefiderocol is a novel siderophore cephalosporin, active against multidrug-resistant pathogens such as carbapenemase-producing Enterobacterales, Pseudomonas aeruginosa, Acinetobacter baumanii and Stenotrophomonas maltophilia. However, limited data are available about its use in the ICU setting.
Objectives: Aim of the study was to assess the efficacy and safety of cefiderocol treatment for infections caused by multidrug and extensively drug-resistant Gram-negative microorganisms in ICU patients.
Methods: This is a retrospective, observational study conducted in the ICU of a tertiary Greek hospital. Critically ill patients admitted in the ICU who received treatment with cefiderocol for infections caused by Gram-negative multidrug-resistant microorganisms were included. We recorded patients' demographics and clinical characteristics, site of infection, responsible pathogens and their antimicrobial susceptibility, clinical response, days from therapy initiation to clinical response, relapse, adverse effects, length of stay in the ICU and outcome (ICU discharge or death). Clinical response was considered as fever remission, improved oxygenation, decreased need for catecholamines, resolution of sepsis or shock and recovery of organ dysfunction until 2 days after end of therapy. New infection with the same pathogen after 2 days following end of therapy was defined as a relapse.
Results: We analyzed data from 12 patients admitted in the ICU between April 2023 and December 2024. Nine were males and 3 were females, with mean age 59 years (31-81) and mean APACHE II score 27 (15-37). Mean ICU length of stay was 59 days (3-150). Five patients had undergone emergency surgical procedures, six were immunocompromised (hematological malignancy, history of solid organ transplantation and chronic corticosteroid therapy). A total of 13 episodes of infections were recorded, 11 bacteremias and 2 VAP. Most common pathogen was *Pseudomonas aeruginosa* (5) followed by *Acinetobacter baumanii* (4), *Klebsiella pneumoniae* (3) and *Stenotrophomonas maltophilia* (3). Other pathogens were *Providencia stuartii* and *Proteus sp*. Four cases were multimicrobial (2 pathogens, 30%). Clinical response was observed in 6 episodes (46%), all of them bacteremias. None of the patients with VAP responded. Among the patients who responded 3 were immunocompromised. Mean time from therapy initiation to clinical response was 4 days (range 3-5 days). As of pathogen-related response to treatment we found no difference among different types of Gram-negative bacilli. One patient had a relapse. Urine discoloration was seen in one patient as an adverse effect of cefiderocol treatment. Three patients were discharged from the ICU (25%).
Conclusions: Cefiderocol had better results in bacteremias than in VAP, in our study. Patients who responded to therapy were eventually discharged from ICU while non-responders died during the infection episode. No major adverse effects linked to Cefiderocol therapy were recorded. More data are certainly needed in order to draw better conclusions about the drug efficiency.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**)***:913***

Introduction: Patient–ventilator asynchrony (PVA), usually termed as the patient "fighting" the ventilator, is a common problem with potential bad outcomes for invasive and noninvasive mechanical ventilation. Mechanical ventilation, extensively utilized worldwide, notably at the bedside and tele-ICU, is often a life-saving intervention but carries potential complications. Multiple studies have shown an association between asynchrony and duration of mechanical ventilation, ICU length of stay, mortality, and patient comfort. Asynchronies are often

unrecognized, underestimated, and inappropriately treated. Manual and automated detection of PVA are two fundamental ways to identify PVAs. Manual methods are time-consuming and demand much knowledge. Manual identification is subject to human errors and comprehension of standardized terminology, taxonomy, and practices of PVAs. Most automated approaches take identifying PVAs as a classification task and are constrained to specific ventilator models/modes and patients/hospitals. Furthermore, automatically detecting PVAs is technically challenging. For a segment of waveforms, e.g., 60 s waveforms, PVAs can occur anywhere from zero to dozens of times and in different locations.

Objectives: Detection of PVAs via three basic ventilator waveforms (pressure of airway, flow, and volume) is a more pragmatic approach. This detection job is a multi-class multi-target detecting problem that includes the localization and classification of PVAs. The primary objective of this study is to design and develop such a detector to identify PVAs using only ventilator waveforms for mechanically ventilated patients at the bedside and tele-ICU.

Methods: In this study, we proposed a light, fast, and end-to-end network to realize multitarget multiclass one-stage detection (PVADet) of six PVAs using only ventilator waveforms (Shown in the Fig. 1). Inventively, we converted the challenge of detecting PVAs to a multiclass multitarget detection problem like detection tasks in computer vision. In practice, assessing rich ventilator data is a cumbersome task subject to patient privacy and hospital information security. We distinctively opted to utilize waveforms alone as inputs to evaluate the possibility of detecting PVAs due to their simple and extensive obtainability. Moreover, we created an one-stage model PVADet innovatively integrating causal separable convolutional blocks and recurrent neural networks (shown in Fig. 2) with novel techniques, label striping and stripe–mask encoding (shown in Fig. 3), simplifying input–output mapping and adapting to muticlass multitarget tasks. A one-stage detector with an end-to-end architecture presents a flexible and pragmatic strategy to develop a monitor tool to support better ventilation. To our knowledge, this is the first effort to train, validate, and test the model detecting PVAs on multiple ventilators, modes, and patients from different hospitals.

Results: The performance of overall PVA detection for testing is displayed in **Table 1**. A proper G (G indicates strips, G = 30) surpasses others in model generalization. Our model performs worse on the test dataset due to the significant diversity between it and the training dataset, as well as the complexity of detecting multiple classes and targets of PVAs. Besides, a small G may lead to better PPV based on our experimental results.

The metrics for cross-validation and test are expressed as mean standard deviation.

Table 1 (abstract 000913) Results of test for overall PVA detection. ACC, PPV, TPR, TNR, F1, MCC and mAP denote adopted accuracy (ACC), positive predictive value (PPV) or precision, true positive rate (TPR) or sensitivity, true negative rate (TNR) or specificity, F1 score, Matthews correlation coefficient (MCC), and mean average precision (mAP), respectively

	ACC	PPV	TPR	TNR	F1	MCC	mAP
G = 15	0.946 ± 0.005	**0.604** ± 0.007	0.573 ± 0.007	0.974 ± 0.008	0.551 ± 0.003	0.602 ± 0.005	**0.657** ± 0.003
G = 30	0.968 ± 0.007	0.588 ± 0.009	**0.620** ± 0.009	0.981 ± 0.007	**0.566** ± 0.004	**0.613** ± 0.004	0.650 ± 0.004
G = 60	**0.980** ± 0.006	0.527 ± 0.008	0.523 ± 0.008	**0.990** ± 0.009	0.480 ± 0.006	0.531 ± 0.005	0.520 ± 0.003

Conclusions: The findings prove that automatically recognizing PVAs utilizing only ventilator waveforms is promising, and the performance of the model is decent. PVA is clinically tricky, and identifying it costs a lot. We bring a new insight to the identification of PVAs via ventilator waveforms. This model could be applied as a monitoring tool at the bedside and tele-ICU to improve patient comfort, reduce potential risks, and better outcomes.

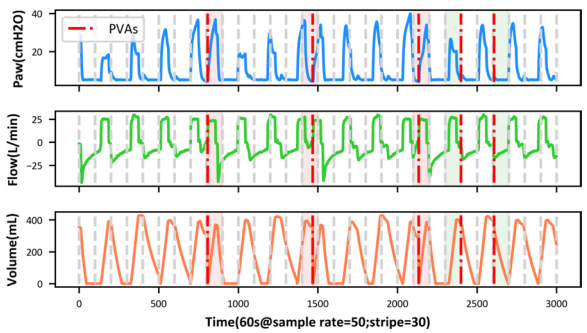

Fig. 1 (abstract 000913) Demonstration of the label striping. The time axis is gridizated to areas (stripes) denoted by grey vertical lines. Red dash-dotted vertical lines indicate raw labels, with light red transparent bars (stripe labels) denoting double triggers and green ones representing ineffective efforts. Paw denotes airway pressure. PVAs denote patient–ventilator asynchronies. In this example, we divide the 60 s waveform into 30 stripes and six classes of PVAs. The sample rate is 50 Hz (samples per second)

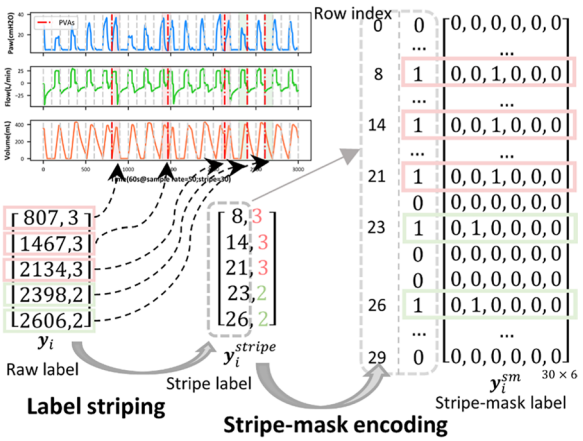

Fig. 2 (abstract 000913) Demonstration of the stripe-masking encoding. The raw labels of a 60-s waveform segment are striped and encoded to stripe-mask labels. In stripe labels, the elements in the first column of stripe labels denote the row indexes in the right matrix. Only these indexes in stripe labels are valid for class representation. Specifically, the corresponding index rows represent category while the others are all zeros. The category representation is the one-hot encoding without a negative category. PVAs represent patient–ventilator asynchronies. Note that we split the 60-s waveform into 30 stripes and six classes of PVAs

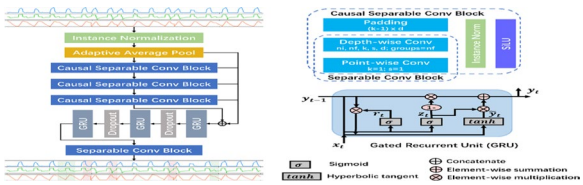

Fig. 3 (abstract 000913) The architecture of the proposed PVADet network

Olink proteomics analysis platform identifies protein biomarkers associated with cardiac arrest and brain injury

D. Duziyelebai[1]
[1]Intensive Care Medicine, Shanghai Tenth People's Hospital, Shanghai, China
Correspondence: D. Duziyelebai
Intensive Care Medicine Experimental 2025 **13(Suppl 1)*:914***

Introduction: Cardiac arrest, a leading cause of global mortality, often results in post-resuscitation brain injury (PCABI), the primary determinant of adverse outcomes. The existing biomarkers like Tau, NfL, and NSE lack sufficient sensitivity and specificity, necessitating novel markers for improved prognostic accuracy.
Objectives: This study aimed to identify serum protein biomarkers associated with neurological injury following cardiac arrest using the high-sensitivity Olink proteomics platform and machine learning, enhancing early diagnosis and outcome prediction.
Methods: Serum samples from 170 participants (8 healthy controls, 8 acute cerebral infarction patients, and 154 cardiac arrest survivors) were analyzed via Olink's 384-protein panel. Differentially expressed proteins (DEPs) were identified, clustered, and correlated with clinical scores (CPC, GCS). Four machine learning algorithms (LASSO, random forest, Elastic Net, XGBoost) prioritized key biomarkers, validated by ELISA in 120 samples.
Results: Differential analysis revealed 156 upregulated proteins across groups. Hierarchical clustering identified three subtypes (CC1-CC3), with CC1 showing persistent upregulation and strong clinical correlation. Machine learning selected five biomarkers: Tau, NfL, NSE, ANXA10, and IDI2. ELISA confirmed elevated levels in cardiac arrest patients, with ANXA10 demonstrating the highest predictive power (AUC: 0.714). A logistic regression model integrating all five proteins outperformed individual markers (AUC: 0.81) and the conventional three-protein model (AUC: 0.748).
Conclusions: The Olink platform successfully identified ANXA10 and IDI2 as novel serum biomarkers for post-cardiac arrest brain injury. Combined with established markers, these proteins enhance prognostic accuracy, offering a robust tool for clinical management. Further validation in larger cohorts is warranted to confirm their translational potential.

Intensive Care Medicine Experimental 2025 **13(Suppl 1):*915***

Introduction: Sepsis is a leading cause of mortality globally, requiring prompt diagnosis and intervention to improve clinical outcomes. The current diagnostic tools often suffer from low sensitivity and long processing times, delaying effective treatment. SeptiLoop® is a novel in vitro diagnostic (IVD) lateral flow test designed to detect ex vivo tumor necrosis factor-alpha (TNFα) production in whole blood stimulated with lipopolysaccharide (LPS), providing an indication of bloodstream infection related to immune dysregulation in early sepsis.
Objectives: This study aims to evaluate the analytical validity of SeptiLoop® for early detection of immunosuppression induced by bacterial bloodstream infections (including sepsis) through measurement of TNFα production in LPS-stimulated whole blood.
Methods: SeptiLoop® employs an endotoxin (LPS) to stimulate immune cells in whole blood samples. After a 2.5-h incubation at 37 °C, TNFα levels are assessed using a lateral flow strip (Fig. 1). The analytical performance was evaluated based on the sensitivity (Limit of Detection, LoD), specificity (interference and cross-reactivity), precision (repeatability and reproducibility), linearity, accuracy, and stability. Assays were performed using whole blood from healthy volunteers. Stability tests covered blood sample viability, diluted sample stability, reagent stability, and shelf-life.
Results: SeptiLoop® demonstrated a LoD of 250 pg/mL for TNFα, with no observed hook effect. Specificity tests revealed minimal interference from common medications or patient conditions, and no cross-reactivity (Fig. 2). The assay achieved > 95% agreement in both repeatability and reproducibility across varying test conditions. Whole blood samples remained stable for 16 h post-collection, and diluted samples retained integrity for up to 15 min post-incubation. The device functioned reliably under different operational conditions and maintained reagent and strip performance for 6 and 18 months respectively.
Conclusions: SeptiLoop® met all analytical performance criteria, including accuracy, sensitivity, and precision, making it a reliable tool for early sepsis detection. Its rapid time to result and ease of use support its implementation as a frontline diagnostic tool, potentially improving patient outcomes through timely bloodstream infection (including sepsis) diagnosis and intervention.

Intensive Care Medicine Experimental 2025 **13(Suppl 1):*916***

Introduction: Human albumin is an expensive therapeutic agent frequently used in the management of septic shock. However, inappropriate prescribing practices may lead to substantial healthcare costs without corresponding clinical benefit. To address this issue, an

institutional policy was implemented to guide human albumin use as part of a Drug Use Evaluation (DUE) program.
Objectives: This study aimed to evaluate the appropriateness of human albumin prescriptions for indications associated with septic shock and to quantify the potential cost savings resulting from reduced inappropriate use following the implementation of a drug use evaluation program.
Methods: A retrospective evaluation study was conducted using data from the Drug Use Evaluation (DUE) based on paper records at the intensive care units of university hospital, Thailand. The study included adult patients (aged > 18 years) who received either 5% or 20% human albumin for the treatment of septic shock. Prescriptions were assessed for appropriateness according to the hospital's DUE criteria. The primary outcomes were the rates of appropriate versus inappropriate use and their corresponding cost implications. The reasons for inappropriate use were categorized and analyzed. The secondary outcome involved estimating the financial loss based on the volume of albumin used and its unit cost.
Results: Of the prescriptions reviewed between June 2024 (after the implementation of the DUE policy) and December 2024, a total of 201 prescriptions were reviewed. The use of 5% and 20% human albumin accounted for 46.8% and 53.2%, respectively. The appropriate use of human albumin was identified in 28.7% of 5% formulations and 26.2% of 20% formulations. The most common reason for inappropriate use was insufficient administration of crystalloid fluids prior to albumin therapy, accounting for 18.4% of 5% and 21.4% of 20% albumin prescriptions. The second most common reason was prescribing without meeting the indication criteria, found in 10.9% of 5% and 17.9% of 20% human albumin prescriptions. A detailed breakdown of the reasons for inappropriate use is illustrated in Fig. 1. The total estimated financial loss due to inappropriate albumin use was 435,180 baht comprising 204,288 baht from 5% albumin and 230,892 baht from 20% albumin. Specifically, 117,072 BAHT was attributed to insufficient crystalloid fluid administration, and 113,820 baht to failure to meet indication criteria.
Conclusions: This study revealed a high proportion of human albumin prescriptions for septic shock in the ICU unit that did not comply with hospital guidelines, leading to significant unnecessary expenditure. Improving adherence to DUE criteria through ongoing education, regular monitoring, and policy enforcement is essential to minimize inappropriate use and promote cost-effective human albumin therapy practices at a tertiary care center in Thailand.

Inflammation afterlife: how donor immune signals shape transplant futures

A. Tridente[1]; AM. Goncalves Bullock[2]; N. Dempsey[2]
[1]Critical Care, Whiston Hospital, St Helen's, United Kingdom; [2]Life Sciences, Manchester Metropolitan University, Manchester, United Kingdom
Correspondence: N. Dempsey
Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**)*:917*

Introduction: Systemic hyper-inflammation is an established cause of organ dysfunction, evidenced by the multi-organ failure observed in sepsis [1]. Similarly, the process of death invokes a complex set of events leading to profound hyper-inflammation [2]. It is reasonable that in deceased organ donors, death-induced hyperinflammation could have significant consequences for organs being offered for transplant (Tx), hence current donor management guidelines advocating the administration of steroids early in the donor management process (DMP) to modulate donor inflammation and maximise organ utilisation [3]. Notably, disparities in graft quality and Tx success have been identified in organs received from deceased versus living donors [4-5]. It is hypothesised that donor death mechanisms and ensuing inflammation likely contribute to pre-Tx organ quality variations, with lasting effects on graft function.
Objectives: We performed a systematic review which aimed to 1) clarify what is currently known about the sources of inflammation following death, and 2) systematically evaluate the current body of evidence reporting higher levels of inflammation in deceased donors versus living donors and linking donor inflammation with kidney Tx outcome.
Methods: The review was conducted in agreement with the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) reporting guidelines 8. We searched Medline, Web of Science, Scopus and CINHAL databases from January 2000 to March 2023 for articles relating donor inflammation with kidney Tx outcomes. National Institute of Health 'Quality Assessment Tool for Observational Cohort and Cross-Sectional Studies' was used to assess validity of studies.
Results: From 530 articles screened, 21 studies were analysed, which included a total of 3397 donors and 4596 recipients. There was a very high degree of heterogeneity between studies in terms of the inflammatory markers assessed and the measured Tx outcomes, yet collective evidence showed higher inflammation, complement activation, and tissue injury in deceased donors compared with living donors and strongly suggested associations with less favourable short- and long-term Tx outcomes.
Conclusions: To improve organ viability and Tx outcomes, a paradigm shift toward precision donor therapies is critical. Future efforts should prioritise disrupting specific drivers of inflammation and graft dysfunction, particularly dysregulated complement pathways, rather than relying on nonspecific immunosuppression. This targeted approach may suppress donor-derived inflammation more effectively, preserving organ function and also may expand the pool of transplantable grafts.

Intensive Care Medicine Experimental 2025 **13(Suppl 1)*:921***

Introduction: Neuromuscular diseases comprise a broad spectrum of disorders that can significantly compromise respiratory function and, in severe cases, require admission to intensive care units. Descriptive studies in patients with Guillain–Barré syndrome have documented that a considerable proportion require prolonged mechanical ventilation and experience associated complications such as sepsis and respiratory failure[23]. However, integrated analyses that include various neuromuscular conditions along with therapeutic variables and the weaning process remain scarce. The present study, based on data collected at our institution and following a methodological protocol inspired by the recent published studies, provides updated information on the critical management of these patients as well as on the distribution of the different neuromuscular diagnoses identified[456].
Objectives: To analyze the demographic and clinical characteristics, as well as the evolution of patients with neuromusculardiseases admitted to an Andalusian ICU over the last decade, including variables related to respiratory support,the immunological treatment used, and the weaning process.
Methods: A retrospective study was conducted in the ICU of the Universitario Clínico San Cecilio (2016–2025), whichincluded 32 patients diagnosed with neuromuscular diseases (such as Guillain–Barré syndrome, myastheniagravis, and others). Demographic variables (age and sex) and clinical variables (need and duration of mechanical ventilation, performance of tracheostomy, respiratory complications, and sepsis), the type ofimmunological treatment (immunoglobulins, plasmapheresis, combined therapies), and the type of weaning(classification of the mechanical ventilation liberation process as successful, difficult, or failed) were analyzed. Descriptive analyses (means, medians, ranges, and percentages) were performed and the findings werecompared with the recent studies published in indexed databases.
Results: The cohort showed a mean age of 60.2 years (range: 24-88 years) and a predominance of males (78%). The meanICU stay was 18.8 days. Approximately 60% of patients required mechanical ventilation, with a mean durationof 29 days; in 50% of these cases, a tracheostomy was performed. Regarding immunological treatment, 65% ofpatients underwent this intervention (45% received immunoglobulins, 15% plasmapheresis, and 5% combinedtherapies). The weaning process was classified as successful in 70% of cases, difficult in 20%, and failed in 10%.Regarding the type of neuromuscular disease, the distribution was as follows: Guillain–Barré syndrome 50%(16/32), myasthenia gravis 25% (8/32), and other entities (including inflammatory neuropathies andmyopathies) 25% (8/32). The incidence of respiratory complications ranged between 30 and 35%, and sepsis was identified inapproximately 40% of cases. These results are consistent with the findings reported in the recent studies2345.
Conclusions: This descriptive study demonstrates that patients with neuromuscular diseases in the ICU exhibit a high needfor ventilatory support and immunological treatment, along with variability in the weaning process. Thesignificant incidence of respiratory complications and sepsis, coupled with the distribution of differentneuromuscular diagnoses—predominantly Guillain–Barré syndrome—highlights the importance of optimizingintensive care management protocols. These findings contribute relevant data for clinical practice and futureresearch in this field.

Intensive Care Medicine Experimental 2025 **13(Suppl 1)*:922***

Introduction: Previous studies have reported conflicting results about the prevalence of seizures in AD, and few epidemiological studies in the Asia have been found. We examine the demographic, clinical characteristics and the incidence for seizures with AD patients compared with non-AD patients in a prospective, longitudinal, community-based cohort with long follow-up.
Methods: The data were collected from National Health Insurance Service-National Elderly cohort (NHIS-elderly) database to define patients with AD from 2014 to 2016 based on having KCD code G30, F00. We performed a 1:5 case–control-matched analysis using
propensity score matching, which were based on the age, sex and household income. We conducted Cox proportional hazards regression analysis to estimate the risk of epilepsy in AD.
Results: In the cohort study, the patients with AD have higher chances for epilepsy than those without AD The Hazard ratios for epilepsy with AD are 2.773(95% CI: 2.515-3.057). The study also shows that the gender male, comorbidities, such as hypertension, hyperlipidemia, diabetes, and chronic kidney disease increases the risk of developing epilepsy. Patients have 1.527 (95% CI: 1.375-1.695) times higher mortality rate when epilepsy occurred in the AD group than in the control group.
Conclusions: Out data show that AD significantly has higher risk for the development for epilepsy

Role of miRNAs shuttled by LPS-primed mesenchymal stem cell-derived extracellular vesicles in modulating macrophage activation

A. Areny-Balagueró[1], M. Camprubí-Rimblas[1], E. Campaña-Duel[1], A. Berenguer-Llergo[2], A. Ceccato[1], A. Artigas[3], D. Closa[4]

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***923***

Introduction: Mesenchymal stem cells (MSCs) exhibit significant therapeutic potential due to their regenerative and immunomodulatory properties, largely mediated by the extracellular vesicles (EVs) they secrete [1]. Our previous research demonstrated that priming MSCs with lipopolysaccharide (LPS) boosts the therapeutic efficacy of their EVs, particularly in the context of acute lung injury (ALI) [2].
Objectives: The main objective of this study is to investigate the role of differentially expressed miRNAs between EVs derived from naïve (C-EVs) and LPS-primed MSCs (LPS-EVs) and their immunomodulatory capacity.
Methods: miRNA transcriptomic analysis of C-EVs and LPS-EVs (n = 2) was performed using GeneChip miRNA 4.0 Array. Differential expressed miRNAs between both types of EVs were identified establishing a threshold to fold-change ≥ 1.5. Pathway enrichment was conducted using the pre-ranked GSEA with KEGG, GO, Biocarta, Broad Hallmarks, and PID data. Among the overexpressed miRNAs in LPS-EVs, key miRNAs were selected and their expression was verified by RT-qPCR. Their immunomodulatory effects were evaluated in macrophage-like THP-1 cells infected with Pseudomonas aeruginosa, both individually and in combination (MIMIX).
Results: Microarray analysis revealed 21 differentially expressed miRNAs between C-EVs and LPS-EVs, with 16 up-regulated and 5 down-regulated in LPS-EVs. Pathway enrichment analysis showed that these miRNAs regulate critical pathways involved in inflammation, epithelial regeneration, and endothelial barrier integrity. RT-qPCR confirmed the overexpression of miR-297, let-7b-5p, and miR-93-5p in LPS-EVs, which significantly reduced the expression of pro-inflammatory cytokines—specifically IL1B, IL6, and IL8—in Pseudomonas aeruginosa-infected macrophage-like cells. Interestingly, only the combined administration of these three miRNAs induced a significant upregulation of M2-associated markers CD206 and CD163, as well as increased TGFβ expression, indicating a synergistic effect that promotes the polarization of THP-1 cells towards an M2 phenotype.
Conclusions: Our study reveals that LPS-priming of MSCs could enhance the immunomodulatory potential of their secreted EVs partly through the overexpression of miR-297, miR-93-5p, and let-7b-5p.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***925***

Introduction: Social interaction is a core function of health related quality of life and health status can directly impact the fulfilment of roles within society (Yuan et al., 2021). In addition to the presence of PICS many COVID-19 ICU Survivors also report enduring symptoms of pain, dyspnea and fatigue (Wiertz et al., 2022). Understanding COVID-19 ICU survivors experiences will facilitate the development of comprehensive rehabilitation programs.
Objectives: The aim of this study was to explore Covid 19 ICU survivors' experiences and perceptions of their participation in society.
Methods: Qualitative study based on an interpretive paradigm. Purposeful maximum variation sampling of participants enrolled in an umbrella study investigating the physical mental and cognitive outcome of COVID 19 ICU survivors up to three years of hospital discharge HREC S22/02/003_Covid-19. All participants provided written informed consent. In person semi structured interviews were conducted by PI, and transcribed verbatim. Inductive thematic analysis of data.
Results: Twelve participants were interviewed (Table 1) Four themes and nine subthemes emerged (Table 2). Survivors were still affected by their illness and hospitalisation three years after discharge from hospital.
Conclusions: COVID-19 ICU survivors experienced impact on all aspects of life i.e. physical; mental; spiritual; emotional; family; social; work. Moving forward, this data will inform the development of a holistic multi-sectoral approach to address the healthcare needs of Covid 19 ICU survivors.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***926***

Introduction: Timely discontinuation of mechanical ventilation (MV) is crucial to prevent complications such as diaphragm dysfunction, ventilator-associated pneumonia, and airway trauma(1). About 20% of patients in the intensive care unit face challenges when attempting to be removed from mechanical ventilation(2). We conducted an assessment to evaluate the effectiveness of a protocol that combines lung, diaphragmatic, parasternal intercostal muscle, and respiratory drive to anticipate the risk of extubation failure.
Objectives: The primary objective is to assess the predictive power of the combination of respiratory muscle strength, P0.1, and LUS for weaning failure from MV in critically ill patients. Secondary objectives include assessing extubation failure and the requirement for non-invasive respiratory support after extubation.
Methods: All patients who met the inclusion and exclusion criteria and were successfully extubated after a spontaneous breathing trial were included in the study. At the end of the spontaneous breathing trial, the lung ultrasound score (LUS), diaphragmatic thickness fraction (DTF), parasternal thickness fraction (PIMT), diaphragmatic excursion (DE), and respiratory drive were recorded. The change in LUS from the beginning of the spontaneous breathing trial was also recorded.
Results: An interim analysis of 72 patients out of a total sample size of 149 (Group S: $n = 57$, Group F: n = 15) revealed no significant differences in age, gender, height, weight, BMI, APACHE II, SOFA, and LUS score. However, diaphragm thickening fraction (DTF), diaphragm excursion (DE), parasternal intercostal muscle thickness (PIMTF), and P0.1 showed significant differences ($p < 0.001$) between groups.
Conclusions: Preliminary findings suggest a significant relationship between lower diaphragmatic thickness fraction, diaphragm excursion, parasternal muscle thickness fraction, and high drive associated with more failed weaning and tracheal extubation in mechanically ventilated patients. Further data collection and analysis are essential to confirm these trends and assess their clinical utility.

Table 1 (abstract 000926) xxxx

Characteristics	Group S (n=57)	Group F (n=15)	Total (n=72)	p-value
Age in years (Mean ± SD)	46.01 ± 15.3	45.9 ± 17.8	46.0 ±15.7	0.758

Introduction: Although central venous pressure (CVP) value and its interpretation could guide fluid resuscitation, it is less and less used in clinical practice (1-3). The potential clinical significance of a more precise analysis of CVP waveform among critically ill patients is still undetermined.
Objectives: We investigated whether changes in continuously monitored CVP waveform during ventilatory pauses and during passive leg raising (PLR) could detect differences between preload responders (R) and nonresponders (NR), as established by means of continuous, calibrated cardiac output (CO) monitoring.
Methods: We included critically ill patients receiving invasive mechanical ventilation, with no spontaneous breathing activity and in whom calibrated hemodynamic monitoring (PICCO2 system) was in place. CVP, intra-abdominal pressure, airway pressure, EKG, and invasive blood pressure were continuously recorded. With this monitoring, we performed three sets of 15-s inspiratory and expiratory pauses in semi-recumbent position (at 40°) and we repeated these measurements during a PLR test. Patients were defined as preload responders if PLR test produced an increase > 10% in CO (4), as established by analysis of PICCO2 data. We analyzed offline the CVP waveform and specifically measured: z-point, the amplitude of the (a-x) wave, and the magnitude of y descent.
Results: Analysis of the CVP waveform was completed in 28 patients (13 R, 15 NR), whose characteristics are reported in the Table. No significant difference in average CVP z-point was found between R and NR. However, CVP variability during the ventilatory pauses was larger in R than in NR (28.2% [20.2-36.2] vs. 16.9% [9.3-24.5], respectively, $p = 0.04$). Moreover, R patients showed a significatively smaller y-descent than NR (2.5 [1.6-3.4] vs. 4.1 [3.0-5.2] mmHg, respectively, $p = 0.02$) and a lower (a-x) amplitude (3.9 [2.7-5.2] vs. 6.5 [5.6-7.4] mmHg, respectively, $p = 0.002$) (Fig. 1). ROC curve analysis showed that (a-x) amplitude had better performance in detecting preload responsiveness than y-descent (AUC 0.86 [0.71-1.0], $p < 0.001$ and AUC 0.79 [0.62-0.96], p 0.01, respectively) (Fig. 2). Moreover, both variables performed better than standard monitoring of CVP value under the same conditions (AUC 0.76 [0.58-0.94], $p = 0.01$). Cutoff value for (a-x) amplitude at 5.47 mmHg detected R patients with 83% sensitivity and 80% specificity, whereas y-descent cutoff at 3.13 mmHg detected FR patients with 84% sensitivity and 67% specificity.

Table 1 (abstract 000927) xxxx

Variable	Mean (95% CI)
F/M ratio	10/18 (35%)
Age (years)	59 (31 – 78)
Body mass index (kg/m2)	28 (18 - 49)
SAPS-II at admission	47 (26 - 83)
ICU stay (days)	16 (4 - 51)
Time to inclusion (days)	4.05 (2.5 – 5.6)
Average ventilation (mL/kg IBW)	5.9 (5.7 – 6.2)
PaO2/FiO2 ratio at inclusion	154 (123.8 – 184.7)
Arterial lactates at inclusion	2.3 (1.5 – 3)
Noradrenaline dosage at inclusion (mcg/kg/min)	0.46 (0.2 – 0.6)
P(a-v)CO2/C(a-v)O2 ratio at inclusion	1.6 (0.9 – 2.3)
Primary diagnosis at admission	
Septic shock, n (%)	11/28 (39.3)
Acute respiratory distress syndrome, n (%)	11/28 (39.3)
Intoxication, n (%)	4/28 (14.3)
Others, n (%)	2/28 (7.1)

Conclusions: Components of the CVP waveform such as the y descent or the (a-x) wave amplitude, when precisely measured, seem to have higher performance in detecting preload responsiveness, than standard monitoring of CVP. Further investigation is ongoing.

Intensive Care Medicine Experimental 2025* 13(Suppl 1):*928

Introduction: Pulmonary embolism (PE) is a major thrombotic complication with high morbidity and mortality, especially in intensive care unit (ICU) patients. Its presentation is often nonspecific, complicating timely diagnosis. Although clinical risk factors are well known, genetic predisposition remains incompletely understood. Genome-wide association studies (GWAS) offer a means to identify common genetic variants contributing to PE susceptibility.
Objectives: To identify genetic variants associated with PE in a Swedish population and assess concordance with previous GWAS findings. We also performed exploratory GWAS restricted to ICU and postoperative subgroups to evaluate genetic determinants of PE in these high-risk settings.
Methods: We performed a GWAS using data from the Merged Anaesthesia and Intensive Care cohorts from Sweden (MAICS), including 57,423 individuals (2,277 PE cases and 55,146 controls). Logistic mixed-effect regression models were adjusted for age, sex, and population

structure. Median age was 70 years (IQR 14), and 63% of PE cases were male.

Results: Five loci with known roles in hemostasis and thrombosis reached genome-wide significance. On chromosome 1, a lead SNP in F5 (Factor V), a procoagulant in the coagulation cascade, was strongly associated with PE (β = -0.762 [ln(OR)], $P = 3.71 \times 10^{-}21$). An adjacent signal was detected near SELP, encoding P-selectin. On chromosome 4, two independent loci were found: one in FGA (fibrinogen alpha chain; $\beta = 0.289$ [ln(OR)], $P = 2.65 \times 10^{-}1^{6}$), linked to SELP expression in platelets; and another in F11 (Factor XI; $\beta = 0.238$ [ln(OR)], $P = 5.30 \times 10^{-}14$), near KLKB1. On chromosome 9, the lead SNP mapped to ABO ($\beta = 0.263$ [ln(OR)], $P = 3.00 \times 10^{-}1^{7}$), known to influence von Willebrand factor levels, with adjacent ADAMTS13 involved in clot degradation. On chromosome 11, associations were found at F2 (prothrombin; $\beta = 0.885$ [ln(OR)], $P = 1.24 \times 10^{-8}$), and at C11orf49 ($\beta = 0.894$ [ln(OR)], $P = 3.92 \times 10^{-8}$), a locus not previously linked to PE (Fig. 1). These loci highlight the roles of thrombin generation, fibrin polymerization, and platelet adhesion in PE pathophysiology (Fig. 2). No genome-wide significant variants were found in the ICU- or postoperative-specific analyses, likely due to limited power.

Conclusions: This study replicates known genetic associations with PE and identifies novel loci, including SELP and C11orf49. These findings advance understanding of PE risk and may inform future risk prediction strategies. This GWAS is ongoing, and the data presented are preliminary and unpublished.

Intensive Care Medicine Experimental 2025* 13(Suppl 1):*929

Introduction: Sepsis remains a leading cause of hospital admissions globally, characterized by life-threatening organ dysfunction due to a dysregulated host response to infection. This prospective observational study aimed to evaluate the prognostic value of various shock indices in adult patients with sepsis presenting to the emergency department.

Objectives: To study the role of various shock indices as a prognostic marker in the mortality of patients with sepsis within 28 days. The shock indices analyzed were: Shock Index (SI = HR/SBP), Modified Shock Index (MSI = HR/MAP), Reverse Shock Index (RSI = SBP/HR), Diastolic Shock Index (DSI = HR/DBP), Reverse Shock Index GCS (RSIG = SBP/HR × GCS), and Age Shock Index (ASI = HR/SBP × Age).

Methods: In this prospective observational study, 354 patients with clinical signs and symptoms consistent with sepsis were recruited from the emergency department from August 2023 to December 2024. The calculation of various shock indices was done at the time of presentation and at the 4th hour within the hospital. These patients were followed till 28th day for the clinical outcome.

Results: In the present study, the mean age was 47.2 years. Males were predominant (60.8%). Comorbidities included hypertension (20%), diabetes (20.5%), and COPD (3.8%). Intubation was required in 32.4%, while 19.7% underwent renal replacement therapy (RRT). Overall mortality was 20.3%. Significant predictors of mortality included low GCS, MAP, and SPO2, and elevated SI, SOFA, and RSIG scores. RRT, intubation, and comorbid conditions were significantly associated with higher mortality. The ideal RSIG cutoff for predicting survival was ≥ 11.18, with 81.4% sensitivity and 80.0% specificity.

Conclusions: The study supports the clinical utility of shock indices—especially RSIG—as early, non-invasive prognostic tools in emergency settings. These findings highlight the importance of early recognition and aggressive intervention based on hemodynamic markers to improve sepsis outcomes.

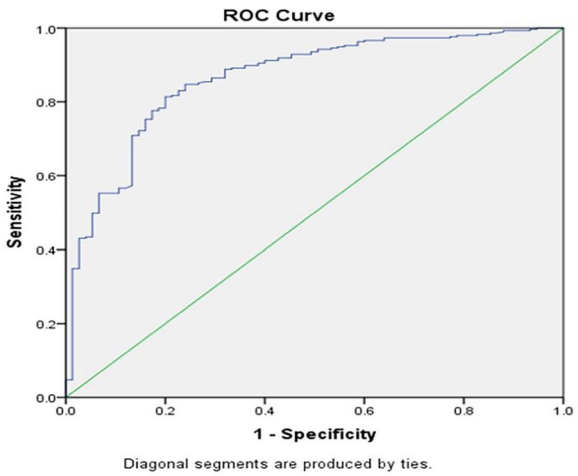

Fig. 1 (abstract 000929) ROC curve for reverse shock index GCS (RSIG) to predict survival

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***930***

Introduction: Fluid challenge (FC) is essential in critically ill patients' resuscitation, with transthoracic echocardiography (TTE) as a key bedside tool for assessing hemodynamic effects. However, most Doppler-derived indices, including cardiac index (CI), evaluate systolic or diastolic function separately and are preload-dependent. In contrast, the myocardial performance index (MPI), derived from tissue Doppler imaging (TDI-MPI), is minimally preload-dependent and integrates both phases within a single cardiac cycle, reflecting the ratio of energy-consuming isovolumic periods to effective ejection time. Elevated TDI-MPI denotes impaired global cardiac function. We hypothesize that TDI-MPI offers a practical and integrated approach to assess the hemodynamic effects of FC in critically ill patients.
Objectives: To evaluate the effects of FC on TDI-MPI in critically ill patients and to assess whether MPI normalization correlates with fluid responsiveness. In addition, we compared TDI-MPI changes between patients with and without diastolic dysfunction.
Methods: We conducted a prospective observational study involving ICU patients who received a 4 mL/kg FC of crystalloids. TDI-MPI was calculated as the ratio of isovolumic relaxation (IVRT) and contraction time (IVCT) divided by ejection time (ET), assessed using TTE before and after the FC within a single cardiac cycle. Fluid responsiveness was defined as a ≥ 15% CI increase. TDI-MPI normalization was defined as a reduction from abnormal (≥ 0.42) to normal (< 0.42) or the maintenance of normal values. Diastolic dysfunction was defined by an early diastolic mitral inflow velocity to early diastolic mitral annulus velocity (E/E') ratio of > 8 before the FC.
Results: Among 59 patients, 24 (41%) were fluid responders. TDI-MPI significantly decreased in responders (0.48 [0.43-0.58] to 0.42 [0.33-0.54], p < 0.01) but remained unchanged in non-responders (p = 0.28). MPI normalization was associated with fluid responsiveness (OR 3.37, 95% CI 1.12-10.78, p = 0.03). Responders exhibited a greater decrease in IVRT compared to IVCT, while nonresponders showed negligible changes in these two variables. The ET was elevated in both groups after FC. Patients with diastolic dysfunction displayed more dynamic TDI-MPI changes. Responders in this subgroup experienced a marked reduction in TDI-MPI, whereas nonresponders exhibited a more pronounced increase in MPI as compared to those without diastolic dysfunction, with these changes driven by substantial IVRT shortening or prolongation, respectively.
Conclusions: TDI-MPI provides an integrated, beat-to-beat assessment of FC response by capturing both systolic and diastolic adaptations, particularly in those with baseline diastolic dysfunction. These findings support the incorporation of TDI-MPI into routine bedside TTE to guide fluid management, offering a more physiologically meaningful evaluation than CI alone.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***931***

Introduction: Some septic patients recover, while others develop chronic critical illness (CCI) and persistent inflammatory, immunosuppression, and catabolism syndrome (PICS), characterized by prolonged organ dysfunction, protein catabolism, sarcopenia and increased vulnerability to secondary infections. This in turn leads to poor functional outcomes and indolent death1.
Objectives: To evaluate predictive and prognostic factors for CCI and PICS phenotype in Medical ICU septic patients.
Methods: Prospective observational study. Septic patients who developed CCI (and PICS) were compared to non-CCI, based on the previously published definitions[1]. CCI: at least 2 clinical criteria on 7thday of ICU (prolonged mechanical ventilation, tracheostomy, recurrent infections, severe wounds, MOF, malnutrition, weakness, and cognitive impairment). PICS: subset of CCI persisting beyond day 14 in ICU or hospital ward plus at least 1 analytical criterion (CRP > 1.5 mg/L, albumin < 3 g/dl, prealbumin < 10 mg/dl, or lymphocyte count < 800). Clinical and analytical variables, including circulating histones[2], were assessed at ICU admission as well as outcomes. Univariate analysis was performed. A p value < 0.05 was considered statistically significant.
Results: 94 patients were included over a 4-year period; 36% with S and 63.8% SS. 35p. (37.2%) met criteria for CCI, representing 8% of all septic ICU admissions during the study period. Of these, 29 developed PICS, while the remaining 6 non-PICS died during the 2nd week of ICU stay. 59 patients comprised the non-CCI, of whom 54 (91.5%) were discharged from ICU within the 1st week. Baseline clinical and analytical variables are shown in Table 1. Early follow-up revealed significantly higher 28-day mortality in the CCI group compared to non-CCI [9 (25.7%) vs. 6 (10.2%); OR = 2.52 [0.98-6.50]; p = 0.04], as well as longer ICU length of stay (17.34 ± 12.1 vs. 4.19 ± 2.79 days; p = 0.001) and hospital stay (34.2 ± 25.53 vs. 14.83 ± 25.1 days; p = 0.001). Six-month mortality was also higher in the CCI group [12 (34.3%) vs. 10 (16.9%); OR = 2.02 [0.97-4.18]; p = 0.049] (Fig. 1). No differences were observed in long-term functional outcomes, as assessed by the SF-36 questionnaire (558.59 ± 152.51 vs. 571.95 ± 146.67 points, P = NS). (Table 1).

	CCI (*N* = 35)	**Non-CCI (*N* = 59)**	***P* value**
Age (years)	57.31 ± 10.69	64.57 ± 13.73	***p* = 0.009**
APACHE II score	20.79 ± 6.08	16.7 ± 7.3	***p* = 0.01**
SOFA score 1st day	8.29 ± 3.59	6.2 ± 2.88	***p* = 0.004**
Septic Shock	23 (68.6%)	36 (61%)	NS
ISTH overt DIC	3 (8.8%)	6 (10.2%)	NS
Lactate Clearance	13 (37.1%)	41 (69.5%)	***p* = 0.002**
Charlson Index	2.86 ± 2.01	3.37 ± 2.2	NS

	CCI (*N* = 35)	Non-CCI (*N* = 59)	*P* value
C. Clinical Frailty Scale	2.55 ± 1.27	2.57 ± 1.3	NS
Analytical serum data 1st day:			
White blood cells	17,386 ± 11,463	17,584 ± 10,993	NS
CRP (mg/l)	262.78 ± 133.45	290.05 ± 132.29	NS
Procalcitonin (ng/mL)	56.33 ± 4.39	53.58 ± 3.23	NS
H2B (ng/ml)	1161,69 ± 414,03	16,185,69 ± 12,891,36	NS
H3 (ng/ml)	235,33 ± 59,52	1792,43 ± 1380,39	NS
Creatinine (mg/dl)	1,94 ± 0.28	1.90 ± 0.20	NS

Conclusions: We confirmed the previous data regarding the bad prognosis of CCI including PICS in a specific septic medical population although age and frailty conditions did not contribute to this phenotype. CCI appears to come from a lower level of circulating histones. Wide studies are necessary to help predicting this ominous entity.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**)***:932***

Introduction: The International COSMOS Registry prospectively collects real-world data on the use of CytoSorb (CS) hemoadsorption in critically ill patients.

Methods: Following informed consent, critically ill patients treated with CS as part of routine clinical care were enrolled in the registry. Data collection timepoints included: 24 h prior, during and 24 h after CS treatment, at discharge from both ICU and hospital, and again at the 90-day follow-up. Data are presented as either mean ± standard deviation or as median with interquartile range [Q1 — Q3].

Results: A total of 280 consecutive eligible patients (31% female, mean age 58 ± 17 years, mean APACHE II and SOFA scores on admission of 24 [18 — 30] and 12 [9 — 15], respectively) from 20 centers across Germany, Italy, Spain and Portugal were enrolled. The indications for CS (with some patients having multiple indications) included septic shock (54%), rhabdomyolysis (14%), cardiogenic shock (13%), acute or acute-on-chronic liver failure (13%), ARDS (6%) and other (12%). On average, each patient received 3.3 ± 3.4 adsorbers, with 27% receiving four or more. CS was applied in conjunction with renal replacement therapy (88%), standalone hemoperfusion (7%) or ECMO (5%). After CS application, IL-6 was significantly lowered (from 574 [187 — 20,358] pg/mL to 100 [49 — 1,299]; $p < 0.0001$), as norepinephrine doses (from 0.20 [0.09 — 0.39] to 0.08 [0.02 — 0.20] µg/kg/min; $p < 0.0001$, Fig. 1), while daily fluid balance was reduced (from + 1400 [+ 84 — + 3,197] mL to + 180 [− 840 — + 1,500] mL; $p < 0.0001$). The PaO2/FiO2 ratio also significantly increased (from 132 [72 — 217] to 178 [115 — 254] mmHg; $p < 0.0001$). Platelet count dropped significantly after CS compared to baseline (from 123/nL [74, 181] to 75/nL [42, 121]; $p < 0.0001$), in particularly among septic patients. In patients with rhabdomyolysis ($n = 36$), median myoglobin levels were significantly reduced (from 11,799 [2,877 — 34,275] to 2959 [1252 — 7,008] µg/L; $p < 0.0001$), as bilirubin in patients with liver failure (n = 34) from 15.0 [7.3 — 22.2] to 8.1 [5.6 — 11.9] mg/dL; $p = 0.0015$). ICU mortality was 31.9% (32.4% in the septic shock group).

Conclusions: In this international, multi-center, prospective real-world registry, CS was associated with significant clinical improvements in hemodynamics, fluid balance and oxygenation. Significant reductions were seen in inflammatory markers, platelets, as well as myoglobin in rhabdomyolysis and bilirubin in liver failure cases.

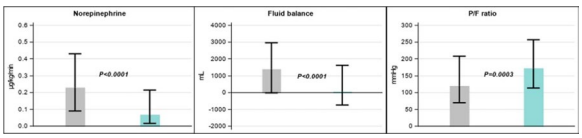

Fig. 1 (abstract 000932) Changes in norepinephrine, fluid balance and P/F ratio in 24 h periods before (grey) versus after CytoSorb® treatment (blue), data are presented as median and interquartile range

Topic: Acute kidney injury and hemofiltration

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***933***

Introduction: Sepsis is a life-threatening organ dysfunction caused by a dysregulated host response to infection (1). In cases of endotoxemia or Gram-negative sepsis, excessive activation of the coagulation cascade leads to disseminated intravascular coagulation (DIC)—a life-threatening coagulopathy that promotes multiple organ dysfunction. The occurrence of DIC significantly increases mortality in sepsis, which remains one of the leading causes of death in hospitals (3).
A study on sepsis-associated DIC demonstrated that bacterial endotoxin activates the extrinsic coagulation pathway through tissue factor, which is triggered by caspase-11. This process promotes the formation of gasdermin pores and exposure of phosphatidylserine, thereby activating the coagulation cascade (3). In sepsis patients, activation of the pyroptosis pathway amplifies inflammatory responses in tissues and contributes to the development of organ failure (1-2). However, there is limited information on the interaction between pyroptosis and gasdermin D in the pathology of sepsis and DIC. Our aim is to reveal the clinical impact of this pathway, specifically the role of pyroptosis, and to determine the predictive and prognostic value of Gasdermin D levels in DIC development in patients with sepsis.
Methods: The study was prospective, observational and conducted between March 2024 and May 2024 at two centers. Ethical approval was obtained (approval number:TBAEK-72). Patients diagnosed with sepsis based on the Surviving Sepsis Campaign Guidelines 2021 and those who scored ≥ 5 according to the International Society of Thrombosis and Hemostasis (ISTH) DIC scoring system were included in the study. Patients with the following diagnoses were excluded: bone marrow transplantation, dysfibrinogenemia, hemolytic uremic syndrome, immune thrombocytopenia, thrombotic thrombocytopenic purpura, heparin-induced thrombocytopenia, catastrophic antiphospholipid syndrome, and liver cirrhosis. Patients with sepsis (n = 20) and DIC (n = 17) were included in the study and blood samples were taken. Plasma IL-1β (BT LAB Shanghai, China), IL-6 (Invitrogen, USA), IL-18 (Elabscience, USA), Toll-Like Receptor 4 (TLR4) (Elabscience, USA), Tumor Necrosis Factor α (TNFα) (Quantikine, USA), Transforming growth factor β TGF-β (Elabscience, USA) and Gasdermin D (Sun Red, Shanghai, China) ELISA kits were used. Readings and evaluations were made using Thermo Microplate Spectrophotometer.
Results: The mean age of the study population was 65.4 ± 15.3 (between 30.0 and 89.0) years, and 29.7% (11 patients) of whole group was female. There was no difference between groups regarding age, sex, multimorbidity, history of malignancy and hospitalization in ICU (p > 0.05) The main clinical and demographic characteristics of the study population is shown in Picture 1. The levels of inflammatory markers measured on the day of diagnosis in sepsis and DIC patients are presented in Picture 2. Inflammatory markers related to IL-6, IL-1B, TNF-A, TLR-4, IL-18 and TGF-B were significantly higher in the DIC group. The ROC curve and analysis are presented in Fig. 1-2. The predictive effect of gasdermin-D on DIC was analyzed and the AUC was found 0.774 (95% CI. 618-0.929) indicating that Gasdermin-D has good discriminatory ability for DIC. The cutoff value for the prediction of DIC was determined as 1.058 with 88.2% sensitivity and 65.0% specifity.
Conclusions: In our study, we observed that Gasdermin D levels, which play a role in the activation of inflammatory pathways in sepsis, were significantly and markedly elevated in patients with DIC. These findings suggest that Gasdermin D may serve as a valuable predictive marker for the development of DIC in sepsis patients, a condition associated with high mortality in intensive care units.

Alterations of lung microbiota in sepsis-induced acute respiratory failure

Y. Tang[1], Y. Jing[1], Y. Kang[1]
[1]Department of Critical Care Medicine, West China Hospital, Sichuan University, Chengdu, China

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***934***

Introduction: Patients with sepsis-induced acute hypoxic failure (ARF) are hallmarked by high mortality rates. Different initial sites of infection are likely to affect the composition and diversity of the pulmonary microbiome in patients with septic ARDS. The clinical significance of altered lung bacteria in extrapulmonary sepsis-induced ARF is unknown.
Methods: We performed a prospective, observational cohort study of patients after surgery for gastrointestinal perforation in an ICU at a university hospital. The bronchoalveolar lavage fluid of mechanically ventilated patients was collected within 48 h of intubation. We sequenced the DNA in the bronchoalveolar lavage fluid collected from patients using metagenomic next-generation sequencing to analyze the changes in the lung microbiome.
Results: A total of 30 patients with gastrointestinal perforation were enrolled in the study, 20 patients who develop ARF after surgery and 10 patients who does not.
The alpha diversity was significantly decreased in ARF patients compared with that of the patients without ARF. The lower airway bacteriobiota and mycobiota compositions (β-diversity) were dissimilar between patients with ARF and without ARF.
Conclusions: Extrapulmonary sepsis-induced ARF is associated with a significant dysbiosis of patients' pulmonary-microbiom.

Bioinformatic analysis of metagenomic sequencing data in the exploratory cohort.

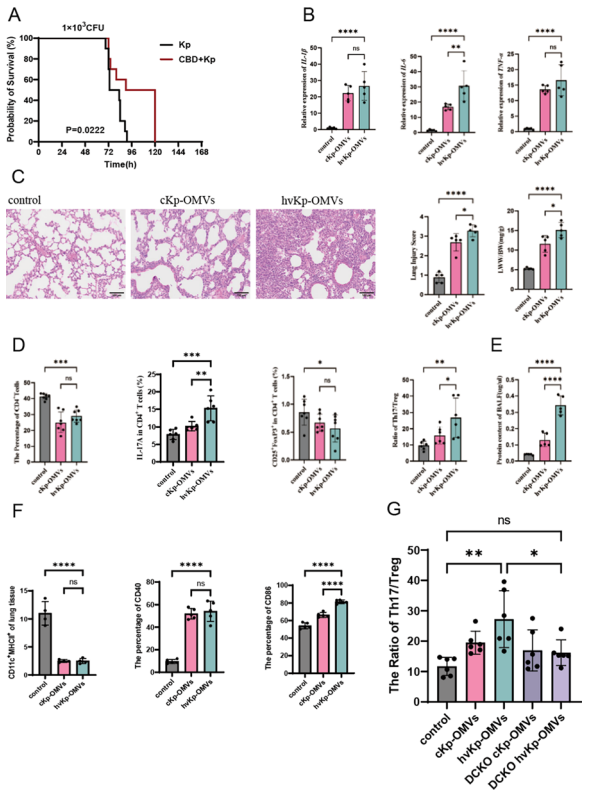
The role of *Klebsiella pneumoniae* outer membrane vesicles in modulating dendritic cell phenotypes and immune imbalance in acute respiratory distress syndrome



SS. Meng[1], Y. Zhang[1], Y. Tang[1], FM. Guo[1]
[1]Department of critical care medicine, zhongda hospital, school of medicine, Southeast University, Nanjing, Jiangsu, China

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***936***

Introduction: Acute respiratory distress syndrome (ARDS) is a critical condition characterized by severe pulmonary inflammation and immune dysregulation. *Klebsiella pneumoniae* (Kp) is a major bacterial pathogen associated with ARDS, especially in immunocompromised individuals. The recent studies highlight the immunomodulatory role of outer membrane vesicles (OMVs) derived from Kp, yet their effects on dendritic cells (DCs) and downstream T cell responses remain unclear. OMVs are nanoscale vesicles released by Gram-negative bacteria that carry bioactive molecules capable of influencing host immunity. In this study, we explored how Kp-derived OMVs affect DC phenotype and function, and how these changes contribute to the imbalance between Th17 and regulatory T (Treg) cells during ARDS. Using both wild type and DC-depleted mouse models, we demonstrate that Kp-OMVs promote DC maturation and skew $CD4^+$ T cell differentiation toward a Th17-dominant profile, contributing to immune imbalance in ARDS,
Objectives: This study aimed to investigate the role of outer membrane vesicles (OMVs) derived from Klebsiella pneumoniae (Kp) in modulating dendritic cell (DC) phenotypes and their impact on the Th17/Treg balance during the development of acute respiratory distress syndrome (ARDS).
Methods: Kp was cultured overnight in Luria-Bertani (LB) broth to isolate OMVs, which were subsequently characterized by transmission electron microscopy (TEM) and nanoparticle tracking analysis

(NTA). Wild-type (WT) and diphtheria toxin receptor transgenic (DTR) mice were administered Kp-OMVs intratracheally to establish an ARDS model, while control mice received an equal volume of PBS. After 48 h, the following assessments were conducted: (1) histopathological analysis of lung tissue using hematoxylin and eosin (H&E) staining to quantify lung injury scores; (2) quantification of inflammatory cytokines by real-time quantitative reverse transcription PCR (RT-qPCR); (3) flow cytometric analysis of naïve $CD4^+$ T cell differentiation in bronchial lymph nodes; (4) evaluation of OMV uptake by immune cells following intratracheal administration of DiD-labeled Kp-OMVs. Bone marrow-derived dendritic cells (BMDCs) were generated from WT mice and stimulated with OMVs for 24 h. Flow cytometry was used to assess changes in DC phenotype and function, including cytokine expression.

Results: TEM and NTA confirmed that purified Kp-OMVs were spherical or ovoid with an average diameter of approximately 120 nm, and sterility was verified via plate assays. Compared to the control group, mice in the disease model group exhibited pronounced inflammatory cell infiltration, tissue edema, and alveolar destruction, with significantly increased lung injury scores, lung wet-to-dry weight ratios, pro-inflammatory cytokine levels, and protein content in bronchoalveolar lavage fluid. Flow cytometry revealed that Kp-OMVs promoted naïve $CD4^+$ T cell differentiation into Th17 cells while suppressing Treg differentiation, leading to Th17/Treg imbalance. Uptake of Kp-OMVs by T cells was markedly lower than by DCs, suggesting that OMVs modulate immune responses primarily through DCs. Kp-OMVs significantly upregulated MHC II, CD86, and CD40 expression on DCs. Selective depletion of DCs in DTR mice via intraperitoneal injection of diphtheria toxin (150 ng/mouse) reversed the Th17/Treg imbalance observed in the ARDS model.

Conclusions: This study demonstrates that Kp-OMVs promote DC maturation and drive naïve $CD4^+$ T cell differentiation toward the Th17 lineage, contributing to immune imbalance in ARDS. These findings provide novel insights into the immunopathogenesis of Kp-induced ARDS and suggest potential targets for therapeutic intervention.

Klebsiella pneumoniae outer membrane vesicles drive dendritic cell polarization and immune dysregulation in acute respiratory distress syndrome

A Kaplan–Meier survival analysis revealed a significant difference between groups, with the Gehan–Breslow–Wilcoxon test showing improved survival in the CBD + Kp group compared to Kp alone ($p = 0.0222$).CBD, Cannabidiol, Inhibit vesicle secretion.

B mRNA expression levels of pro-inflammatory cytokines (IL-1β,IL-6, and TNF-a) in lung tissue, quantified by quantitative real-time PCR (qRT-PCR).

C Representative images of hematoxylin and eosin (HE)-stained lung tissue sections and corresponding lung Inury scores, assessed based on alveolar wall thickness, hemorrhage, and inflammatory cell infiltration.

D Total protein content in bronchoalveolar lavage fluid (BALF).

E Flow cytometry was performed to assess naïve $CD4^+$ T cell differentiation in mouse bronchial lymph nodes 48 h post-modeling. The proportions of intracellular IFN-γ, IL-17A, and CD25 + FoxP3 + within $CD4^+$ T cells were analyzed. Data are presented as mean ± SD from triplicate assays and were analyzed by one-way ANOVA (*$p < 0.05$, **$p < 0.01$, and ***$p < 0.001$ vs. control). Group abbreviations: cKp-OMVs, classical *Klebsiella pneumoniae* outer membrane vesicles; hvKp-OMVs, hypervirulent *K. pneumoniae* OMVs.

F Single-cell suspensions from lung tissue were prepared 48 h post-ARDS induction. Expression levels of $CD11c^+MHCII^+$ dendritic cells, CD86, and CD40 on DCs were assessed by flow cytometry. Data are presented as mean ± SD from triplicate experiments and analyzed using one-way ANOVA. **** $p < 0.0001$ vs. Control.

G Selective depletion of dendritic cells (DCs) in DTR mice via intraperitoneal injection of diphtheria toxin effectively reversed the Th17/Treg imbalance observed in the ARDS model. Data are expressed as mean ± SD from triplicate experiments and were analyzed using one-way ANOVA ($p < 0.05$, $p < 0.01$). Group abbreviations are as follows: NODT cKp-OMVs, non-depleted classical *Klebsiella pneumoniae* outer membrane vesicles; NODT hvKp-OMVs, non-depleted hypervirulent *K. pneumoniae* OMVs; DCKO cKp-OMVs, DC-depleted classical *K. pneumoniae* OMVs; DCKO hvKp-OMVs, DC-depleted hypervirulent *K. pneumoniae* OMVs.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***938***

Introduction: Acid–base is commonly deranged during open-heart surgeries, but there is limited data of how this influences the outcome.
Objectives: The aim of the present study was to analyze the acid–base status of cardiac surgical patients who were admitted to the Intensive Care Unit (ICU) and investigate whether acid–base disorders are correlated with extubation time.

Methods: This is a retrospective study conducted in the ICU of a tertiary University Hospital between August 2023 and January 2025. Acid–base, demographic, clinical and biochemical data from cardiac surgical patients admitted to the ICU for postoperative care were collected at admission. Time to extubation and ICU length of stay were included. Quantitative acid–base analysis was based on the principles of physicochemical (Stewart) approach.
Results: The results are expressed as median values (1st, 3rd quartiles). 118 patients aged 65.5 (59.3, 72) years old were included. Coronary artery bypass surgery was the primary indication for ICU admission. Acid–base analysis indicated pH 7.31 (7.31, 7.36), partial pressure of carbon dioxide (PaCO2) 44 (40, 47) mmHg, strong ion difference effective (SIDe) 34.35 (32.15, 36.18), strong ion difference apparent (SIDa) 46.5 (44.7, 48.35) and strong ion gap (SIG) 12.4 (10.1, 14.95). Laboratory tests revealed an albumin concentration of 3.3 (2.8-3.5) g/dl and a phosphate concentration of 3.9 (3.4-4.7) mg/dl. Patients had a median time to extubation of 12 (5-22) hours and a median ICU stay of 2 (2,3) days. In the multivariable Cox proportional hazards regression analysis higher values of noradrenaline (NA) (mcg/kg/min), transfused red blood cells (RBCs) and SIG were the only factors independently associated with prolonged time to extubation (Table 1).

Table 1 (abstract 000938) Multivariable regression analysis on factors associated with time to extubation. Values are expressed as mean (standard deviation)

Time to extubation	all	HR (univariable)	HR (multivariable)
NA dose	0.2 (0.1)	0.01 (0.00-0.07, $p < 0.001$)	0.02 (0.00-0.19, $p = 0.001$)
age (years)	65 (9.0)	1.02 (0.99-1.04, $p = 0.173$)	1.02 (0.99-1.06, $p = 0.128$)
BMI (kg/m2)	29.1 (4.8)	1.01 (0.96-1.05, $p = 0.783$)	0.97 (0.92-1.02, $p = 0.272$)
Extracorporeal duration (hrs)	122.6 (43.0)	0.99 (0.99-1.00, $p = 0.041$)	1.00 (0.99-1.00, $p = 0.395$)
RBCs	0.4 (1.0)	0.73 (0.58-0.91, $p = 0.006$)	0.60 (0.45-0.81, $p = 0.001$)
PaO2/FiO2	294 (114)	1.00 (1.00-1.00, $p = 0.055$)	1.00 (1.00-1.01, $p = 0.054$)
PH	7.3 (0.0)	7.8 (0.09-671.9, $p = 0.365$)	3.38 (0.01-1641.7, $p = 0.7$)
PCO2 (mmHg)	44.9 (9.6)	1.01 (0.98-1.03, $p = 0.593$)	1.01 (0.99-1.04, $p = 0.32$)
SIDe	34.3 (2.7)	1.09 (1.01-1.18, $p = 0.026$)	0.98 (0.87-1.1, $p = 0.688$)
SIG	11.9 (3.6)	0.87 (0.81-0.93, $p < 0.001$)	0.88 (0.82-0.95, $p = 0.002$)

BMI = body mass index

Conclusions: Acid–base status of cardiac surgical patients on ICU admission is characterized by mild acidemia and multiple acid–base disorders. SIG along with other factors is significantly associated with extubation time.

Introduction: During a hyper-inflammatory state, such as sepsis, glycocalyx degradation can lead to exposure of the procoagulant endothelial surface, which is associated with worse outcomes. Resuscitation using crystalloids may worsen endotheliopathy. There is increasing evidence showing plasma transfusion might preserve glycocalyx health. We hypothesized that resuscitation with plasma reduces glycocalyx degradation and inflammation in a controlled human endotoxemia model.
Objectives: To investigate the effects of plasma versus crystalloid infusion on the development of glycocalyx degradation, endotheliopathy, and inflammation in a human volunteer lipopolysaccharide (LPS) induced endotoxemia model.
Methods: This study was a human volunteer, open-label, randomized study. Volunteers were injected with 2.0 ng/kg lipopolysaccharide to induce endotoxemia, which is a controlled systemic inflammatory response, similar to that observed in sepsis. Thirty minutes following LPS administration, participants received either 10 mL/kg balanced salt solution (BSS) or 10 mL/kg solvent detergent plasma (SDP). The primary outcome was the difference in syndecan-1, as a reflection of glycocalyx degradation, between groups. Neutrophil count and plasma levels ICAM-1 and MMP-9 were measured as markers of endotheliopathy and inflammation. Plasma levels of myeloperoxidase (MPO) were measured to assess neutrophil extracellular trap (NET)-formation. All measurements were performed at 2-h intervals.
Results: LPS induced an inflammatory response with tachycardia (Fig. 1), fever, a decrease in monocyte count and an increase in inflammatory cytokine levels and cardiac output but did not elevate lactate or prolonged capillary refill time. Subjects developed mild endothelial injury with increased levels of syndecan-1 ($p < 0.05$) and ICAM-1 ($p < 0.001$) (Fig. 1). Over the duration of the experiment, participants receiving SDP had lower levels of neutrophils ($p < 0.05$) and matrix metalloproteinase-9 (MMP-9) ($p < 0.01$) when compared with those receiving BSS (Fig. 1). However, markers of glycocalyx degradation (syndecan-1) and markers of NET formation did not differ between groups (Fig. 1).
Conclusions: In human endotoxemia, as plasma compared to crystalloid resuscitation reduced inflammation with decreased neutrophil counts, with a concomitant reduction of MMP-9, while not affecting endothelial injury and glycocalyx degradation.

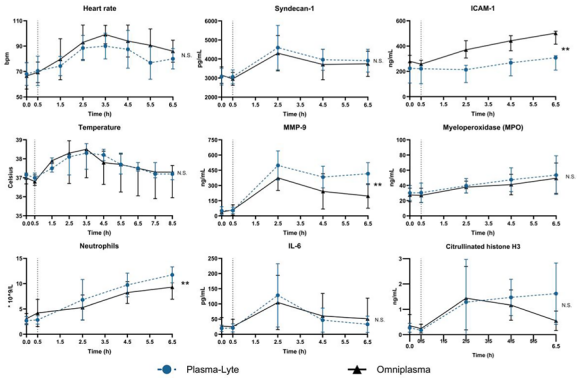

Fig. 1 (abstract 000939) Lipopolysaccharide was given to all volunteers at $T = 0$, the vertical dashed line represents the timepoint resuscitation was started. N.S = not significant, *$p < 0.05$, **$p < 0.01$, ICAM-1 = Intercellular Adhesion Molecule 1, MMP-9 = matrix metalloproteinase 9

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***940***

Introduction: COVID-19, caused by SARS-CoV-2 infection, has created devastating worldwide consequences for both public health systems and economic stability [1]. Emerging evidence indicates that COVID-19 with acute respiratory distress syndrome (ARDS) often presents high respiratory drive and excessive inspiratory efforts and that this could lead to a relapse of respiratory failure [2]. Mechanical signals transduced by airway-innervating sensory neurons control respiratory drive. Specifically, PIEZO2 in sensory neurons is essential for the Hering–Breuer mechanoreflex, and its ablation results in an increased tidal volume under normal conditions [3]. It is noteworthy that our previous whole exome sequencing, which aimed to explore the relationship between genetic variants and ARDS, identified four single nucleotide polymorphisms (SNPs) of PIEZO2 (rs73943314, rs9954308, rs875956 and rs2277858) associated with ARDS outcomes [4]. However, whether these PIEZO2 SNPs are associated with COVID-19 outcomes remains unclear.
Objectives: To investigate the association between SNPs of PIEZO2 and clinical outcomes in COVID-19 patients.
Methods: This observational, single-center cohort study was conducted at Zhongda Hospital, Southeast University, China, between December 1, 2022, and January 31, 2023. Inclusion criteria were adult patients (aged ≥ 18 years) with confirmed SARS-CoV-2 infection, defined by at least one positive real-time reverse transcription polymerase chain reaction (RT-PCR) test result. Exclusion criteria were inability to provide informed consent, death within 24 h of admission, pregnancy or lactation. PIEZO2 single nucleotide polymorphisms (SNPs) rs73943314, rs9954308, rs875956, and rs2277858 were genotyped using Sanger sequencing. The primary outcome was overall 28-day mortality. Genotype distributions at individual SNP loci were compared using χ^2 tests. We employed univariate logistic regression followed by multiple logistic regression to evaluate associations between PIEZO2 minor allele genotypes and 28-day mortality.
Results: A total of 348 patients were screened, and we enrolled 313 patients in the study. Including 270 survivors, median age was 76 years (IQR 64.0-83.0). For non-survivors (n = 43), median age was 78, and more patients transferred ICU for further management (10.4% vs. 48.8%, $p < 0.001$). Non-survivors had a significantly higher SOFA score (2.0 vs. 7.0, $p < 0.001$), neutrophil-to-lymphocyte ratio (6.6 vs. 9.7, $p < 0.001$). The genotype frequencies observed in this study did not deviate from the expected frequencies under Hardy–Weinberg Equilibrium ($p > 0.05$). For these SNPs, we calculated linkage disequilibrium (LD) with PIEZO2 variants. rs73943314 and rs9954308 (LD, $r2 = 1$), rs875956 and rs2277858 (LD, $r2 = 1$) are complete linkage disequilibrium. The PCR products containing SNPs were TA cloned, and positive clones were sequenced, which also confirmed that they are completely linked. rs73943314 and rs875956 (LD, r2 = 0.26) are incomplete linkage disequilibrium. The minor allele frequency (MAF) was greater for the four SNPs of PIEZO2 (rs73943314 and rs9954308, 18.6% vs. 8.0%, $p < 0.001$; rs875956 and rs2277858, 34.9% vs. 12.4%, $p < 0.001$) in non-survivors than in survivors. To determine whether PIEZO2 SNPs are independently associated with a poor prognosis in COVID-19, we conducted multiple logistic regression analysis, including both variant pairs in the same model. We found that PIEZO2 rs875956 CT/TT genotype and rs2277858 TC/CC genotype were independent prognostic risk factors (OR = 5.42, 95%CI 1.79-17.97, $p = 0.004$).
Conclusions: In this study, we found that PIEZO2 SNPs (rs875956, rs2277858) genotypes serve as novel genetic factors that significantly influence the 28-day mortality in COVID-19 patients.

Mechanisms of neurofunctional recovery post-liver transplantation: a comprehensive analysis based on electroencephalography and metabolomics

T. Wang[1], M. Zhou[1]
[1]Department of Critical Care Medicine, Anhui provincial hospital, Hefei, China

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***943***

Introduction: Liver transplantation is a key therapeutic approach for patients with end-stage liver disease, but the changes in neurological function and the mechanisms of recovery postsurgery are not fully understood, and there is a lack of systematic neurological monitoring and comprehensive evaluation [1-3]. Mounting evidence suggests that metabolites substantially influence brain physiology and pathophysiology [4].
Objectives: This study aims to assess the neurological damage and repair mechanisms in patients before and after liver transplantation by integrating electroencephalogram (EEG) data and metabolomics data, providing strong biomarkers and technical support for early diagnosis and intervention.
Methods: We included 18 patients who underwent liver transplantation and recorded their resting-state EEG data both preoperatively and three weeks postoperatively. Plasma samples were also collected preoperatively and three weeks postoperatively for nontargeted metabolomics analysis to identify key metabolic products and pathway changes.
Results: The results show that compared with presurgery, the EEG power spectral density of these patients post-transplantation showed a significant increase in the alpha, beta, theta and delta frequency bands (Fig. 1). The main changes in brain network functional connectivity postsurgery were also concentrated in the alpha and beta frequency bands, involving important areas, such as the premotor cortex, primary motor cortex, and sensorimotor cortex, suggesting an improvement in neurological function after surgery. Further analysis showed a significant decrease in the levels of brain injury biomarkers in the postoperative plasma of patients. Moreover, we performed nontargeted metabolomics to profile and analyze alterations in plasma metabolites of transplant patients presurgery and post-surgery, revealing a significant postoperative increase in S-methyl-5′-thioadenosine (MTA) levels (Fig. 2A-C). Subsequent patch–clamp electrophysiological recordings in mouse brain slices demonstrated that MTA administration enhanced ion channel activity and promoted neuronal activation (Fig. 2D). These results suggest that metabolic pathway remodeling, potentially driven by MTA-mediated mechanisms, may critically contribute to restoring neuronal activity and cognitive recovery in these patients.
Conclusions: In conclusion, this study not only provides the first detailed description of the impact of liver transplantation on neural network connectivity but also further confirms the important role of improved metabolic pathways in restoring neuronal activity and cognitive function after transplantation.

Hypoxia-driven DNT cell activation in bronchoalveolar lavage fluid predicts acute rejection after lung transplantation

F. Xu[1], M. Zhou[1]
[1]Department of Critical Care Medicine, Anhui provincial hospital, Hefei, China
Correspondence: M. Zhou
Intensive Care Medicine Experimental 2025* 13(Suppl 1):*944

Introduction: Lung transplantation serves as the definitive therapeutic intervention for end-stage pulmonary diseases; however, long-term survival of lung allograft recipients remains suboptimal compared to other solid organ transplants, primarily attributable to chronic lung allograft dysfunction (CLAD)-related mortality [1-2]. The current gold-standard surveillance modalities such as transbronchial biopsies are invasive and lack sensitivity for early CLAD detection [3]. Crucially, the pathophysiological underpinnings linking CLAD progression to early post-transplant mortality, particularly hypoxia-driven immune dysregulation in the early post-transplant phase, remain poorly characterized [1-3].
Objectives: This study integrates multi-omics approaches to elucidate the pathological role of double-negative T (DNT) cells in early-stage allograft rejection and investigate hypoxia-mediated immunoregulatory networks contributing to adverse outcomes.
Methods: Flow cytometry was performed on bronchoalveolar lavage fluid (BALF) from 17 recipients during the early postoperative period. Two external transcriptomic datasets (N = 16) were analyzed to validate immune cell-specific markers [4]. Murine left lung scRNA-seq under normobaric hypoxia/normoxia was conducted to elucidate hypoxia's role in immune cell differentiation.
Results: Flow cytometry revealed significantly elevated proportions of double-negative T cells (DNT, CD4-CD8-) in BALF from patients who died within 1 month post-transplantation compared to survivors (Fig. 1A). Transcriptomic validation demonstrated upregulation of DNT-specific marker LCK in incipient CLAD cases (Fig. 1B), indicating T cell hyperactivation and Graft-versus-host disease (Fig. 1B). Murine scRNA-seq (Fig. 2A 2B) showed hypoxia-induced DNT expansion with enhanced expression of activation markers (Lck, Cd3d, Zap70). Differential pathway analysis identified MHC-II overexpression in hypoxic–DNT cells, activating antigen presentation pathways associated with allograft rejection (Fig. 3).
Conclusions: Early elevation of DNT cells in post-transplant BALF correlates with acute rejection and poor prognosis. Hypoxia promotes DNT activation via MHC-II-mediated antigen presentation, driving immune rejection. These findings provide novel insights into targeting hypoxia–DNT crosstalk for improving lung transplant outcomes.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***945***

Introduction: Contrast-enhanced ultrasound (CEUS) is a promising tool to assess renal microcirculation. However, its reproducibility has never been formally assessed.
Objectives: We aimed to assess the reproducibility and variability of repeated CEUS measurements in critically ill patients.
Methods: We conducted an observational trial in 20 critically ill patients in a stable cardiopulmonary condition for > 12 h. In group 1 (n = 10), we performed renal CEUS examinations with similar settings at three time points: baseline (T0), 30 min (T1), and 1 h (T2). In group 2 (n = 10), we performed CEUS at T0 and T1, with the ultrasound contrast agent (UCA) infusion rate doubled at T1. CEUS-derived parameters assessed included relative blood volume (RBV), mean transit time (mTT) and perfusion index (PI). The primary endpoint was the inter-measurement variability of these parameters across different time points. Linear quantile mixed models were used. Secondary endpoint was intra-measurement variability as assessed by the parameters' coefficient of variability. Finally, logistic regression analysis was performed to identify patients-related factors associated with high variability.
Results: In Group 1 (patients 1 to 10), CEUS derived parameters remained similar across the three study timepoints (3289 vs 3680 vs 3590 for RBV, 4.1 vs 4.2 vs 4.2 for mTT and 684 vs 762 vs 735 for PI, all p values > 0.05), indicating stability of these parameters within individual patients over time. In Group 2 (patients 11 to 20), doubling the UCA rate at T1 resulted in a significant increase in RBV (3207 vs 1624, $p = 0.01$), and in PI (977 vs 617, $p = 0.01$), while mTT remained stable (4.6 vs 3.8, $p = 0.08$). Coefficient of variability was 23.2% (RBV), 13.9% (mTT) and 33.8% (PI). The median of five CEUS assessments yielded reliable estimates. No parameter was found to be associated with CEUS parameters variability.
Conclusions: CEUS derived parameters demonstrate reproducibility, supporting the utility of CEUS in renal microcirculation monitoring. The observed rise in RBV after an increase in UCA infusion suggests that mTT might be more reliable under varying infusion conditions. Further studies are required to establish the clinical utility of CEUS in critically ill patients.

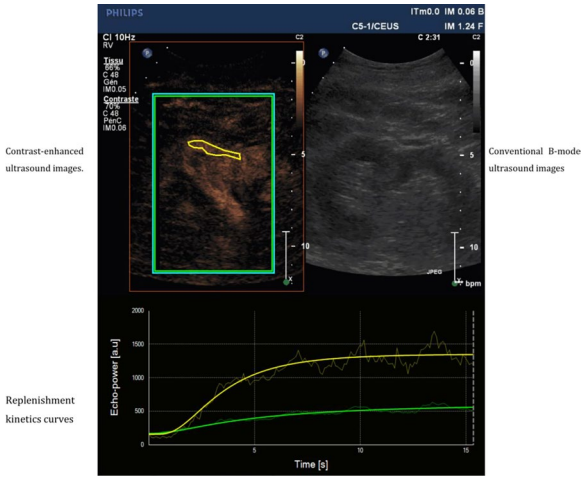

Fig. 1 (abstract 000945) Sequence analysis with Sonotumor®. A region of interest was drawn (yellow line) in the largest possible area of renal cortex closer to the ultrasound probe. The software generates a time intensity curve. This curve is used to generate CEUS-derived parameters

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):*946*

Introduction: Many critically ill patients suffer from persistent symptoms long after intensive care therapy has ended. These cognitive, psychological or physical impairments are summarized under the term Post-Intensive-Care Syndrome (PICS). Previous studies have demonstrated notable reductions in the quality of life and survival of patients, but the extent and causes of the condition remain opaque. The aim of this study was to determine the 3-month prevalence of PICS in a cohort of ICU survivors, and to identify key influencing factors in an effort to aid hypothesis generation and the design of future studies.
Methods: This was a monocentric, retrospective cohort study including patients who spent at least four days in an intensive care unit. PICS prevalence was assessed through structured interviews and clinical testing 3 months after the completion of intensive care therapy as part of follow-up care. Relevant individual and intensive care-related factors were documented from the hospital's patient data management system. The study was approved by the Ethics Committee of the Medical Association of Westphalia–Lippe and the University of Münster. Statistical analyses were done using Chi-square test and Welch's t test without correction for multiple testing. The results are considered exploratory and hypothesis generating.
Results: Among the 94 ICU survivors who were enrolled and clinically evaluated, the prevalence of PICS was 34%. Patients who suffered from PICS 3 months after intensive therapy were more likely to have required vasopressors, sedatives, antibiotics, or invasive ventilation during their ICU stay, and had a longer duration of non-oral nutrition, as well as more frequent organ dysfunctions and intensive care complications such as infections. Surgical patients with PICS had longer operation times. Statistically notable variables (p value < 0.05) are summarized in Table 1. No statistically significant differences were found between groups in terms of age, gender, BMI, and most pre-existing conditions.

Table 1 (abstract 000946) xxxx

Demographic Parameters	PICS	No PICS	p-Value
Male gender, %	62	73	0.36
Age, Mean (SD), years	59 (14)	58 (19)	0.74
BMI, Mean (SD), kg/m²	27 (6)	28 (6)	0.41
Therapy during ICU stay			
Surgery duration, Mean (SD), minutes	322 (175)	201 (98)	0.002*
ICU stay duration, Mean (SD), days	19 (10)	13 (10)	0.03*
Days without vasopressors in 30 days, Mean (SD), days	18 (9)	26 (4)	< 0.01*
Days without ventilation in 30 days, Mean (SD), days	24 (8)	28 (4)	0.04*
Days without sedation in 30 days, Mean (SD), days	25 (6)	28 (3)	0.24
Days without gastric tube in 30 days, Mean (SD), days	20 (12)	27 (8)	0.03*
Medication during intensive therapy			
Sedatives, %	88	61	0.03*
Antibiotics, %	88	64	0.04*
Complications during intensive therapy			
Infection, %	54	27	0.05*
Bleeding, %	81	52	0.03*
Hypoxia, %	58	24	0.01*
Vasoplegia, %	69	39	0.03*
Acute liver damage, %	50	24	0.05*
Acute kidney damage, %	69	39	0.03*

Conclusions: The occurrence of PICS after surviving a critical illness is common and should be considered in the ongoing care of patients. Further research is necessary regarding the potential risk factors and possible preventive measures.

Clinical characteristics of *Chlamydia psittaci* pneumonia: a single-center, retrospective study over 5 years

C. Zhu[1], T. Ye[1], C. Ye[1], M. Zhou[1]
[1]Department of Critical Care Medicine, Anhui provincial hospital, Hefei, China
Correspondence: M. Zhou
Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**)*:947*

Introduction: Psittacosis is a zoonotic infectious disease caused by Chlamydia psittaci and manifests primarily as community-acquired pneumonia, which is often atypical. Previous data indicate that C. psittaci infection accounts for approximately 1.03% of cases of community-acquired pneumonia [1]. However, owing to technological limitations, there is a high risk of missed or incorrect diagnoses. Diagnosis of psittacosis pneumonia has become easier with the introduction of metagenomic next-generation sequencing (mNGS), which enables direct sequencing of nucleic acids in samples, allowing precise identification of pathogens by database analysis, especially pathogens that are difficult to culture or detect using traditional methods [2, 3].
Objectives: To identify the clinical characteristics of *Chlamydia psittaci* pneumonia and its risk factors with the aim of improving decision-making regarding diagnosis and treatment.
Methods: According to the guidelines for CAP, 59 patients with *Chlamydia psittaci* pneumonia were divided into a nonsevere pneumonia group and a severe pneumonia group, and their clinical characteristics and the differences were analyzed and compared.
Results: The incidence of consciousness disorders is higher($P = 0.020$), and the time from onset to diagnosis is longer (8 days vs 14 days, $P = 0.002$),it is more prone to myocardial injury, kidney injury, hypoalbuminemia, coagulation abnormalities, and venous thrombosis ($P < 0.05$) in the severe group, while fatigue is more common in the nonsevere group ($P = 0.022$). On laboratory indicators, the severe pneumonia group had a significantly longer prothrombin time ($P = 0.007$), higher WBC and neutrophil percentages and lower lymphocyte count and percentages, higher lactate dehydrogenase and D-dimer values (all $P < 0.001$). After adjustment for sex and age, logistic regression analysis identified myocardial injury as an independent risk factor for severe C. psittaci pneumonia (OR,124.3, [95%CI,4.25 ~ 3633.24]; $P = 0.005$).
Conclusions: Impaired consciousness indicates severe illness and myocardial injury is an independent risk factor for severe *C. psittaci* pneumonia.

Early predictors of delayed cerebral ischemia: vasospasm timing and clinical severity after aneurysmal subarachnoid hemorrhage

DP. Martins Fernandes[1], E. Marques Mendes[2], JA. Paiva[3], C. Dias[4], E. Monteiro[4]
[1]Intensive Care Medicine Department, Unidade Local de Saúde de São João, Porto, Portugal; [2]Intensive Care Medicine Department, Unidade Local de Saúde do Alto Minho, Viana do Castelo, Portugal; [3]Intensive Care Medicine Department, Unidade Local de Saúde de São João. Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**)*:949*

Introduction: Among aneurysmal subarachnoid hemorrhage (aSAH) patients who survive the initial bleed, delayed cerebral ischemia (DCI), often leading to infarction, remains the leading preventable factor contributing to mortality and poor neurological outcome [1]. Reliable prediction models are still lacking, and diagnosis is challenging, particularly with high-grade aSAH, where serial neurological examinations have limited value [2]
Objectives: To identify and validate clinical and radiological predictors associated with DCI-related infarction in aSAH patients.
Methods: Single-center retrospective study including 221 consecutive aSAH patients admitted to a Neurocritititical Care Unit at a tertiary hospital, between 2018 and 2022. Logistic regression models were used to evaluate the predictive value of clinical and radiological admission variables for DCI-related infarction. Procedure-related infarctions were not included. Model performance was assessed using measures of discrimination and calibration. Cerebral vasospasm was diagnosed with transcranial Doppler or cerebral angiography.
Results: Baseline characteristics of the cohorts are presented in Table 1. DCI-related infarction occurred in 69 patients (31.2%). In a multivariate logistic regression (Table 2), time to vasospasm was a robust and consistent predictor of DCI-related infarction, showing an inverse association, suggesting earlier vasospasm may aligns more frequently with DCI development (OR 0.824, 95% CI 0.385-09.968, $p = 0.019$). The Hunt and Hess and Fisher scales were also among the strongest predictors of DCI-related infarction, confirming their established role in clinical severity and initial hemorrhage burden. No significant association was found between intraventricular hemorrhage and DCI-related infarction in this cohort. Other ICU-related variables, including SAPS II, duration of invasive mechanical ventilation, and analgo-sedation contributed modestly to DCI risk. Predictors like anemia, epileptiform activity or rebleeding showed clinical relevance and large effect sizes, though they did not reach statistical significance. The multivariate logistic regression achieved a moderate discriminative performance with an AUC of 0.65 (95% CI 0.729-0.909) (Fig. 1).
Conclusions: This work provides clinically relevant insights on predictors of DCI-related infarction in aSAH. Classic severity scores (Hunt and Hess and Fisher scores) remain strong indicators of risk, while earlier vasospasm onset appears to play a central role in DCI development. These findings can guide early risk stratification and patient monitoring strategies.

Intensive Care Medicine Experimental 2025 **13(Suppl 1)*:950***

Introduction: Given that post-treatment with endovascular treatment(EVT) for acute ischemic stroke often leads to complications, such as hyperperfusion syndrome, hemorrhagic transformation, or ineffective recanalization, it is recommended to admit patients to the neurocritical care unit in the acute phase within 24 h for strict and necessary blood pressure management (1). The American Stroke Association recommends maintaining blood pressure at or below 180/105 mmHg (2). However, due to the broad guidelines, several clinical trials(3-7) have explored systolic blood pressure thresholds, but results are inconsistent. Therefore, inconsistency in study conclusions

on postoperative blood pressure control targets for EVT patients may stem from the focus on a single peripheral blood pressure target.
Objectives: The objective is to regulate brain blood flow and oxygenation, control cerebral perfusion, and maintain normal brain microcirculation to enhance prognosis.
Methods: This study is designed as a single-center, prospective, controlled clinical trial to observe patients with anterior circulation acute ischemic stroke who have undergone endovascular treatment and achieved blood flow restoration. The objective is to monitor cerebral blood flow velocity in the middle cerebral artery using transcranial Doppler (TCD), and to regulate blood pressure to maintain cerebral blood flow within the normal range. This is accomplished by comparing quantitative EEG and brain oxygen monitoring data before and after the intervention to assess benefits.
Results: The study included 62 patients who underwent endovascular treatment for anterior circulation stroke, with 46 in the cerebral blood flow regulation group (33 males, 13 females) and 16 in the normal cerebral blood flow group (13 males, 3 females). In the cerebral blood flow regulation group, 37 patients received antihypertensive treatment with TCD indicating hyperperfusion; 9 patients received hypertensive treatment with TCD indicating hypoperfusion. In terms of brain function evaluation, oxygen levels on the affected side increased with faster cerebral blood flow ($P = 0.088$) and decreased with slower cerebral blood flow ($P = 0.005$), whereas oxygen levels on the healthy side remained unchanged despite regulation. In quantitative EEG, the ratio of θ waves on the healthy side decreased with cerebral blood flow regulation ($P = 0.021$), indicating improved EEG activity on the healthy side. On the affected side, the ratio of δ waves showed no significant difference but an increasing trend with cerebral blood flow regulation ($P = 0.248$).
Conclusions: The use of blood pressure regulation to manage cerebral blood flow during endovascular treatment of acute stroke will subsequently change the oxygenation of the affected hemisphere and the quantitative EEG function of the healthy hemisphere. This represents a novel approach to blood pressure regulation in the clinical practice of endovascular treatment for acute stroke.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**)*:951*

Introduction: Prolonged disorders of consciousness (pDOC) refer to prolonged alterations in consciousness lasting more than 28 days due to various brain injuries, such as traumatic brain injury (TBI), intracerebral hemorrhage, ischemic stroke, and cardiac arrest. Spinal cord stimulation (SCS) is commonly used to treat back pain and has also shown some potential in treating disorders of consciousness (DoC). Neurovascular coupling is an efficient intrinsic vascular regulation mechanism that reflects the adjustment and adaptation of neuronal activity and cerebral blood flow (CBF). SCS involves surgically implanting electrodes into the epidural space to stimulate the dorsal columns, but it may also influence the ascending reticular activating system. The research indicates that SCS increases cerebral blood flow and alters the concentrations of neurotransmitters in cerebrospinal fluid. However, the precise mechanisms through which it benefits DoC patients remain unclear.This study hypothesizes the following: 1. A relationship exists between EEG and cerebral blood flow velocity (CBFV) in DOC patients, reflecting the state of NVC. 2. SCS surgery affects thalamic connectivity and NVC. 3、Certain patients benefit more from SCS in terms of thalamocortical activity.
Objectives: To explore changes in neurovascular coupling and EEG dynamics in patients received short-term spinal cord stimulation (SCS),providing a Biomarker for the evolution of consciousness in patients with prolonged disorders of consciousness (pDOC).
Methods: Analysis of the prognosis of implantation of spinal cord neurostimulation in patients with traumatic brain injury, cerebral hemorrhage and ischemic–hypoxic encephalopathy admitted to the Neurological Intensive Care Unit of Hefei Hua'an Brain Hospital. The resting EEG signals were collected by continuous monitoring of 19-lead (FP1, FP2, F3, F4, C3, C4, P3, P4, O1, O2, T3, T4, T5, T6, Fz, Pz, Cz) EEG and cerebral blood flow velocities (CBFV) in bilateral middle cerebral arteries were synchronously collected by transcranial Doppler ultrasound (TCD). The prognosis of patients implanted with SCS was calculated and compared in terms of resting-state brain topography, middle cerebral artery blood flow, and neurovascular coupling. Neurovascular coupling values were obtained by calculating the cross-frequency phase-amplitude coupling (PAC) between the CBFV phase in the frequency band of (0.01-0.1 Hz) and the EEG amplitude in five frequency bands (δ, θ, α, β, γ). The global PAC for each frequency band was calculated as the sum of all PACs for each patient's 19 EEG channels with the corresponding EEG bands.
Results: Twelve patients met our inclusion criteria. Their age was 50.75 ± 12.55 years. The PAC enhancement of the patients in the minimally conscious state (MCS) was more pronounced by surgery compared to patients in the vegetative state (VS), and all five EEG frequency bands of the Global PAC was significantly elevated in all five EEG frequency bands. The global PAC in the gamma band was significantly elevated in the postoperative awakening patients. Preoperative PAC was 0.92 ± 0.39, postoperative PAC was 1.84 ± 1.30, and γ-segment global PAC was elevated 0.93 ± 1.34 ($P = 0.0011$).
Conclusions: The SCS surgery significantly improved the patients' PDA values,especially in γ-segment global PAC.This study may provide guidance for the selection of patients for SCS surgery and the research on its mechanism of action.

Evaluation of noninvasive central venous pressure in mechanically ventilated patients using handless carotid artery doppler ultrasound

M. Zhao[1]; Q. Mei[1]; L. Zhang[1]; J. Chen[1]; M. Zhou[1]
[1]Department of Critical Care Medicine, Anhui provincial hospital, Hefei, China

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***952***

Introduction: Assessment of right atrial pressure (RAP) is an important component of hemodynamic evaluation [1]. Central venous pressure (CVP) is an approximation of RAP and is equivalent to right ventricular pressure during diastole; thus, CVP can reflect the cardiac preload [2]. CVP is determined by the interaction between cardiac function and venous return [3] and can assist in diagnosing right heart failure and guiding fluid resuscitation, especially as a crucial indicator for sufficient fluid resuscitation in shock patients. However, the measurement of CVP requires the placement of a central venous catheter, which can be time-consuming [4-6]. In emergency situations or when a patient's condition deteriorates rapidly, quick insertion of a central venous catheter may not be feasible. In addition, as an invasive procedure, it may lead to complications such as pneumothorax, arrhythmias, and site infections [7]. Noninvasive portable bedside ultrasound can obtain Doppler ultrasound parameters related to CVP from structures, such as the internal jugular vein, inferior vena cava, and hepatic vein. However, it requires specialized ultrasound training and measurements can be influenced by subjective human factors. The relative motion and pressure changes between the ultrasound probe and the skin make it difficult to maintain continuous blood flow measurements during the assessment. The handless carotid artery Doppler ultrasound (hCDU) is a monitoring ultrasound that has a patch component which can be applied to the skin, allowing for continuous blood flow monitoring. The data obtained will be automatically analyzed and measured, converting it into various hemodynamic indicators. This ultrasound, due to its innovative patch design, can ensure measurement objectivity while avoiding the confounding factors that commonly affect conventional ultrasound measurements, all while ensuring ease of use and minimizing the need for extensive training. This study intends to utilize patch-based automatic Doppler blood flow measurement technology to obtain immediate and continuous hemodynamic information to develop a new noninvasive method for CVP assessment.
Objectives: To develop a new method for noninvasive assessment of central venous pressure (CVP) in mechanically ventilated patients using the handless carotid artery Doppler ultrasound (hCDU).
Methods: This prospective study included patients admitted to the Intensive Care Unit (ICU), who underwent invasive mechanical ventilation and had a central venous catheter for CVP monitoring from November 2024 to January 2025. Within 24 h of ICU admission, blood pressure, heart rate, mean arterial pressure, CVP, and ventilator parameters were collected. The carotid artery velocity time integral (cVTI) and the internal jugular vein velocity time integral (jVTI) were obtained by using the hCDU. Simultaneously, conventional ultrasound was performed to measure the cross-sectional area of carotid artery (CSAa) and the cross-sectional area of internal jugular vein (CSAj). We analyzed the correlation between the aforementioned parameters and CVP, constructed a regression equation, and used receiver operating characteristic (ROC) curve analysis to predict the optimal cutoff value for CVP > 10 cm H2O.
Results: A total of 94 patients were included. Correlation analysis showed that both CSAj ($r = 0.422$, $P < 0.001$) and CSAj/CSAa ($r = 0.444$, $P < 0.001$) had a moderate positive correlation with CVP, while CSAa ($r = -0.073$, $P = 0.484$) had a weak correlation with CVP. We also confirm a weak positive correlation between cVTI ($r = 0.384$, $P < 0.001$) and CVP, a moderate negative correlation between jVTI($r = -0.677$, $P < 0.001$) and CVP, and a strong positive correlation between cVTI/jVTI($r = 0.846$, $P < 0.001$) and CVP. Subsequently, we constructed a univariate linear regression equation: CVP = 6.937 × (cVTI/jVTI) + 3.147, which yielded an area under the ROC curve of 0.9734 for predicting CVP > 10 cm H2O. The optimal cutoff value of 1.15 provided the best predictive performance, with a sensitivity of 92.1% and a specificity of 93.5%.
Conclusions: The cVTI/jVTI parameter obtained from the hCDU can serve as a new method for noninvasive assessment of CVP.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***954***

Introduction: Hematological critically ill patients have become a challenge in our units in the recent years, with constantchanges and updates regarding their treatment and prognosis
Objectives: To analyze and compare hematological patients admittedto our Intensive Care Unit (ICU) over two different time periods.
Methods: A descriptive comparative analysis is performed betweentwo similar studies conducted over different periods (2004 to 2016 and 2018 to 2024). Both studies collected clinicalinformation from patients' medical records (in the firststudy using analog records and in the second one usingdigital records).
Results: The first study was conducted from 2004 to 2016 (13 years) and the second from 2018 to 2024 (7 years) including 102 and 61 patients respectively, suggesting anupward tendency in the number of hematological patientsadmitted to the ICU (annual mean 7.8 vs. 8.7).
In both periods, the main source of these patients was the Haematology ward, followed by the EmergencyDepartment and Internal Medicine ward. The mostcommon underlying hematological pathology was non-Hodgkin lymphoma, followed by multiple myeloma. Themeanageatadmissionofthesepatientshasslightlyincreased(57.8vs. 61.67), and these patients also tend to present a greater number of comorbidities. The mean number of days prior the ICU admission has decreased slightly (10.56 days vs. 9.02), and the number of cases where dopamine infusion was initiated on theHaematology ward, a common practice in our hospital, has decreasen (14.7% to 9.8%), suggesting an earlier ICU admission.
Severity index at admission (measured according to theAPACHE score) is very similar in both periods (24.18 vs. 24.70), but the invasive measures implemented haveincreased: vasoactive infusion (75% vs. 83.61% $p = 0.24$), invasive mechanical ventilation (36.27% vs. 45.95% $p = 0.29$), and continuous renal repleacement therapy(16.3% vs. 22.95% $p = 0.34$), which leads to an increase in ICU admission days (7.94 vs. 10.52).
Mortality during ICU admission also decreased slightly(53% vs. 45.9%, $p = 0.47$), although we also observed anincrease in subsequent mortality (11% vs. 16%), whichcould be biased by age and underlying pathology
Conclusions: Despite the limitations in the comparability of both studies(probably related to the short time difference between theperiods and the difference in sample size), we can observe an ascendant tendency regarding the admission of haematological patients in our critical care units, accompanied by a greater implementation of aggressivetherapeutic procedures. Despite this, and given the complexity of these patients, mortality is still a challenge. The importance of early diagnosis and treatment of thecomplications must be emphasized.

What is the appropriate feeding strategy in patients with traumatic brain injury: the role of central GLP-1 resistance

H. Liu[1], M. Zhou[2]

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***955***

Introduction: Neuroinflammation following traumatic brain injury (TBI) can disrupt the dynamic balance of the brain-gut axis, leading to gastrointestinal dysfunction [1]. Inappropriate nutrition delivery exacerbates the mechanisms of secondary brain injury and results in short- and long-term complications [2]. The ideal nutritional therapy in patients with TBI is currently controversial due to the lack of high-quality data from large-scale prospective clinical trials [3-5]. So, what is the ideal nutritional therapy for TBI patients? Glucagon like peptide-1 (GLP-1) is an insulin stimulating glucocorticoid that enhances postprandial insulin release [6]. Central GLP-1/GLP-1R system activation plays a crucial role in regulating feeding by delaying gastric emptying and suppressing appetite [7]. In the previous study, we found severe neural damage may lead to dysfunction of the central GLP-1/GLP-1R system, which cannot effectively regulate peripheral insulin secretion and glucose metabolism, resulting in sustained hyperglycemia [8]. We wonder whether disruption of central GLP-1/GLP-1R signaling could lead to GLP-1 resistance, resulting feeding intolerance in patients with TBI. Therefore, we performed a prospective observational study in patients with severe TBI to investigate the 14-day kinetics of plasma GLP-1, insulin, and tolerable enteral caloric intake. In this study, we verify our hypothesis that the elevation of endogenous GLP-1 secondary to central GLP-1 resistance, leads to feeding intolerance, which could possibly be used to predict appropriate feeding strategies for individual TBI patients.
Objectives: We propose a hypothesis that disruption of central GLP-1/GLP-1R system is involved in mediating the occurrence of feeding intolerance in TBI patients.
Methods: We conducted a prospective observational study on patients with severe TBI to investigate the first 2-week kinetic of plasma GLP-1, insulin and the relationship with feeding tolerance. Enteral feeding was conducted with the target of 25 kcal/kg·d and adjusted according to the tolerance. The blood samples were collected

on four timepoints: postinjury days 1-3 (PID1), PID 4-7 (PID2), PID 8-10 (PID3), and PID 11-14 (PID4).
Results: It was found that those with feeding intolerance (lower than 70% target calorie) showed higher serum GLP-1 and insulin levels ($p < 0.01$) than fully fed (achieved 70-100% target calorie) patients, which was more prominent in patients with severe intolerance (lower than 40% target calorie) (both $p < 0.001$). In addition, insulin supplementation dose in intolerant patients was comparable with that of adequately fed patients ($p = 0.202$). GLP-1 on days 8-10 and insulin on days 1-3 were positively associated with feeding tolerance.
Conclusions: Central GLP-1/GLP-R system malfunction can lead to elevated peripheral GLP-1 levels, inducing feeding intolerance. The GLP-1 based feeding strategy may be a breakthrough for personalized feeding strategy in TBI patients.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***956***

Introduction: Aneurysmal subarachnoid hemorrhage (aSAH) is a common cause of admission to the Intensive Care Unit (ICU) and leads to significant functional impairment in patients at discharge.
Objectives: To describe the characteristics of patients with aSAH admitted to the ICU at a tertiary hospital.
Methods: Retrospective, observational study conducted on patients diagnosed with aSAH who were admitted to the ICU of HGU Gregorio Marañón between January 2022 and November 2024. Epidemiological data, aSAH risk factors, comorbidities, severity scales (APACHE II, SOFA, GCS, FOUR), modified Fisher scale (mFS), World Federation of Neurological Surgeons scale (WFNS) and Hunt and Hess scale (H&H), organ support, aneurysm location, treatment type, and complications were collected. Functional status at discharge was evaluated using the modified Rankin scale (mRS). In the descriptive analysis, quantitative variables were expressed as mean (SD) if the distribution followed a normal pattern or median (IQR) otherwise. Qualitative variables were expressed as percentages.
Results: Seventy-six patients were included. The mean age was 57 ± 12 years, with 72.4% being female. aSAH risk factors included hypertension (50%), smoking (29%), and dyslipidemia (20%). Severity scales: APACHE II 11 ± 7, SOFA 5 ± 4, GCS 11 ± 4 at admission; 88% had mFS ≥ 3, 21% were classified as WFNS 5 and 29% had H&H ≥ 4. In 70% of cases the aneurysm was located in the anterior circulation with the most common location being the anterior communicating artery (29%). 70% of patients had intraventricular hemorrhage, 41% required external ventricular drainage and 9% experienced rebleeding. The most frequent treatment was endovascular (71%). In the sample 25% developed delayed cerebral ischemia (DCI) at 6 ± 3 days and 15% experienced delayed cerebral infarction. ICU complications occurred in 58% of patients. 62% required mechanical ventilation (MV) and 33% underwent tracheostomy. The ICU stay was 12 days (6-34) with a mortality rate of 18.4%. Hospital stay was 26 days (17-61) with favorable functional outcomes at discharge (mRS 0-3) in 56.6% of cases.
Conclusions: Aneurysmal subarachnoid hemorrhage was more frequent in middle-aged women with no significant comorbidities. Nearly one-third of patients developed delayed cerebral ischemia. A high proportion of patients had an unfavorable modified Rankin score at hospital discharge.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***706***

Introduction: Acute anaemia is a common clinical problem in the critically ill. Ninety-five percent of patients in intensive care units (ICU) for 72 h or more suffer from anaemia and approximately 40% of them receive transfusions of packed red blood cell units. Disease-specific factors and phlebotomy sampling contribute to this event, but non-invasive haemoglobin measurement methods are available to benefit patients in these situations.
Objectives: To determine the correlation and concordance of non-invasive haemoglobin measurement to determine the validity of its use in critically ill patients.
Methods: Prospective analytical study that analysed and evaluated the correlation and concordance of serum haemoglobin values with Masimo Radical-7® Pulse CO-Oximeter® (SpHb) plethysmograph haemoglobin concentration monitoring.
Results: A total of 329 patients were analysed. 54.74% were male with a mean age of 59.91 ± 18.71 years. Vasopressor support was required in 29.18%. Mean haemoglobin values were 11.52 ± 2.88 g/dL at serum level and measured by SpHb of 11.48 ± 2.14 g/dL with a correlation coefficient $r = 0.805$ ($p = 0.001$) which remains acceptable despite high doses of vasopressors $r = 0.764$ ($p = 0.001$). Concordance analysis showed an average difference of 0.03 ± 1.65 g/dL with moderate limits of agreement between − 1.02-1.05 g/dL.
Conclusions: These findings are concordant with different studies and suggest the use of SpHb as an opportunity to assess the trend of haemoglobin values in critically ill patients. SpHb showed acceptable accuracy and excellent correlation with serum haemoglobin and provides a rapid, feasible and accurate solution for haemoglobin measurement in ICU.

Bland–Altman plot of differences and means between serum haemoglobin and SpHb values.

Correspondence: P. Dilokpattanamongkol
Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***958***

Introduction: Appropriate antimicrobial dosing is critical in sepsis, especially in patients with acute kidney injury (AKI), which alters drug clearance. Timely dose adjustment based on the renal function balance efficacy and toxicity. However, the impact of the timing in dose modifications on safety outcomes remains unclear, particularly in critically ill patients receiving nephrotoxic or antimicrobial agents excreted via kidney, such as piperacillin/tazobactam and colistin.
Objectives: This study aimed to compare the safety outcomes of early (within 24 h) versus delayed (after 24 h) antimicrobial dose adjustment based on the renal function in patients with AKI complicated by sepsis or septic shock.
Methods: A retrospective study was conducted using data from ICU units at university hospital, Thailand, spanning January 2021 to November 2024. Inclusion criteria were patients aged over 18 years diagnosed with sepsis or septic shock who developed AKI, as defined by KDIGO criteria. Major exclusions included patients who required renal replacement therapy or did not receive a loading dose of antibiotics. Primary outcomes assessed were AKI progression within 72 h, resolution of kidney injury within 7 days, ICU-free days, and in-hospital mortality. Secondary outcomes included clinical cure and length of ICU stay.
Results: Of the 785 screened patients, 84 met the inclusion criteria and received piperacillin/tazobactam or colistin therapy. The median age was 74 years. According to KDIGO criteria, most patients (71.5%) had stage 1 AKI, followed by 19% with stage 2 and 9.5% with stage 3. Among these, 43 received antimicrobial dose adjustments within 24 h, and 41 after 24 h. No significant differences were observed between early and delayed groups in AKI progression within 72 h (25.6% vs. 22.0%, P = 0.696), kidney injury resolution within 7 days (9.3% vs. 17.1%, $P = 0.291$), or ICU-free days (median 3 vs. 12 days, $P = 0.080$). However, in-hospital mortality was significantly higher in the early group (65.1% vs. 39.0%, $P = 0.017$).
Conclusions: The study findings suggest that delaying dose adjustment based on renal function for piperacillin/tazobactam or colistin beyond 24 h in patients with sepsis or septic shock and AKI may improve safety outcomes, particularly by reducing in-hospital mortality. However, due to the small sample size and limited data on colistin in the delayed adjustment group, further studies with larger cohorts are needed to clarify the optimal timing for dose adjustments in this population.

Personalized scheme of opioid administration during reconstructive operations after head and heck mine blast injuries

D. Dziuba[1]
[1]Anesthesiology and IC, National Medical Academy of Post-Graduate Education Named After P.L. Shupik, Kyiv, Ukraine
Correspondence: D. Dziuba
Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):959

Introduction: Injuries resulting from blast trauma are complex cases that require numerous surgical interventions and adequate pain management.
Objectives: The goal of this study was to assess the effectiveness and safety of a personalized fentanyl administration method compared to the standard pain management approach. Materials and
Materials and methods: A study was conducted on fifty patients undergoing reconstructive surgeries following head and neck mine blast injuries sustained at the frontlines in Ukraine. These patients were evenly split into two groups based on the intraoperative anesthesia approach. The first group received a standard multimodal analgesia regimen that included paracetamol, dexketoprofen, and fentanyl solutions. The second group was administered multimodal analgesia with paracetamol, dexketoprofen, and a personalized opiate administration approach, which involved assessing the response to a slow fentanyl bolus (1.5 μg/kg) using the Ramsey scale before induction. The fentanyl test outcomes were categorized as follows: 1. Negative: No sedation observed after the fentanyl bolus. 2. Weakly positive: Anxiolysis or Ramsey level 2 sedation observed. 3. Positive: Superficial sedation or Ramsey level 3 sedation observed. For positive tests, 2-3 μg/kg

fentanyl was administered per hour to maintain analgesia. For weakly positive tests, 3-4 µg/kg was given per hour, and for negative tests, more than 5 µg/kg was administered per hour. Analgesia and sedation levels were monitored using the Conex monitoring system.
Results: The personalized fentanyl administration scheme during reconstructive operations showed better outcomes compared with the standard anesthesia protocol. It was associated with improved blood pressure control, like lower blood pressure during and after surgery, lower stress markers (intraoperative blood cortisol: 14.74 ± 6.48 mcg/dL in group 1 vs. 9.58 ± 6.73 mcg/dL in group 2), and reduced incidences of perioperative pain, postoperative nausea, and vomiting.
Conclusions: A method of personalized anesthesia was elaborated, based on an individual scheme of fentanyl administration («fentanyl test») during reconstructive operations after head and heck mine blast injuries. Its usage is safe (due to the optimal parameters of hemodynamics and fewer side effects, such as nausea and residual sedation) and more effective (due to the lower level of stress markers and less frequent complaints of pain of various origins) than when the routine technique was used.

Bioactive adrenomedullin levels and endothelial stress in cardiac surgery patients

S. Ryz[1], J. Tichy[1], J. Lanzersdorfer[1], A. Lassnigg[1] M. Bernardi[1]
[1]Division of cardiac thoracic vascular anaesthesia and intensive care medicine, Medical University of Vienna, Wien, Austria
Correspondence: S. Ryz
Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***960***

Introduction: Cardiac surgery with cardiopulmonary bypass (CPB) induces significant endothelial disorder, often leading to postoperative complications. Bioactive Adrenomedullin (Bio-ADM) is a marker that reflects the integrity and function of the endothelial structure, where a higher level indicates a decline in endothelial function. The perioperative trajectory of Bio-ADM and its relationship to postoperative complications remains underexplored. The aim of this study is to evaluate the dynamics of Bio-ADM levels in relation to various outcomes as inflammation, renal dysfunction and fluid balance.
Methods: In this preliminary study we analyzed the perioperative Bio-ADM course in ten patients undergoing cardiac surgery. Bio-ADM levels were measured preoperatively and at three postoperative time points, postoperative day (POD) 1, 2 and 5. Based on the preoperative median (17.8 pg/mL) Bio-ADM level patients were divided into two groups (low and high).
Results: Patients in the high Bio-ADM group developed significantly higher postoperative Bio-ADM levels (POD1: 71.30 ± 29.69 pg/mL vs. 29.08 ± 15.06 pg/mL in the low group; p = 0.030). Whereas no difference in preoperative CRP levels was found (high Bio-ADM 0.16 ± 0.20 mg/dL vs. low Bio-ADM 0.19 ± 0.23 mg/dL; p = 0.787), postoperative CRP levels were elevated in the high Bio-ADM group (POD1: 3.65 ± 1.70 mg/dL vs. 3.04 ± 2.96 mg/dL; p = 0.677; POD2: 14.46 ± 5.09 mg/dL vs. 8.34 ± 5.33 mg/dL; p = 0.085). Also, the high Bio-ADM group showed a higher intraoperative fluid balance (4335.8 ± 1623.0 mL vs. 3847.8 ± 1439.0 mL; p = 0.615). Furthermore, a higher incidence and severity of postoperative edema was found in the high Bio-ADM group on POD1 (high Bio-ADM 0.75 ± 0.25 cm vs. low Bio-ADM 0.17 ± 0.26 cm; p = 0.029) and on POD2 (0.83 ± 0.14 cm vs. 0.21 ± 0.25 cm; p = 0.002).
Conclusions: These findings indicate that high preoperative Bio-ADM levels are associated with elevated postoperative Bio-ADM and CRP values, higher intraoperative fluid balances and a higher risk of developing postoperative edema. These findings underline the value of Bio-ADM as a predictive marker for postoperative complications in cardiac surgery patients.

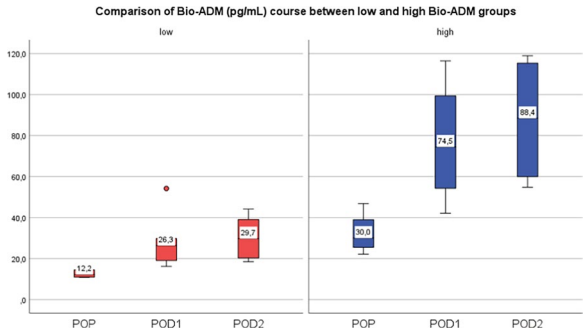

Fig. 1 (abstract 000960) Perioperative Bio-ADM course: the boxplots show the perioperative course of Bio-ADM between patients with high (blue) vs. low (red) preoperative Bio-ADM at different time points. In the boxplots, the lower boundary of the box indicates the 25th percentile, a black line in the box marks the median, and the upper boundary of the box indicates the 75th percentile. Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***961***

Introduction: Pneumonia has a significant burden in hospitalized patients with high morbidity and mortality and it is one of the most common infections observed in Intensive Care Units (ICUs). The patient-related factors, local antibiogram and infections with multidrug-resistant organisms (MRDO) are fundamental risks that are associated with higher mortality. This study evaluated the 90-day survival of critical ill patients diagnosed with bacterial pneumonia.
Objectives: This study aims to evaluate the 90-day survival in patients diagnosed with bacterial pneumonia during their ICU stay.
Methods: This retrospective study conducted in a 22-bed intensive care unit at a tertiary care center in the eastern province, Saudi Arabia that included adult patients diagnosed with pneumonia (community acquired pneumonia (CAP), hospital acquired pneumonia (HAP) and ventilator associated pneumonia (VAP)) with positive sputum culture for bacterial organism from January 2023 to March 2024. The ICU database was utilized to identify all patients who were diagnosed with pneumonia. Demographic data, type of pneumonia, the isolated pathogens susceptibility testing, the appropriateness of empirical antimicrobial regimen, and the 90-day survival were recorded. The primary outcome was the 90-day survival among the patients diagnosed with any type of pneumonia during their ICU stay.
Results: A total of 98 patients diagnosed with bacterial pneumonia during their ICU stay were included in our analysis. Mean age was 56 Years, 56 (57.1%) patients were males, 76 (77.5%) were immunocompromised (55.1% with malignancies, 10.2% transplant, and 12.2% with liver disease), 82 (83.7%) required vasopressors, and 95 (96.9%) were mechanically ventilated. HAP was the most common type of pneumonia followed by VAP, and CAP, 52 (53.1%), 34 (34.7%), and 12 (12.2%), respectively. Multidrug-resistant organisms (MDROs) were detected in 46 (46.9%) patients. The most frequently encountered MDROs were extended spectrum beta lactamase (ESBL)-producing organisms, followed by Stenotrophomonas, and carbapenem-resistant Enterobacteriaceae (CRE), 13.3%, 11.2%, and 10.2%, respectively. Sixty-one patients (62.2%) received empirical antibiotics that appropriately covered the isolated pathogens. Vasopressors use was identified as a significant risk for ICU mortality ($p = 0.025$). Seven (7.1%) patients were alive upon ICU discharge and only 4 (4.1%) survived at 90-day follow up.
Conclusions: Most patients in this study didn't survive at 90-days from the pneumonia diagnosis during their ICU stay. Despite advancement in diagnosis, management, antimicrobial therapy, and prevention, pneumonia continues to have a major impact on critically ill patients' outcomes.

Exploring the clinical experiences of nurses to understand the contextual nature of sepsis recognition expertise: a phenomenographic study

M. Nemeckova[1], T. Conner[1], A. Steven[1]
[1]Department of Nursing, Midwifery and Health Faculty of Health and Life Sciences, Northumbria University, Coach Lane Campus (East), Newcastle upon Tyne, United Kingdom
Correspondence: M. Nemeckova
Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***962***

Introduction: Sepsis is a common but often unrecognised condition associated with high mortality [1]. Educational programmes designed to improve sepsis recognition, often structured around standardised sepsis screening tools are being produced at an increasing rate [2]. While these initiatives have been effective in improving knowledge outcomes, change in clinical practice remains suboptimal [2]. The challenge is that sepsis education research has tended to focus on knowledge acquisition related to sepsis screening tools [2], often neglecting the necessary step of translating that knowledge into the clinical context where sepsis exhibits a broad spectrum of disease manifestation [3,4].
Objectives: This study examined the nurses' clinical experiences to understand the contextual nature of sepsis recognition expertise. Such an understanding may allow future sepsis educational programmes to be grounded in a framework of a relevant and personalised approach to sepsis recognition which is currently lacking [3,4].
Methods: Twenty-six nurses from various hospital settings were interviewed. Transcripts of the interviews were analysed by a phenomenographic approach, a research method aiming to determine the various ways a group of people experience a phenomenon [5]. The findings were arranged into categories based on the Cynefin Framework [6].
Results: The findings revealed that sepsis recognition takes on a range of meanings, depending on the complexity of the clinical context. In the simple context (with well-known cause/effect links), sepsis recognition meant understanding how the patients' physiological values match predetermined criteria from a protocol. In the highly complex context (webs and loops of cause/effect with unpredictable, emergent properties), sepsis recognition meant learning about the individual patient, where a patient was considered to have a disease which might manifest in a unique and unpredictable manner. Clinical problems were comprehended via learning from the patient's evolving and dynamic state, paying attention to unique and adaptive responses to interventions. Nurses used the information of patient responses and symptom progression as supplemental knowledge to construct and reconstruct their understanding of patient problems.
Conclusions: Our findings suggest that sepsis education, as we know it, in which sepsis is taught to be recognised by the application of standardised sepsis criteria, irrespective of clinical context, may be of limited value. We suggest that learning about sepsis criteria remains a valuable starting point but no longer the only one. Rather, optimising sepsis education towards learning to apply them in a personalised manner is more relevant, with understanding whether the sepsis criteria apply to the individual patient at all and, if so, how it should be integrated into a clinical decision. Considering the characteristics of the clinical contexts, such as the availability of data can help guide an appropriate approach to sepsis recognition.

Italian ICU, UK clinical pharmacy skills: a frontline report on integration

D. Giudici[1], L. Barberis[2], E. Cerutti[3], G. Fazzina[3], E. Pennone[3], M. Borthwick[1], C. McKenzie[4], F. Racca[2], A. Gasco[3]

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***963***

Introduction: The positive role of critical care pharmacists in the Intensive Care Unit (ICU) Multiprofessional Team (MPT) on improving patient outcomes such as mortality, ICU length of stay, and incidence of preventable adverse drug events (ADE) has been well evidenced (1,2,3). Building on the recent European momentum to expand the clinical pharmacy role in ICU MPTs, the ICU team at the Azienda Ospedaliera Ordine Mauriziano di Torino expressed interest in evaluating the feasibility and potential impacts of a new clinical pharmacy service in ICU.
Objectives: To explore the potential contributions of care an UK specialist ICU clinical pharmacist can make in an Italian ICU.
Methods: A UK trained and specialist critical care pharmacist joined the ICU team as an observer for 5 working days. The pharmacist attended the daily ward/board rounds, recorded clinical activities, and possible areas for pharmacy contributions in a Microsoft Excel spreadsheet. In addition, a short narrative summary of each patient encounter was collected in Microsoft Word. Specific data were collected for 5 clinical topics, which are key performance indicators for the host ICU. Contributions were graded using the Adapted Severity Rating by Bates et al.; contributions that targeted improvements in the safety of the care provided were recorded as "Safety" interventions. Grading was verified by two independent UK ICU pharmacists.
Results: Data for 22 patient encounters were recorded, of which 10 were for patients newly admitted into the unit. Overall, 408 prescription items were reviewed by the visiting pharmacist, 200 of which were for newly prescribed items. Some 200 prescription items were screened for possible ADEs, with 2 identified and prevented. Overall, 48 interactions (consults or communications) with medical and nursing teams were recorded, 14 interactions with Nurses (7 consults, 7 Communications) and 34 with doctors (21 Consults, 13 Communications). A total of 49 contributions were recorded, 39 low severity rating (79.6%), 8 Moderate (16.3%) and 2 Severe (4.1%); in addition to these 42 Safety contributions were recorded. An additional 6 major interventions around medicines related clinical guidance and standard operating procedures (SOPs) were identified during the data collection period; 3 with Severe safety rating and 3 with Moderate.

Conclusions: This observational experience demonstrates that introducing a clinical pharmacy service led by an advanced pharmacist with specialist critical care expertise into a "naïve" ICU setting could yield significant benefits. The pharmacist's participation in daily clinical rounds led to valuable contributions, particularly in preventing ADEs, ensuring patient safety, and sparked protocol and SOPs review processes. Further research with larger sample sizes and a prolonged service period is needed to fully assess the scope, long-term impact on ICU outcomes and acceptability into the Italian healthcare system.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***964***

Introduction: Tetanus is a rare and fatal condition if airway and neuromuscular relaxation are not properly managed. Current therapies show little change in the clinical course of the disease and management requires opioid medications and neuromuscular relaxants that can have deleterious effects.
Methods: Clinical case report: A 77-year-old female patient with chronic kidney disease who had no history of tetanus vaccination. She presented with a lower limb injury caused by a sharp metal object. During the 7 days following the event, she began to present nuchal and masseter rigidity, sardonic laughter and finally dancers' feet and opisthotonos, and was diagnosed with severe clinical tetanus with acute respiratory failure requiring invasive mechanical ventilation and sedation with isoflurane on arrival at the ICU. During his clinical stay, it was observed by means of brain function monitoring and electromyography with SedLine that after administration of isoflurane he maintained adequate sedation and coupling to mechanical ventilation, as well as adequate neuromuscular relaxation, without the need to use opiates or neuromuscular relaxants.
Results: No changes in blood chemistry or elevation of creatine phosphokinase were observed. The patient was considered to have a benign course of disease with complete resolution, no further sedation or relaxation was required and adequate rehabilitation was achieved. There are few cases in the literature on the use of inhaled sedation in tetanus, however, the current evidence shows that isoflurane used in different settings is an opioid and neuromuscular relaxant sparing agent.
Conclusions: Isoflurane could represent a supportive measure in tetanus patients in order to reduce the use of opioids and neuromuscular relaxants as it provides an adequate state of sedation-analgesia and relaxation, helping to avoid the complications associated with these drugs. Consent to publish had been obtained.

Fig. 2 (abstract 000964) **A** Brain function monitoring and electromyography (EMG) with SedLine under isoflurane sedation (EMG at 0%). **B** Monitoring of brain function and electromyography with SedLine without sedation (EMG at 39%)

Introduction: Statins have well-established pleiotropic effects by interrupting delirium pathogenesis through their anti-inflammatory, immunomodulatory, and antithrombotic properties. The existing literature presents conflicting findings regarding the potential effects of statins on critically ill patients with delirium. It is still unknown whether the pleiotropic properties of statins and their influence on delirium are influenced by their lipophilicity, dose, agent-specific, or statin intensity. Therefore, this study aims to assess the impact of statin therapy intensity on the risk of delirium in critically ill patients.
Methods: This multicenter, retrospective cohort study evaluated critically ill patients. All adult patients aged 18 who received statin therapy were admitted to the Intensive Care Unit (ICU). Patients were categorized into high-intensity vs. low-moderate intensity groups. The primary endpoint was the delirium occurrence during ICU stays. The secondary endpoints were delirium recurrence, delirium-free days (DFD) within 60 days, mortality (30-day and in hospital), hospital and ICU length of stay. Propensity score (PS) match procedure (SAS Cary, NC) at (1:1 ratio) was used. Multivariable logistic regression was used to determine the adjusted *p* value and odds ratio for outcomes.
Results: After PS matching, a total sample of 1054 patients were included: 527 patients in each statin group. The odds of delirium were numerically higher in the high-intensity group but not significantly different between the two groups (OR: 1.10, 95% CI 0.774,1.571, $P = 0.5886$). In contrast, the odds of delirium recurrence were lower in the high-intensity statin group (OR: 0.92, 95% CI 0.44,1.94, $P = 0.84$). Moreover, there was no statistically significant difference between the two groups' DFDs, mortality, and ICU length of stays. However, the length of hospital stay in high-intensity statin was significantly shorter than low-intermediate group (beta coefficient: -0.12, 95% CI (– 0.23, -0.01), $P = 0.04$).
Conclusions: The use of high-intensity statin in medical ICU patients was not associated with a lower risk of delirium as compared to low-moderate-intensity statin. Delirium risk may be a factor to consider with additional indications of statin when choosing the intensity of statin used in patients admitted to the ICU. However, to confirm that further studies are required to explore various hypotheses and deepen the understanding of this correlation.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**)***:968***

Introduction: Delayed cerebral ischemia (DCI) occurs in 20-30% of patients after subarachnoid hemorrhage (SAH) and is one of the most modifiable factors associated with poor outcome in this population. However, few data are available on the optimal treatment in this context.
Objectives: The aim of this study was to assess if endovascular treatment of cerebral vasospasm was associated with less development of cerebral infarction and better neurological outcome than no endovascular therapy
Methods: This is an international multicentre (n = 20) retrospective study including the last 20-25 adult patients with aneurysmal SAH who developed DCI per center (2022-2023). Patients who received endovascular therapy (e.g. intra-arterial vasodilators and/or angioplasty) were compared with those not receiving such therapy. The primary outcome was the development of DCI-related cerebral infarction, as reported by local investigators. Secondary outcome was the occurrence of unfavourable neurological outcome at 3 months, assessed by a modified Rankin scale 3-6.
Results: A total of 444 patients were included, of which 249 (56.1%) received endovascular treatment for cerebral vasospasm. The mean age was 56 (± 12) years and 311 (70.0%) patients were female. The median admission World federation of neurological surgeons score (WFNS) was 4 (2-5). Aneurysms were most commonly localized in the anterior communicating artery (155/444, 34.9%) followed by the middle cerebral artery (104/444, 23.4%). Most aneurysms were secured by coiling (342/444, 77.0%). A total of 275 patients (61.9%) developed DCI-related cerebral infarction and 205 experienced unfavourable neurological outcome. Patients who underwent endovascular therapy had higher WFNS scores on admission, received less nimodipine prophylaxis and underwent induced hypertension more frequently than others. The occurrence of DCI-related cerebral infarction and unfavourable neurological outcome was similar between groups. In a multivariate logistic regression, endovascular therapy was not independently associated with DCI–cerebral infarction (OR 0.83 95% CI 0.55-1.27), when adjusted for age, pupillary light reflex, WFNS,

rebleeding during aneurysm securement, intracranial hypertension, pneumonia, septic shock, stress cardiomyopathy, nimodipine prophylaxis and induced hypertension Similarly, endovascular therapy was not associated with unfavorable neurological outcome (adjusted OR 0.97 95% CI 0.61–1.52).
Conclusions: In this cohort study of SAH patients with DCI, endovascular therapy was not associated with less cerebral infarction and better neurological outcome than other interventions.

Intensive Care Medicine Experimental 2025 **13(Suppl 1):*970***

Introduction: In the last several decades, the importance of deranged microcirculation in the development of organ failure in shock has gained prominence (1). Early plasma transfusion is one of the well-established approaches to treating bleeding caused by trauma (2); however, its effect on microcirculation is unknown. Here, we hypothesize that plasma transfusion effectively mitigates microcirculatory disturbances, as well as having a beneficial effect on correcting systemic hemodynamics after traumatic hemorrhagic shock.
Objectives: Determining the effectiveness of plasma resuscitation on the muscle microcirculation in a rat model of poly trauma and hemorrhagic shock.
Methods: Under deep anesthesia and mechanical ventilation ($n = 30$), traumatic injury was induced by clamping the gut and liver, and inflicting a femur fracture. Shock was induced with arterial blood withdrawal and kept at a mean arterial pressure of 40 mmHg for 1 h. Trauma groups were resuscitated with either crystalloid (TC) or rat plasma (TP) for 2 h. The right biceps brachii muscles were exposed and used for microcirculatory measurement by a handheld vital microscope (HVM, Cytocam, Braedius Med. The Netherlands) and tissue laser-Doppler (O2C, LEA Medizintechnik, Germany), in 6 h. Each time point (T0-T6), total vessel density (TVD), functional capillary density (FCD), tissue red blood cell perfusion (tRBCp) were measured by HVM and microvascular red blood cell velocity (mRBCv), and capillary blood flow (CBF) by O2C.
Results: Plasma resuscitation increased the MAP and HR at T3 and T4 compared to trauma + crystalloid ($p < 0.05$). Lactate increased dramatically in both trauma groups at T1 compared to the sham ($p < 0.05$) (Table 1). Trauma led to a significant reduction in TVD and mRBVc in comparison to the sham ($p < 0.05$). Plasma resuscitation improved TVD, FCD, tRBCp, and mRBCv compared to the trauma group resuscitated with crystalloid ($p < 0.05$) (Fig. 1-2).

Table 1 (abstract 970) Hemodynamic parameters; data are represented as mean (SEM). *($p < 0.05$), *($p < 0.001$) vs. sham. + ($p < 0.05$), + + ($p < 0.01$) vs. trauma + crystalloid**

MAP (mmHg)	T0	T1	T2	T3	T6
Sham	87,3 (6,4)	79,5 (3.2)	102,1 (3,8)	87,7 (4.4)	70,3 (3,6)
Trauma + Crystalloid	89,9 (8,2)	39,6 (1) *	57,7 (2,2)	58,8 (2,4)	55,4 (7,9)
Trauma + Plasma	79,1 (3,5)	41,0 (0,7) *	66,3 (1,3)	66,6 (2,1) + +	45,4 (3)
HR (BPM)	T0	T1	T2	T3	T6
Sham	215 (6,7)	247 (13,1)	270 (19,1)	291 (16,7)	325 (12,9)
Trauma + Crystalloid	225 (14,1)	236 (16,3)	255 (10,6)	253 (8,5)	269 (9,1)
Trauma + Plasma	237 (6,4)	210 (9,2)	263 (8,2)	287 (8,7) +	280 (6,3)
Lactate (mmol/L)	T0	T1	T2	T3	T6
Sham	0,8 (0,1)	1,6 (0,1)	1,9 (0,1)	1,8 (0,2)	1,1 (0,1)
Trauma + Crystalloid	0,8 (0,1)	3,8 (0,2) ***	2,5 (0,2)**	2,4 (0,3)	2,7 (0,6) *
Trauma + Plasma	1,0 (0,1)	3,8 (0,2) ***	3,1 (0,1) ***	2,7 (0,2) ***	3,9 (0,5) ***

Conclusions: Our study has shown that plasma resuscitation has beneficial effects on the microcirculatory convection (tRBCp, mRBCv) and diffusion (TVD, FCD, tRBCp) parameters in a rat model of poly-trauma and hemorrhagic shock. Further studies are required to ascertain the fundamental mechanisms of plasma and microcirculation interaction.

Introduction: Bloodstream (CBSI) is a frequent healthcare-associated infection in Greek ICUs that merits systematic surveillance.
Objectives: A (second) national Point Prevalence Study (Bact.GR 2024) was conducted to describe the current epidemiology of BSIs in Greek ICUs and delineate necessary and targeted infection control measures at a national level.
Methods: Prospective, observational 2-month PPS between November and December 2024. All ICU-acquired BSIs in patients with a central venous catheter (CVC) in place were included. Definitions were according to CDC-NHSN and ECDC criteria. Demographic and clinical patients' characteristics along with ICU-level data were collected. Results are reported as means ± SD or median values as appropriate.
Results: 43 adult and 6 pediatric ICUs in 47 hospitals participated and 312 patients were included (67% males, 8% pediatric patients). Most ICUs (85%) were mixed-polyvalent. Mean patient age was 63.18 (± 15.13). Reasons for ICU admission were mainly medical (55%), surgical (29%) and trauma (17%). Mean APACHE II and SOFA scores on ICU admission were 20 ± 7.01 and 8.9 ± 3.1, respectively. Septic shock and mechanical ventilation were recorded in 41% (19% for pediatric patients) and 84% (48% for pediatric patients) of the cases. The overall ICU mortality was 39%. The central line was inserted in internal jugular, femoral and subclavian sites in 58%, 26% and 15% of the cases, respectively, while PICC was present in 1.4% of the cases. 27930 patient-days and 26587 catheter-days were analyzed (pooled central line utilization ratio 0.95) and 367 BSIs were recorded. 263/367 BSIs (72%, 9.89/1.000 catheter-days) were primary bacteremias and characterized as CLABSIs and 104/367 cases (28%, 3.91/1000 CVC-days) were secondary BSIs (primary site of infection was the lung 40%, the abdomen 23%, the urinary tract 14%, trauma 15%). Seventy-three out of 263 primary BSIs (28%, 2.74/1000 catheter-days) were considered Catheter-Related BSIs (CR-BSIs) as compared to 4.7/1000 catheter-days reported in the first national PPS conducted in 2012 in Greek ICUs (statistical analysis is actually in progress).
Conclusions: BSIs represent an important burden in the ICU setting in Greece. CR-BSIs tend to decline compared to historical cohorts. Secondary BSIs derive mainly from the lung and the abdomen. Evidence-based preventive bundles should be promptly implemented to prevent further ventilator-associated pneumonia and CR-BSI cases in critically ill patients.

Use of vibroacoustic therapy in geriatric patients with respiratory pathology after orthopedic surgery on the lower extremities: a retrospective analysis

A. Bekniyazova[1], A. Konkayev[2]
[1]Department of Anesthesiology and Intensive Care, Astana Medical University, Astana, Kazakhstan; [2]Anesthesiology and Intensive Care Department, Astana Medical University, Astana, Kazakhstan

Intensive Care Medicine Experimental 2025* 13(Suppl 1):*972

Introduction: Respiratory pathology ranks third in geriatric patients among the causes of an unfavorable outcome [1]. Given that the average duration is steadily increasing, the management of this category of patients with diseases of the respiratory system requires an integrated approach [2]. Early physiotherapy with the use of vibro-acoustic chest massage can prevent the development of pulmonary complications, especially in patients with limited activity after orthopedic surgery on the lower extremities. Previously, vibroacoustic therapy has demonstrated positive results in patients with coronavirus infection complicated by acute respiratory failure [3].
Objectives: To evaluate the effect of gases in arterial blood (PaO2, PaCO2), cough and shortness of breath when using vibroacoustic therapy in geriatric patients with various respiratory pathologies based on retrospective data.
Methods: The study was approved by the National Scientific Center of Traumatology and Orthopaedics named after N.Batpenov in Astana on 19.11.2024. A retrospective analysis of $n = 71$ medical records of patients who were observed after orthopedic surgery on the lower extremities in the intensive care unit was performed. The inclusion criteria were patients aged 65 to 85 years with verified respiratory pathology. Exclusion criteria for patients who were on a ventilator and in critical condition. All patients received a course of VAT 4 times a day for 5 min for 3 days. The study included patients with COPD ($n = 50$), post-COVID syndrome ($n = 5$), community-acquired pneumonia ($n = 16$). Descriptive statistics were performed using SPSS Statistics version 23.
Results: As a result, the following statistically significant data were obtained. The greatest effectiveness was demonstrated in patients with COPD mean PaO2 value was increased by 10.8 mmHg, median by 8.4 mmHg, 95% CI ± 9.3 mmHg, SD 17.6 mmHg on the third day after application. The largest decrease in PaCO2 was in the same group on the third day after the session: mean 7.7 mmHg, median at 6.8 mmHg 95% CI ± 8.1 mmHg, SD 9.2 mmHg. A reduction in dyspnea and cough was noted in 89% of patients.
Conclusions: Thus, vibroacoustic therapy can be a useful component in the treatment of geriatric patients with respiratory pathology after orthopedic surgery on the lower extremities. The method has shown an advantage in patients with COPD. The data obtained confirm the expediency of using vibroacoustic therapy in this category of patients.

Sepsis induces redistribution of cholesterol from plasma to erythrocyte membranes

E. Braun[1], X. Ming[1], A. Kleyman[1], M. Gräler[2], D. Brealey[1], C. Sgura[1], M. Singer[1]
[1]Bloomsbury Institute for Intensive Care Medicine, University College London, London, United Kingdom; [2]Department of Anesthesiology and Intensive Care Medicine, Jena University Hospital, Jena, Germany
Correspondence: E. Braun
Intensive Care Medicine Experimental 2025* 13(Suppl 1):*975

Introduction: Sepsis is characterised by both hypocholesterolaemia [1] and by dysfunctional erythrocytes[2]. Underlying mechanisms; however, remain poorly understood. Erythrocyte membrane cholesterol (EMC) content is known to modulate the membrane's mechanical properties, such as deformability, fluidity and oxygen diffusion [3-5]. EMC levels are also heavily influenced by plasma cholesterol levels [3].
Objectives: To investigate cholesterol levels in plasma and erythrocyte membranes in septic patients and healthy volunteers and the relationship to erythrocyte osmotic fragility.
Methods: Blood samples were collected from healthy volunteers and from septic patients on ICU days 1-2. The erythrocyte membrane was isolated by ultracentrifugation [6] and non-esterified cholesterol (the only cholesterol constituent in erythrocytes) measured by an Amplex Red enzymatic assay. Non-esterified and esterified cholesterol levels in plasma were also measured by Amplex Red (± esterase). An osmotic fragility test was performed by incubating erythrocytes in a series of hypotonic NaCl concentrations with haemolysis quantified by optical density measurement of the supernatant at 538 nm. Statistics were performed using unpaired Student´s t-tests with significance established at $p < 0.05$.
Results: Compared to healthy controls, septic patients showed a significant increase in EMC levels despite a fall in total plasma cholesterol (Table 1). Notably, plasma non-esterified cholesterol rose but the esterified fraction fell by 63%. Osmotic fragility was decreased in erythrocytes from septic patients compared to healthy controls (example shown in Fig. 1).

Table 1 (abstract 975) Cholesterol concentration in plasma and erythrocyte membrane from septic patients taken on day 1–2 after ICU admission ($n = 5$) and healthy controls ($n = 12$)

	Erythrocyte membrane cholesterol (μg/10^8 cells)	Plasma total cholesterol (μg/mL)	Plasma non-esterified cholesterol (μg/mL)	Plasma cholesterol ester (μg/mL)
Healthy controls	49 ± 8	1560 ± 304	305 ± 52	1254 ± 302
Septic patients	80 ± 19	911 ± 282	443 ± 135	468 ± 344
P value	0.0003	0.0012	0.0091	0.0004

Conclusions: Our findings indicate that decreased cholesterol esterification may explain the well-recognised fall in plasma cholesterol seen during sepsis, since esterified cholesterol (mainly contained within HDL and LDL) is the main fraction of circulating cholesterol. The increase in erythrocyte membrane cholesterol points to a redistribution of non-esterified cholesterol to the red blood cell membrane. The reduced osmotic fragility of erythrocytes in sepsis suggests changes in membrane properties, which may be related to the increase in membrane cholesterol. Further studies are needed to confirm whether higher membrane cholesterol levels seen during sepsis directly affects red blood cell functionality, (e.g. deformability and oxygen carriage/release).

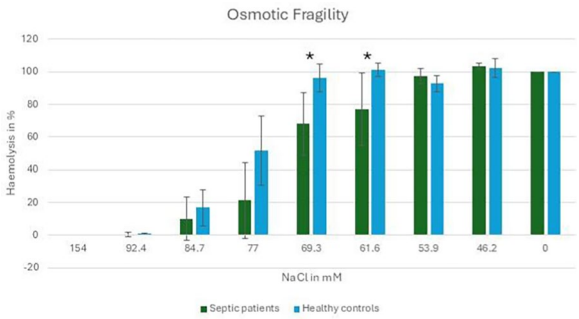

Fig. 1 (abstract 000975) Osmotic fragility of erythrocytes from healthy controls ($n = 6$) and septic patients taken on day 1-2 after ICU admission ($n = 5$); *$p < 0.05$

Intensive Care Medicine Experimental 2025* 13(Suppl 1):*977

Introduction: Approximately 25% of adults admitted to intensive care units (ICUs) have pre-existing cardiovascular disease (CVD). (1,2) Although acute CVD is a strong predictor for mortality in ICU (3), the effect of pre-existing CVD on critical care outcomes is unknown. Moreover, defining CVD as a comorbidity varies in research and depends on the data sources available. Linked primary care data are often challenging to obtain. (4)
Objectives: This study aimed to define pre-existing CVD using data-driven methods to best identify patients at highest risk of mortality. We hypothesised that different data sources for CVD identification would impact ICU outcomes differently.
Methods: This was a retrospective cohort study using Scotland's national ICU, hospital and primary care prescribing (PIS) databases, and the population included all ICU admissions from 01/01/2010 to 31/12/2022 aged 18 or older. We used three definitions of CVD based on three different data sources: APACHE II severe CVD comorbidity definition (5) (ICU data), selected ICD10 codes (hospital data) (6,7) and selected CVD medications (PIS data). (8) We excluded hypertension from both hospital and PIS data to enhance the models' discrimination of ICU outcomes. The primary outcome was 60-day mortality, and secondary outcomes included: ICU mortality, hospital mortality, 30-day mortality and ICU length of stay. Associations with outcomes were estimated using binary logistic regression and used to calculate unadjusted and adjusted (by age, sex, deprivation, ethnicity, comorbidity) odds ratios between the different definitions of CVD (Fig. 1).

Results: The cohort included 144,515 patients. CVD amongst the ICU patients had the highest prevalence when hospital data was used (53.5%) and lowest when the APACHE II CVD definition was used (2.5%). The prevalence of CVD identified in any of the three data sources was 61.25%. The percentage agreement of people identified as having CVD in both hospital and prescribing data was 47% (Fig. 2). The overall 60-day mortality in the ICU cohort was 19.4%. The 60-day mortality increased with increasing severity of CVD, ranging from 14.9% for patients with no CVD to 32.5% for patients with Apache II defined CVD. Adjusting for age, sex, deprivation and non-CVD comorbidities, the OR for mortality was highest when ICU-defined CVD was used (1.92, 95%CI 1.78–2.07, $p < 0.001$) followed by hospital data-defined CVD (OR 1.24, 95%CI 1.20–1.28, $P < 0.001$). There was no association between PIS defined CVD and 60-day mortality (0.99, 95%CI 0.94-1.03, $p = 0.539$, Fig. 3).
Conclusions: Our study shows a much higher pre-existing CVD prevalence in ICU compared to previous research. Using the APACHE II definition of CVD comorbidity identifies only a small number of patients. Where primary care data is not available, using previous hospital admissions for CVD excluding hypertension will identify ICU patients with CVD at higher risk of mortality.

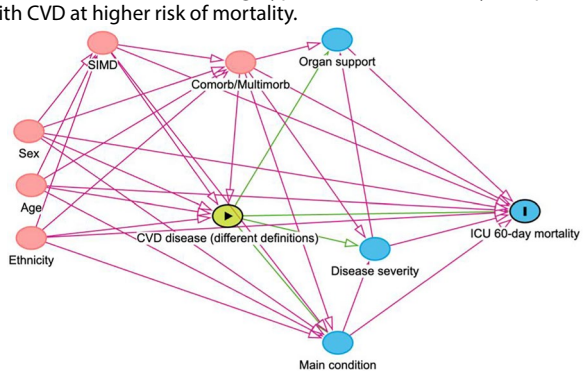

Fig. 1 (abstract 000977) Directed acyclic graph (DAG) identifying the minimal sufficient adjustment set for estimating the total effect of CVD disease (different definitions) on ICU 60-day mortality: age, comorbidities, ethnicity, Scottish Index of Multiple Deprivation (SIMD) and sex

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***978***

Introduction: Sepsis is a heterogeneous life-threatening condition related to the dysregulated immune response to an infectious hit with different molecular transcriptomic patterns. However, their temporal variation and the influence of the sepsis source remains poorly understood.
Objectives: This study aims at assessing the influence of both infectious site and time from sepsis onset on the whole-blood transcriptomic profiles of circulating cells is severe sepsis patients admitted in intensive care unit (ICU).
Methods: We analyzed transcriptomic data of peripheral blood leukocytes from healthy individuals (HV) and from severe septic shock patients at two time points (day 1-3 and day 5-7) after ICU admission. We compare the expression level of genes between both timepoints and infectious site (pulmonary, abdominal, urinary tract and skin and soft tissue). We also performed unsupervised analysis between conditions and timepoints using principal component analysis. Patients and HV were part of the REALISM study (NCT02638779). Statistical analyses were performed using R.
Results: 30 HV and 60 septic patients were included in this study. Infectious sites were distributed as follow: 30 (50%) pulmonary, 18 (30%) abdominal, 7 (12%) skin and soft tissue and 5 (8%) complicated urinary tract infection and soft tissue skin infection ($n = 7$, 11.6%). The median age of septic patients was 67.5 [Q1:59.00–Q3:78.00] years old, the median SOFA score at day 1 was 9 [Q1:6.75–Q3:11.0] and 5 patients (8.3%) died at day 28. We have observed a specific transcriptomic signature in septic patients compared to healthy donors, mostly due to an increase in the expression of genes related to neutrophil activation, regardless of the time point or infection site. The amount of differentially expressed genes between different infectious sites were low and non-discriminating. We observed that the evolution of the transcriptome leading to patient recovery is not the same for patients depending on the infection site.
Conclusions: This study allows us to show that the transcriptomic profile of septic patients is distinct from that of healthy donors, without transcriptomic molecular signature specific to infection sites in blood. We identified dynamic transcriptomic molecular signature associated with differences in mortality.

Automated segmentation of CT scans successfully quantifies changes in kidney volume in ICU patients

AGW. Biersma[1], B. Van Leer[1], MH. Renes[1], J. Pillay[1], J. Koeze[1]
[1]Department of Critical Care, University Medical Center Groningen, Groningen, Netherlands
Correspondence: A.G.W. Biersma
Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***979***

Introduction: ICU admissions are frequently complicated by acute kidney injury (AKI) (1). Kidney volume is associated with kidney function. Fluid overload is an independent risk factor for AKI and can increase kidney volume (2-4). In contrast, chronic kidney disease (CKD) is associated with decreased kidney volume (5). AKI can progress into CKD (6). Both increases and decreases in kidney volume can be associated with AKI, creating a U-shaped association. Therefore, anthropometric features, such as total kidney volume (TKV), could play a role in evaluating and/or predicting the risk of AKI and its potential progression. Automated segmentation can provide an objective technique to assess multiple anthropometric features (7).
Objectives: This study aims to validate automated segmentation as a tool for measuring TKV and to analyse the association between (changes in) TKV using CT imaging with automated segmentation and AKI incidence and/or severity in patients acutely admitted to the ICU.
Methods: This retrospective pilot cohort study was part of the HEALICS, which focuses on associations between characteristics of patients acutely admitted to the ICU and the severity of diseases (8). In this study, patients were included when at least two abdominal CT scans (CT1 and CT2) were performed during ICU admission. In addition, baseline abdominal CT scans up to one year before hospital admission were included. TKV was measured by automated segmentation using DAFS (version 3.11.0, Voronoi Analytics Incorporated, Vancouver,

Canada). ΔTKV was calculated between baseline CT and CT1 (ΔTKVCT1-baseline) and CT1 and CT2 (ΔTKVCT2-CT1). AKI was defined following the KDIGO guidelines (9). Primary outcomes were AKI incidence and severity on the day of scanning related to TKV. The Mann–Whitney *U* test and Kruskal–Wallis *H* test were applied appropriately.
Results: Twenty-six patients were included, of whom 18 developed AKI during ICU admission. Manual correction of the automated segmentations was needed in 22% (left) and 23% (right) of the kidney segmentations. No significant differences in kidney volume were found before and after manual correction. Median TKV during ICU admission was 377 cm3 (IQR 330—461). TKV did not correlate with AKI incidence or severity on the day of scanning. Longitudinal intraindividual changes in TKV were observed, as seen in Fig. 1. Median ΔTKVCT1-baseline was 12 cm^3 (-35—37), while the median ΔTKVCT2-CT1 was 27 cm^3 (-4—78). Median ΔTKVCT1 baseline proved statistically significantly different for AKI versus non-AKI patients (-22 cm3 (-49—9) versus 42 cm3 (23—43), P = 0.03) on the day of scanning and also among the different KDIGO groups. No differences in ΔTKVCT2-CT1 were found.
Conclusions: This study is the first to successfully demonstrate the possibility of measuring TKV in ICU patients using automated segmentation software. Changes in TKV were observed, however, no clear association between TKV and the incidence or severity of AKI was found.

Cerebrospinal fluid to blood sCD14-ST (presepsin) ratio as a biomarker for early diagnosis of health-care associated ventriculitis/meningitis

M. Karapetsa[1], M. Papadonta[1], T. Amanatidis[1], K. Parisi[1], E. Zakynthinos[1], V. Tsolaki[1]
[1]Intensive Care Unit, University Hospital of Larissa, University of Thessaly, Faculty of Medicine, Larissa, Greece

Intensive Care Medicine Experimental 2025 **13(Suppl 1)*:981***

Introduction: Health care-associated meningitis/ventriculitis (HAVM) is often difficult to diagnose in the ICU setting and is associated with adverse outcomes, longer duration of hospital stay and increased costs [1]. New biomarkers are needed for early diagnosis and prompt treatment initiation [2].
Presepsin is the residue of CD14 protein, anchored on the macrophage's membrane which binds to bacterial cell wall lipopolysaccharide. Presepsin has been measured in blood and cerebrospinal fluid to identify infections [3].
Objectives: We aimed to investigate the diagnostic performance of cerebrospinal fluid (CSF) presepsin levels and its ratio to the corresponding blood concentration in neurosurgical ICU patients with fever, in order to explore its potential as an early indicator of bacterial CNS infection.
Methods: Neurosurgical patients (including patients with traumatic brain injury, intracranial and subarachnoid hemorrhage, acute brain injury needing drainage catheter insertion) admitted in a tertiary ICU in Central Greece were included. Cerebrospinal fluid was collected for CSF infection evaluation. Laboratory examinations included blood and CSF measurements of leukocytes, glucose, lactate, culture and presepsin [PATHFAST technology (PHC Europe, LSI Medience, Tokyo, Japan)]. CSF/blood presepsin ratio was calculated. Definite diagnosis of meningitis/ventriculitis was established by a positive CSF culture.
Results: Fifty patients were included, 14 with confirmed CSF infection and 36 without. Patients with a CNS infection presented a significantly higher number of CSF WBC [93 (5, 80000) vs 5 (0, 342)/μL, $p = 0.005$], lower CSF glucose levels [27 (0, 84) vs 83 (18, 157) mg/dl, $p < 0.0001$] and CSF/blood glucose ratio [0.20 (0, 0.75) vs 0.65 (0.17, 0.98), $p < 0.0001$], higher CSF protein [430 (89, 1084) vs 52.5 (11, 656) mg/dl, $p < 0.0001$] and lactate [4.2 (1.4, 15) vs 2.5 (0.1, 6.6) mmol/lt, $p = 0.003$]. CSF presepsin levels were significantly higher in the infection group [1762 (361, 3000) vs 227 (18.5, 6913) pg/ml, $p < 0.0001$] while the corresponding blood levels did not differ [733.5 (191, 1980) vs 588.5 (119, 13988) pg/ml, $p = 0.713$]. CSF/blood presepsin level ratio was significantly higher in the CNS infection group [1.59 (1.26, 15) vs 0.46 (0.03, 2.88), $p < 0.0001$]. CSF/blood presepsin ratio was the test with the highest accuracy in identifying a CNS infection [cut-off 1.24, sensitivity 100% specificity 94%, AUC 0.944 95%CI (0.838-1.000, p < 0.0001)], followed by CSF to blood glucose ratio with an AUC 0.887, CI (0.767-1.000), cut-off 0.47, sensitivity 86%, specificity 83%,(p < 0.0001) while CSF presepsin levels presented a cut-off value of 1198 pg/ml, sensitivity 78% specificity 75%, AUC 0.847 95%CI (0.693-1.000), $p = 0.005$.
Conclusions: CSF/blood presepsin ratio seems to accurately predict HAVM in neurosurgical patients and it could be used as an adjunct tool for early diagnosis. Certainly, larger studies are needed to support these findings.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***982***

Introduction: Advances in intensive care have increased survival rates, leading to a growing population of chronically critically ill patients. While no longer in acute organ failure, many develop chronic organ dysfunctions that overwhelm routine ward care, resulting in delayed discharge from Intensive Care Units (UCI). In our hospital, these patients tend to remain for prolonged periods on our level 2 Intermediate Care Unit (Level 2 ICU), many of whom have a tracheostomy. Attempts are made to identify those able to be decannulated early in the IntCU as there is a low number of rehabilitation beds and personnel in the general ward of our institution for routine attempts at decannulation.
Objectives: This study aimed to quantify the resource utilization of patients undergoing decannulation training in a level 2 Intermediate Care Unit (Level 2 ICU) in Portugal and to identify predictors of decannulation success.
Methods: We conducted a retrospective cohort study of tracheostomized patients admitted to a level 2 intermediate care unit in Portugal from 2022 to 2024. Inclusion criteria were the presence of a tracheostomy and eligibility for decannulation. Patients without potential for decannulation—due to irreversible neurological impairment or chronic ventilator dependency—were excluded. To evaluate the potential for earlier transfer to a level 1 medical or surgical ward, we retrospectively applied a set of predefined clinical criteria to determine when each patient would have been eligible for transfer. These included: $\geq$ 48 h without vasopressor support, $\geq$ 48 h without mechanical ventilation, Glasgow Coma Scale $\geq$ 9, and the absence of continuous IV infusions requiring level 2 ICU care.
Results: Among 1967 level 2 ICU patients, only 57 (2.8%) were tracheostomized and 43 (2.1%) met inclusion criteria. These 43 patients accounted for 1220 ICU-days, representing 13.5% of total occupancy. Their mean length of stay was 28.3 $\pm$ 18 days relative to 4.6 $\pm$ 3,6 days for non-tracheostomized patients. Only 22/43 (51.1%) were ultimately decannulated: 12 in the level 2 UCI, 8 on the ward, and 2 at a rehabilitation center after hospital discharge. Amongst non-decannulated patients, 3 died in the intermediate care unit, 15 died on the wards, 2 remained tracheostomized post-hospital discharge, and 1 returned to their country of origin with no follow-up data available. Retrospective application of a clinical discharge rule showed that 810 days (66%) of level 2 ICU care were potentially avoidable if adequate support was provided on the level 1 wards. Successful decannulation was associated with younger age (50 vs. 63 years, $p = 0.008$) and lower SOFA scores at level 2 ICU admission (2.5 vs. 4.2, $p = 0.03$). No significant associations were found with sex or pre-tracheostomy duration of intubation
Conclusions: Tracheostomized patients in decannulation training represent a significant care burden for intermediate care units that may not be clinically indicated. In this retrospective cohort, only half of patients achieved decannulation despite a high investment of time and resources. Structural investments in ward-based decannulation teams or chronic critical illness units could reduce ICU length of stay and improve patient flow.

Effect of different phenotypes of reverse triggering on prognosis in critically ill patients based on a real-time monitoring platform

S. Zhang[1], L. Su[1], S. Yuan[1]
[1]ICU, Peking Union Medical College Hospital, Beijing, China
Correspondence: L. Su
Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***983***

Introduction: Reverse triggering (RT) is a complex form of asynchrony with different phenotypes and their clinical implications are underexplored. This study aimed at determining the incidence of RT in ICU patients with long-term monitoring platform, characterizing the phenotype's impacts on mechanical ventilation and identifying risk factors associated with the poor outcome.
Methods: Patients with mechanical ventilation under the remote-ventilate view system for at least 24 h in ICU were included. We investigated two phenotypes of RT (with and without breath stacking) according to the ventilator waveforms and their effects on pulmonary ventilation through the respiratory mechanics monitoring. We also screened out the risk factors associated with prolonged mechanical ventilation in RT.
Results: One hundred and ninety-five patients (22.4%) occurred RT under the unified definition of the RT frequency and 80 patients had RT with breath stacking. RT with breath stacking was associated with greater tidal volume [447 (418, 495) vs. 406 (359, 445) ml, $P < 0.001$], higher minute ventilation [7.0 (6.2, 7.8) vs. 6.5 (5.7, 7,2) L/min, $P = 0.004$], plateau pressure [15.4 (14.3, 17.0) vs. 13.7 (11.3, 14.9) cmH_2O, $P < 0.001$] and driving pressure (DP) [8.5 (7.5, 10.0) vs. 7.0 (5.8, 8.8) cmH_2O, $P < 0.001$]. RT with breath stacking had a longer duration of IMV [7 (3, 15) vs. 4 (2, 7), $p = 0.007$] and a shorter number of VFD-28 [20 (6, 25) vs. 24 (21, 26), $p = 0.004$]. RT with breath stacking (OR, 1.959; 95% CI, 1.053-4.025), higher APACHE II score (OR, 1.078; 95% CI, 1.011-1.149), lower oxygenation index (OR, 0.993; 95% CI, 0.098-0.997), more fentanyl infusion (OR, 1.034; 95% CI, 1.000-1.062) and higher DP (OR, 1.386; 95% CI, 1.125-1.708) were potential risk factors for prolonged mechanical ventilation. There was no difference in hospital mortality between the two phenotypes.
Conclusions: Long-term monitoring-based RT incidence and characteristics of different phenotypes provide more comprehensive information for epidemiological investigations. The poor outcome of RT seems to display the breath stacking, higher APACHE II and DP, worse oxygenation index and more fentanyl infusion.

A case of severe septic shock and septic cardiomyopathy caused by *Pseudomonas aeruginosa* pneumonia, which was managed with V-A ECMO and Impella®

K. Nakamura[1], K. Shimizu[1], J. Hamaguchi[1]
[1]Emergency and critical, Tokyo Metropolitan Tama Medical Center, Fuchu, Japan
Correspondence: K. NAKAMURA
Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***984***

Introduction: *Pseudomonas aeruginosa* is often implicated in severe, community-acquired pneumonia, which can rapidly worsen and often leads to death. Thus, it is essential to make a differential diagnosis accurately and administer the appropriate treatment.
Methods: We report a case of a young adult patient in whom Pseudomonas aeruginosa pneumonia which developed after coronavirus disease 2019 (COVID-19) onset progressed to septic shock and septic cardiomyopathy. The patient was successfully managed with V-A ECMO and Impella®.
Results: A previously healthy man in his 20's presented to the hospital after a persistent, wet cough developed following COVID-19 onset one month earlier. Two days before his current presentation, he began coughing up blood, then experienced chest pain and dyspnea, which prompted an emergency transfer to a previous hospital. Upon arrival, his vital signs were blood pressure 70/- mmHg, heart rate 120 bpm, respiratory rate 40/min, SpO2 96% on oxygen 6 LPM and temperature 39.0 °C. Pneumonia was diagnosed, and the patient was intubated. However, despite intubation, his P/F ratio remained around 80, and shock persisted. He was therefore transferred to our hospital for further management. Upon arrival, intensive treatment, including broad-spectrum antibiotic therapy, was begun. However, his circulatory status continued to deteriorate. Despite administration of norepinephrine 1.0 μg / kg / min and vasopressin 2.0 units/hour, his mean arterial pressure remained around 50 mmHg. His cardiac function markedly decreased, with the left ventricular ejection fraction (LVEF) being approximately 10%. His lactate level remained elevated at 8.1 mmol/L, indicating septic shock and septic cardiomyopathy. Given the severity of his condition, V-A ECMO was introduced. However, his cardiac function and left ventricular dilation continued to worsen. To unload the left ventricle, an ImpellaCP® heart pump was placed. Thereafter, his circulatory dynamics stabilized. After antibiotic therapy brought the infection under control, the vasopressors were tapered, and his cardiac function improved. On day 4, he was weaned off V-A ECMO. On the same day, Pseudomonas aeruginosa was isolated from a sputum culture. On day 5, Impella® was removed, and on day 9, the patient was extubated. The patient regained his ability to walk without assistance and was discharged on day 49.
Conclusions: The present case demonstrates that the combination of V-A ECMO and Impella® can be life-saving in patients with septic shock and septic cardiomyopathy caused by severe Pseudomonas aeruginosa pneumonia. The timely recognition of immune suppression following COVID-19 onset played a crucial role in choosing an appropriate antibiotic. Even in young, healthy adults, it is important to consider the patient's medical history and underlying conditions carefully before choosing a treatment for severe, community-acquired pneumonia. Consent to publish had been obtained.

How liver transplantation alters the ACLF trajectory: a retrospective comparison between transplanted and non-transplanted patients

L. Santos[1]; C. Pratas[1]; R. Captivo[1]; C. Cerca[1]; R. Leite Cruz[1]; M. Cardoso Da Costa[1]; S. Rodeia[1]; N. Germano[1]; L. Bento[1]
[1]Intensive care unit, ULS São José, Lisboa, Portugal
Correspondence: L. Santos
Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***985***

Introduction: Acute-on-chronic liver failure (ACLF) is a clinical syndrome defined as an acute decompensation of chronic liver disease, associated with organ failure and high short-term mortality. The most common precipitating factors include bacterial infections, alcoholic hepatitis and gastrointestinal bleeding.1,3 In 35-40% of patients, no clear precipitating factor can be identified.4 Therapeutic options are limited to organ support; liver transplantation (LT) is the only definitive treatment and has shown substantial survival benefits in ACLF.
Objectives: We aimed to compare clinical characteristics and outcomes of ACLF patients who underwent LT versus those managed without transplant in a specialized ICU.
Methods: A retrospective cohort study was conducted on 42 patients diagnosed with ACLF admitted to a liver transplant centre affiliated intensive care unit (ICU) over three years (2019, 2022, and 2023). Baseline demographics, cirrhosis etiology, precipitating ACLF causes, organ support requirements, and severity scores (MELD-Na and CLIF-C ACLF score) were collected. Patients were grouped by whether they received LT during hospitalization. Descriptive statistics were presented as mean ± SD or percentages. Group comparisons used t tests or Mann–Whitney U for continuous variables and chi-square/Fisher's exact tests for categorical variables. Correlation analysis (Pearson's r) examined relationships between clinical variables. Survival was analyzed by Kaplan–Meier curves (log-rank test) for ICU, hospital, and 1-year outcomes.
Results: Of the 42 patients (mean age 58.9 ± 9.4 years; 81.0% male), 64.3% had alcohol-related cirrhosis, 9.5% due to chronic infection by hepatotropic viruses, 9.5% cryptogenic, 7.1% autoimmune, 2.4% primary biliary cholangitis, and 2.4% sarcoidosis. Common ACLF precipitants were gastrointestinal bleeding (42.3%) and infection (33.3%), with 19% no clear precipitant identified. Sixteen patients (38.1%) underwent LT, and 26 (61.9%) did not. Transplant vs. non-transplant groups had similar baseline age (54.7 vs 61.6 years, $p = 0.02$) and gender (25% vs 15% female, $p = 0.44$) distributions, and comparable severity scores (MELD-Na 28.6 vs 27.3, $p = 0.61$; CLIF-C 58.0 vs 58.5, $p = 0.94$). LT patients required less invasive mechanical ventilation (62.5% vs 84.6%) and renal replacement therapy (43.8% vs 65.4%) than non-LT patients, although these differences did not reach statistical significance ($p > 0.10$). Confirmed infections during ICU stay were more frequent in the LT group (68.8% vs 38.5%, $p = 0.11$), who received a mean of 7.8 ± 3.0 days of antibiotic coverage before transplant. On average, transplantation occurred on the 18th day of hospitalization. Survival outcomes were markedly better with LT: ICU survival was 87.5% with LT vs 46.2% without LT ($p = 0.01$), hospital survival 75.0% vs 34.6% ($p = 0.03$), and 1-year survival 62.5% vs 23.1% ($p = 0.02$).
Conclusions: This study includes two groups of ACLF patients with comparable epidemiology and severity. In this cohort, liver transplantation dramatically improved survival across short-term and 1-year timeframes, supporting liver transplantation as a life-saving therapy for selected ACLF patients.

Lactate-driven natural killer cell dysfunction shapes immune dysregulation in sepsis

J. Chen[1], M. Zhou[1], H. Wei[2]
[1]Department of Critical Care Medicine, Anhui provincial hospital, Hefei, China; [2]Institute of Immunology, University of Science and Technology of China, Hefei, China
Correspondence: M. Zhou
Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***986***

Introduction: Sepsis is a life-threatening condition marked by organ dysfunction due to an uncontrolled immune response to infection, with septic shock carrying a high mortality rate [1, 2]. Immune suppression, especially NK cell depletion, contributes significantly to sepsis-related mortality [3]. Elevated lactate levels, indicative of impaired tissue microcirculation, are a key prognostic marker in septic shock [4]. Lactate not only functions as an epigenetic modifier but also disrupts immune cell function, including effector T cells and macrophages, in sepsis [5, 6]. While the effects of lactate on NK cells have been studied in cancer, its impact during sepsis remains underexplored.
Objectives: In this study, we aimed to elucidate the effects of lactate on NK cell quantity and function in patients with sepsis, exploring the underlying mechanisms to enhance understanding of sepsis pathophysiology and inform potential therapeutic approaches.
Methods: We enrolled 36 patients with sepsis admitted to the ICU. Lymphocyte counts, NK cell frequency, and the expression of activation and inhibitory markers were assessed.
Results: In sepsis, peripheral blood NK cells, including CD11b + and CD16 + subsets, are significantly reduced(Fig. 1A-C). Sepsis also leads to dysfunctional NK cell receptor expression, with decreased NKG2D, NKG2C, and CD226, and increased inhibitory receptors like TIGIT, PD-1, and NKp44 (Fig. 1D-K). Elevated lactate levels further decrease NK cell numbers (Fig. 2A-C). Lactate induces a dose-dependent increase in NK cell apoptosis, with almost complete depletion at concentrations above 20 mmol/L (Fig. 2A-C). Inhibition of lactate transport via AZD3965 reduces NK apoptosis in septic serum, suggesting a potential therapeutic approach to mitigate NK cell death (Fig. 2D, E).
Conclusions: In conclusion,sepsis induces a significant reduction in NK cell numbers and dysfunction in their activation, contributing to increased susceptibility to secondary infections. Elevated lactate levels exacerbate NK cell depletion, and targeting lactate transport may offer a potential therapeutic strategy to mitigate immune dysfunction in sepsis.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***988***

Introduction: Acute respiratory distress syndrome (ARDS) is a life-threatening respiratory syndrome driven in large part by dysregulated neutrophil activation. Activated leukocyte adhesion molecule (CD166) is a transmembrane glycoproteinwhose deficiency mitigates LPS-induced acute lung injury (ALI). We previously showed neutrophil-specific Orai1 deletion ameliorated both acute pancreatitis (AP)-associated and LPS-induced ALI, yet the underlying mechanisms remain unclear. This study aims to investigate how Orai1 deletion affects neutrophil function, and to explore the therapeutic potential of targeting neutrophil Orai1 for treating ALI triggered by systemic inflammation response.

Methods: Neutrophil-specific Orai1-depleted mice were generated by crossing MRP8-Cre mice with Orai1f/f mice. ALI was induced by LPS or sodium taurocholate-triggered AP 24 h before sacrifice. Lung neutrophils and macrophages were sorted via flow cytometry for bulk RNA-seq, and for single-cell proteomic profiling using ultrahigh-sensitivity mass spectrometry with advanced nanoliter-scale oil-air-droplet chips. Integrated transcriptome-proteome correlation analysis was performed. Candidate transcription factors (TFs) and promoter motifs were predicted using PROMO and Promoter-2.0 programs, with TF-promoter binding analyzed via AlphaFold and JASPAR. Neutrophil-like cells (dHL-60), murine bone marrow-derived neutrophils and human polymorphonuclear neutrophils (PMNs) were used for functional assays. Anti-Ly6G-modified liposomes loaded with the Orai1 inhibitor (CM-4620) were designed to target neutrophils and downregulate Orai1 in vivo.

Results: Orai1ΔMRP8 mice exhibited significantly reduced neutrophil infiltration and ameliorated lung injury in both AP and sepsis models compared to littermate controls. Transcriptomic analysis of differentially expressed genes revealed that neutrophil-specific Orai1 deletion is strongly associated with cell motility, while proteomic analysis showed that differentially expressed proteins are significantly enriched in pathways related to cell adhesion. Integrated transcriptome-proteome analysis revealed that Orai1 deletion selectively downregulated CD166 expression in neutrophils ($r = 0.95$). This effect, however, was not observed in alveolar or interstitial macrophages. Five potential TFs were predicted, with NFATC1 and NFATC2 demonstrating the highest binding confidence. Luciferase reporter assay confirmed that NFATC2 effectively activated CD166 transcription, and ChIP-qPCR verified direct binding of NFATC2 to the CD166 promoter between the -598 bp and -553 bp regions. Orai1 inhibition sustained NFATC2 nuclear translocation, whereas NFATC2 knockdown reduced CD166 expression. In addition, both Orai1 and CD166 expression were significantly elevated in PMNs from patients with ARDS, and single-cell RNA-seq of bronchoalveolar lavage fluid (BALF) from ARDS patients revealed that Orai1, NFATC2, and CD166 are markedly elevated in BALF-derived neutrophils. Liposomes targeting neutrophil Orai1 demonstrated good biocompatibility and promising targeting efficiency upon both intranasal and intravenous administration, significantly reducing pulmonary neutrophil infiltration and ameliorating both AP-associated and LPS-induced ALI.

Conclusions: Neutrophil-specific Orai1 deletion ameliorates ALI via the NFATC2-CD166 axis, highlighting liposomes targeting neutrophil Orai1 as a promising therapeutic strategy.

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**)***:990***

Introduction: Sedation in traumatic brain injury patients is essential not only for comfort and ventilator synchrony but also to reduce intracranial pressure and optimise cerebral oxygen consumption. Propofol and opioids like fentanyl are frequently used agents, though their side effects—such as respiratory depression, hemodynamic instability, and opioid withdrawal—can complicate care. Alternatives like dexmedetomidine, which offers sedation with minimal respiratory suppression, and ketamine, known for hemodynamic stability, are increasingly considered in neurocritical settings due to their favourable pharmacologic profiles.1,2,3
Objectives: This study evaluates the efficacy and safety of an opioid-free sedation regimen using ketamine–dexmedetomidin (Group KD) compared to the standard propofol–fentanyl combination (Group PO) in adults patients with severe TBI. The goal is to identify a sedation strategy that ensures effective sedation and analgesia while reducing the opioid-related side effect burden. The primary objective was to find out the "percentage of time spent in goal Richmond Agitation Sedation (RASS) score, i.e., RASS score of -3 to -4" in two groups.
Methods: This study is a single-blinded, prospective randomized controlled trial conducted in trauma ICU of Level 1 Trauma centre. 52 adult patients of severe traumatic brain injury were enrolled into the study (26 in each group). Ketamine and dexmedetomidine combination was given as sedation in Group KD and propofol and fentanyl in Group PO. Sedation was initiated and titrated to achieve a target RASS score of -3 to -4, checked every 15 min initially and hourly thereafter for 48 h. ONSD and TCD were checked at baseline then every 6 hourly for 48 h. Hemodynamic alterations, VAP, withdrawal symptoms, decrease in serum cortisol level at end of 48 h, FOUR score, any neuroworsening during ICU stay and GOSE at 90 days were noted.
Results: Baseline characteristics were comparable between the two groups. Target RASS was maintained in both groups for similar duration (45.27 h vs 45.62 h, p = 0.106) but was achieved a little early in Group PO (40.38 min vs 36.92 min, p 0.095). Group KD demonstrated a significantly higher reduction in serum cortisol compared to Group PO ($p < 0.0001$) pointing towards better control of stress response. Incidence of bradycardia (p0.235) and hypotension requiring noradrenaline support (p = 0.116) was higher in Group KD though statistically not significant. Group PO was found to have statistically significant higher incidence of withdrawal symptoms ($p = 0.001$) and constipation (0.017). No significant difference was observed in the incidence of ventilator-associated pneumonia. Neuroworsening occurred in 2 patients in Group KD and 1 patient in Group PO. FOUR score at ICU discharge ranged from 8 to 16 and was comparable across groups (p > 0.05). GOSE at 90 days had a similar distribution with majority of patient having good outcome with GOSE of > 5 ($p = 1$).
Conclusions: Ketamine–dexmedetomidine sedation for conservative management of severe TBI patients is as effective as the more practiced propofol–fentanyl sedation while avoiding the significant side effects of opioid use. This study highlights nonopioid drug combinations as a promising alternative for regular analgo-sedative in management of TBI patients.

Introduction: Over the past decade, kidney transplantation has faced increasing challenges. This has led to a significant expansion of donation after circulatory death (DCD), particularly controlled DCD (cDCD), also known as Maastricht category III donors. In many regions, cDCD now constitutes a substantial portion of deceased donor kidney transplants. However, cDCD is associated with inherent limitations, notably prolonged warm ischemia time (WIT), which can lead to ischemia–reperfusion injury and delayed graft function (DGF). To mitigate these risks, in situ preservation techniques such as abdominal normothermic regional perfusion (NRP) with extracorporeal membrane oxygenation (ECMO) have been developed. NRP aims to restore warm, oxygenated blood flow to abdominal organs after the determination of death, following the withdrawal of life-sustaining treatments (WLST) and before organ recovery. The objective of this study is to compare the effectiveness of kidney transplantation from cDCD and brain death donors (DBD) and to demonstrate that the outcomes between these two techniques are comparable.
Objectives: Comparative analysis of kidney transplant effectiveness between two populations under 75 years old: donors from controlled donation after circulatory death (cDCD) versus brain death donors (DBD)
Methods: A single-center retroprospective observational cohort study conducted between 2020 and 2024, aiming to compare the effectiveness of kidney transplantation from donors under 75 years of age: controlled donation after circulatory death (cDCD) versus brain death donors (DBD). Quantitative variables are presented as medians and interquartile ranges (IQR, p25-p75), and were compared using the Mann–Whitney *U* test. Qualitative variables are expressed as frequencies and percentages (n, %) and were analyzed using the Chi-square test (χ^2 test)
Results: Between 2020 and 2024, a total of 64 potential kidney donors under 75 years of age were evaluated: 44 were controlled donation after circulatory death donors (cDCD, 68.8%) and 20 were brain death donors (DBD, 31.2%). Among cDCD donors, 61.3% were male, compared to 45% in the DBD group ($p = 0.04$). The median age was similar between groups: 61 years (IQR 56.2-67.2) in cDCD vs. 57.5 years (IQR 49.5-67) in DBD ($p = 0.54$). Median ICU stay was longer in cDCD donors (3 vs. 2 days; $p = 0.03$). Smoking history (current or former) was comparable: 45% in cDCD vs. 50% in DBD ($p = 0.82$). Hypertension was more frequent in the DBD group (55% vs. 34%; $p = 0.04$). Dyslipidemia rates were similar (29.5% in cDCD vs. 25% in DBD; $p = 0.76$), as were diabetes rates (9% vs. 10%; $p = 0.25$). Charlson Comorbidity Index was 0 in both groups ($p = 0.38$). Donation effectiveness was slightly higher in cDCD donors (84%) as compared to DBD donors (80%), but the difference was not statistically significant ($p = 0.46$)

Conclusions: Based on our findings and in line with the current medical evidence, kidney transplantation outcomes from controlled donation after circulatory death with normothermic regional perfusion (cDCD-NRP) are comparable to those from brain death donors (DBD) in individuals under 75 years of age. No statistically significant differences were observed in donation effectiveness between the two groups (84% cDCD-NRP vs. 80% DBD; $p = 0.84$), supporting the clinical equivalence of both donation modalities. The higher prevalence of hypertension observed in the DBD group ($p = 0.04$) may reflect a greater burden of chronic comorbidities typically associated with the pathophysiological mechanisms of brain death. In contrast, the slightly longer ICU stay in cDCD-NRP donors ($p = 0.03$) appears consistent with the procedural and logistical aspects inherent to this type of donation. These findings reinforce the role of cDCD-NRP as a safe and effective alternative to DBD, helping to expand the donor pool without compromising the success of kidney transplantation

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**)***:998***

Introduction: Noninvasive ventilation (NIV) has become a key therapeutic approach in the management of acute respiratory failure (ARF). It encompasses all ventilatory assistance techniques that partially or fully support respiratory effort, ensuring adequate alveolar ventilation.
Objectives: This study aims to evaluate the use of NIV in the prehospital setting with its two modes (BiPAP and CPAP), identify factors associated with success or failure, and characterize the clinical progression of patients managed by the Emergency Medical Services (EMS) in the Central-Eastern region of Tunisia.
Methods: This retrospective study was conducted over one year (January 1 to December 31, 2023), including 263 adult patients who received NIV (BiPAP or CPAP) during prehospital intervention. The data were collected from the online "SI SAMU" records.
Results: The results show a predominance of primary-secondary missions (64.9%), with heterogeneous distribution among the involved SMUR teams. The study population was predominantly male (69.2%) and elderly (68.1 ± 10.8 years), with multiple comorbidities, including hypertension (52.1%), diabetes (41.8%), and chronic obstructive pulmonary disease (COPD) (37.3%). Analysis of clinical parameters revealed a significant improvement in oxygen saturation (from 80.6 ± 13.6% to 92.3 ± 9.5%) and respiratory rate after NIV initiation (from 30.6 ± 6.7 to 26 ± 6.3), confirming the efficacy of this technique in managing acute respiratory failure. The main indications for NIV were acute pulmonary edema (APE) and COPD exacerbations, in line with the international guidelines. The overall success rate of NIV was satisfactory (72.6%), with a positive correlation between therapeutic success and the etiology of ARF (APE). Patients with APE showed the best outcomes, followed by those with COPD. Multivariate analysis identified a history of chronic respiratory failure as the only independent factor associated with NIV success in the prehospital setting.
Conclusions: This study confirms the value of NIV in the prehospital management of acute respiratory failure. However, prospective, multicenter studies are needed to better assess the long-term impact of this approach and identify predictive factors of success.

The interplay between flow rate and respiratory rate during high-flow nasal cannula therapy: a computational study

H. Shamohammadi[1], S. Saffaran[1], JG. Hardman[2], DG. Bates[1]
[1]School of Engineering, University of Warwick, Coventry, United Kingdom; [2]School of Medicine, Injury, Recovery and Inflammation Science Academic Unit, University of Nottingham, Nottingham, United Kingdom

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**)***:1000***

Introduction: High-flow nasal cannula (HFNC) therapy enhances oxygenation and reduces respiratory effort in patients with Acute Hypoxemic Respiratory Failure (AHRF). Its benefits stem mainly from improved CO_2 clearance from anatomical dead space and the delivery of a flow-dependent positive airway pressure.
Objectives: This study aimed to use a detailed model of the anatomical dead space to simulate washout dynamics during HFNC therapy, quantifying clearance efficiency and characterising gas mixing under varying HFNC flow and respiratory rates (RR). Simulation outcomes were validated against in vivo and in vitro studies.
Methods: The ICSM simulator (schematic in Fig. 1) was employed to simulate dead space gas clearance in six healthy subjects [1] across a range of HFNC flow rates and RRs. The anatomical dead space was modelled as a 150 ml volume [2], represented by 50 stacked laminae, each with a volume of 3 ml (Vl_a = 3 ml). HFNC clearance was assumed to occur at the end of exhalation and the start of inhalation [3], [4]. The number of layers cleared of CO_2 by HFNC was calculated as:
Nwashed_layers = (HFNC flow rate × time slice) / Vlam (1)
Gas mixing between fresh HFNC-delivered gas and residual expired gas in the dead space was defined by:
fnew_SD,j,x = ω × finspired,x + (1 -ω) × fold_SD,j,x, for j < Nwashed_layers (2)
where fSD,j,x is the fraction of gas x in lamina j and ω = 0.8 is the mixing factor determining the proportion of gas mixing during washout.
In addition, a gas mixing module [5] was employed with a mixing parameter (σ = 0.1) based on the clearance half-time reported in [6]:
fSD,j,x = (1-σ) × fSD,j,x + σ × fSD,j + 1,x for j < NSD (3)
Results: Similar to the results in [4], mean upper airway clearance increased with HFNC flow but declined with higher RRs. At a RR of 15 bpm, clearance occurred across all flow rates; at 45 bpm, it fell to 31% at 20 L/min and 61% at 60 L/min (Fig. 3B). Increasing HFNC flow rates markedly improved oxygen penetration within the dead space. Layers with > 15% O_2 rose from a mean of 19 at 20 L/min to 26 at 100 L/min (Fig. 2). Mean end-tidal CO_2 pressure at a 5 cm nasal depth fell from 35.9 mmHg to 19.6 mmHg at 30 L/min, further reducing to 10.5 mmHg at 100 L/min. Mean CO_2 pressures were consistently higher at greater nasal depths. For instance, at 60 L/min, end-tidal CO_2 pressure increased from 11 mmHg at 2 cm depth to 15.8 mmHg at 5 cm depth (Fig. 3A).
Conclusions: The findings from this simulation study indicate that higher HFNC flow rates significantly enhance oxygen delivery and facilitate more effective clearance of anatomical dead space, as evidenced by elevated O_2 fractions and reduced end-tidal CO_2 pressures. However, while higher HFNC flow rates improve upper airway clearance, elevated respiratory rates reduce this effect. These results

emphasise the necessity of optimising HFNC settings to achieve effective gas washout and simultaneously reduce patients' respiratory efforts. Future work will develop Digital Twins of AHRF patients receiving HFNC to provide detailed data on the interplay between flow and respiratory rates in acute respiratory conditions.

Noncoding RNAs encoding small peptides are associated with sepsis development

D. Yang[1], Y. Fan[1], Y. Liu[1], Y. Zhou[1], M. Yu[1], Y. Yang[1], W. Huang[1]
[1]Jiangsu Provincial Key Laboratory of Critical Care Medicine,Department of Critical Care Medicine, Zhongda Hospital, School of Medicine, Southeast University, Nanjing, China

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***1001***

Introduction: Immune dysregulation is the fundamental mechanism for the occurrence and development of sepsis [1]. To date, no diagnostic biomarker nor targeted therapeutic agent for sepsis has proven useful or effective, necessitating deeper investigation into its pathogenic mechanisms. Small peptides derived from noncoding RNAs are important regulators of anti-infection immune response [2]. However, due to the lack of a classical open reading frame for noncoding RNAs, there is still a large gap in the understanding of noncoding RNAs that can encode small peptides in sepsis [3]. Therefore, it is necessary to identify novel lncRNAs with coding ability in sepsis.
Objectives: To identify novel lncRNAs with coding potential associated with sepsis.
Methods: Peripheral blood samples were obtained from five healthy controls (HC) and ten patients with sepsis, followed by lncRNA sequencing (lncRNA-seq). Heatmap analysis was performed to compare the expression patterns of differentially expressed lncRNAs between the two groups. LncRNAs with coding potential and size between 1000 and 3000 bp were screened using the CPC2 tool (coding potential calculator 2, http://cpc2.cbi.pku.edu.cn/). The lncRNAs with coding potential was amplified using reverse transcription followed by real-time quantitative PCR (RT-qPCR) with specifically designed primers. PCR products were then separated by gel electrophoresis and subsequently sequenced to confirm the target lncRNA sequence. The diagnostic efficacy of target lncRNA in sepsis was comprehensively evaluated by group t test and area under the relative expression curve (AUC) between the two groups of population.
Results: A total of 1008 up-regulated lncRNAs and 1201 down-regulated lncRNAs were detected in the peripheral blood of sepsis patients compared with healthy controls (HC). (Fig. 1A) Then, we used CPC2, a web tool widely applied to predict the coding potential of noncoding RNA, to identify translatable lncRNA. Notably, we identify 10 lncRNAs with coding potential within the top 50 differentially expressed lncRNA. Gel electrophoresis of RT-qPCR products and sequencing confirmed the existence of the targeted lncRNAs. To evaluate the diagnostic potential of the lncRNAs for sepsis, we performed receiver operating characteristic (ROC) curve analysis. LncRNA ENST00000697493 is highly expressed in HC. The area under the curve (AUC) for [LncRNA ENST00000697493] reached 1.000. (Fig. 2A) LncRNA ENST00000701713 is highly expressed in sepsis patients. The area under the curve (AUC) for [LncRNA ENST00000701713] reached 0.920. (Fig. 2B) LncRNA ENST00000649154 is highly expressed in HC. The area under the curve (AUC) for [LncRNA ENST00000649154] reached 1.000. (Fig. 2C) LncRNA XR_005646961.1 is highly expressed in sepsis patients. The area under the curve (AUC) for [LncRNA XR_005646961.1] reached 1.000. (Fig. 2D) LncRNA ENST00000402027 is highly expressed in sepsis patients. The area under the curve (AUC) for [LncRNA ENST00000402027] reached 1.000. (Fig. 2E) LncRNA ENST00000664650 is highly expressed in sepsis patients. The area under the curve (AUC) for [LncRNA ENST00000664650] reached 0.940. (Fig. 2F) LncRNA ENST00000692968 is highly expressed in HC. The area under the curve (AUC) for [LncRNA ENST00000692968] reached 1.000. (Fig. 2G) LncRNA NR_152604.1 is highly expressed in HC. The area under the curve (AUC) for [LncRNA NR_152604.1] reached 0.960. (Fig. 2H) LncRNA ENST00000688334 is highly expressed in HC. The area under the curve (AUC) for [LncRNA ENST00000688334] reached 0.800. (Fig. 2I) LncRNA ENST00000412250 is highly expressed in sepsis patients. The area under the curve (AUC) for [LncRNA ENST00000412250] reached 1.000. (Fig. 2J).

Conclusions: This study indicated that lncRNAs with coding ability are associated with the occurrence of sepsis. These translatable lncRNAs may shed light on the underlying mechanisms of immune dysregulation, laying the foundation for further studies on the role of the small peptides they encode in the progression of sepsis.

Introduction: Ventilator-associated pneumonia (VAP) is one of the most frequent and severe healthcare-associated infections in intensive care units (ICUs), with significant implications for patient morbidity, mortality, and healthcare costs. Beyond increasing the duration of mechanical ventilation (MV) and hospital stay, VAP often requires escalation of care and prolongs critical illness. Continuous monitoring and implementation of standardized prevention strategies are crucial for improving outcomes in critically ill patients.
Objectives: To evaluate the epidemiological impact of a structured, evidence-based VAP prevention protocol in a tertiary ICU by comparing VAP incidence, density, and mechanical ventilation utilization rates before and after its implementation.
Methods: This was a prospective, observational, and comparative study conducted in the ICUs of a tertiary hospital in a middle income country. All adult patients (≥ 18 years) who received invasive mechanical ventilation were included. The pre-intervention period spanned from January to May 2024, and the post-intervention period from June 2024 to March 2025. Exclusion criteria included pre-existing pneumonia, discharge or death within 48 h of intubation, or incomplete clinical data. The intervention began in June 2024 and involved a multicomponent VAP prevention protocol including: elevation of the head-of-bed (30°-45°), oral hygiene with 0.12% chlorhexidine twice daily, sedation control (RASS target 0 to − 2), cuff pressure maintenance (25-30 mmHg), daily assessment for extubation readiness, and real-time data monitoring. Data were extracted from the EPIMED clinical database, with variables including number of VAP episodes, VAP density (per 1000 MV-days), mechanical ventilation days, MV-days per patient, and ventilator utilization rate.
Results: In the preintervention phase, VAP density ranged from 7.41 to 13.20 cases per 1,000 MV days, with a mean of approximately 9.2. Following protocol implementation, VAP density declined to a range of 0.00 to 9.54, with a mean of 4.73 cases/1,000 MV days—an overall reduction of nearly 50%. Notably, no VAP cases were reported in December. The number of episodes also dropped from 28 (average 5.6/month) to 22 (average 3.1/month) post-intervention. The mechanical ventilation utilization rate remained stable (31.25% to 38.34%), confirming that VAP reduction was independent of MV exposure. The average MV duration per patient (4.8–5.6 days) showed no significant change.
Conclusions: This epidemiological study highlights the effectiveness of implementing a structured, evidence-based VAP prevention protocol in reducing VAP incidence without reducing mechanical ventilation use. The results underscore the critical role of consistent protocol adherence, staff education, and continuous data monitoring in improving patient safety in ICUs. Sustainable reductions in VAP require a coordinated multidisciplinary effort grounded in real-world epidemiological surveillance and best clinical practices.

Monthly comparison: ventilador utilization and VAP incidence density (2023 vs 2024)

Intensive Care Medicine Experimental 2025 **13**(**Suppl 1**):***1005***

Introduction: Point-of-care hemodynamic monitoring, guiding each patient's appropriate inotrope-vasoactive management, is of paramount importance, especially for critically-ill patients in pediatric intensive care units (PICUs). Conventional parameters have proven to be inaccurate and subjective, while studies on continuous cardiac output monitoring techniques have not yet led to definitive conclusions.
Objectives: The goal of the present study is to compare invasive (transpulmonary thermodilution-TPTD by pulse-index contour continuous cardiac output-PICCO) and noninvasive (echocardiography) techniques, to monitor cardiac output normalized to body surface area (cardiac index- CI) and hemodynamic status in critically ill pediatric patients.
Methods: This prospective single-center study consecutively recruited hemodynamically unstable and mechanically-ventilated critically-ill PICU patients aged < 18 years of age in an academic pediatric ICU from March 2024 to March 2025. Patients were stratified based on

vasoactive-inotropic score (VIS) (Group HU, $n = 25$). Hemodynamically stable patients (Group C, $n = 10$) served as the control group. Demographics, clinical data and outcome indices were recorded.
Results: The mean age of patients was 8 years (± 6,7 SD), 52% females, mechanical ventilation duration 9 days (IQR 5-16), and PICU LOS 14 days (8.5-18.5). The diagnoses of HU patients were sepsis/septic shock (n = 8 patients), non-cardiogenic pulmonary edema/ARDS ($n = 10$ patients), pulmonary edema due to cardiogenic shock ($n = 2$ patients), and central nervous system traumatic or nontraumatic pathology ($n = 5$). Crude mortality was 28% ($n = 7$). Pearson correlation analysis showed positive correlations between echo and TPTD cardiac output estimations (Pearson's $r = 0.774$, $p < 0.001$-Fig. 1a). Agreement between invasive and noninvasive techniques was high (Cronbach's alpha 0.867; 95% confidence intervals 0.968-0.941; $p < 0.001$). Both CO TPTD and echo measurements highly predicted mortality (AUROC CI TPTD 0.94; $p < 0.001$, AUROC CI echo 0.980; $p < 0.001$), but differed in cutoff values (CI TPTD 2.6 and CI echo 3.65 lt/min/m^2—Fig. 1b).
Conclusions: The implementation of both invasive and noninvasive advanced monitoring techniques can reliably assess the hemodynamic status and predict the outcome of critically ill pediatric patients. Invasive parameters from transpulmonary thermodilution technologies lead to objective estimations for less experienced intensivists on cardiac ultrasound.

Introduction: Septic cardiomyopathy (SC) is characterized by myocardial dysfunction in patients with sepsis, leading to severe hemodynamic instability. Many uncertainties still remain regarding mechanisms, characteristics, treatment and even prognosis of this condition.
Objectives: To compare intensive care unit (ICU) mortality between patients with septic cardiomyopathy (SC) and patients without septic cardiomyopathy (controls). Also, to compare clinical, laboratory and echocardiographic characteristics of SC patients who survived (SCs) and those who did not (SCd).
Methods: Retrospective, observational, single-center study of patients admitted in ICU during 2022 and 2023 due to sepsis, with or without a diagnosis of SC. Kaplan–Meier survival analysis was performed.
Results: We included 58 SC patients (mean age 66.7 ± 15.4 years, 62.1% male) and 248 controls (mean age 65 ± 16.2 years, 61.3% male). Regarding SC patients, in-hospital mortality was 56.9%, with 55.2% of deaths occurring during ICU stay. The mean time to death was 3.5 days for SC patients and 5 days for non-SC patients. ICU mortality was significantly higher in SC patients than controls ($p = 0.01$, log rank test). Regarding SC patients, length of ICU stay was similar between survivors and non-survivors. However, infection source control was significantly better in survivors (SCs: 80% vs. SCd: 46%, $p = 0.01$). Inotrope and vasopressor doses were higher in non-survivors (peak noradrenaline dose SCd: 220 mcg/min vs. SCs: 60 mcg/min, $p < 0.001$). Organ dysfunction was similar between groups, except for KDIGO III acute renal failure, which was higher in non-survivors, though not statistically significant (SCd: 83.3% vs. SCs: 70%, $p = 0.052$). Non-survivors had higher troponin (SCs: 48 ng/L vs. SCd: 103 ng/L, $p = 0.015$) and peak lactate levels (SCd: 95 mg/dL vs. SCs: 45 mg/dL, $p = 0.05$), at ICU admission. Left ventricular ejection fraction recovery at ICU discharge was significantly higher in survivors (SCd: 10.3% vs. SCs: 93.3%, $p < 0.001$).
Conclusions: SC was linked to higher ICU mortality. Infection source control was better in SC survivors. Non-survivors had higher doses of inotropes/vasopressors and higher troponin and lactate levels, at ICU admission. Early recognition and management are crucial for SC prognosis improvement.

Introduction: Chronic obstructive pulmonary disease (COPD) is the third leading cause of morbidity and mortality globally. The data from low and middle-income countries, with prevalent biomass exposure and tuberculosis, are scarce.

Objectives: We evaluated factors affecting survival among patients with severe and very severe COPD admitted to the ICU, focusing on exposure phenotypes, mental health, and socioeconomic status.

Methods: Data were collected from 2 tertiary care university hospitals in Mysuru, including demographics, laboratory investigations, mechanical ventilation requirements, complications (corpulmonale, pulmonary hypertension, acute kidney injury, septic shock), pulmonary function tests, medications, mental health (assessed by HAM-A and HAM-D), and socioeconomic status (standardized living index). Exposure phenotypes were classified as tobacco smoke (TS) exposure (≥ 10 pack-years), biomass smoke (BMS) exposure (≥ 10 years of solid fuel use), combined tobacco and biomass exposure (TS & BMS), and tuberculosis-associated obstructive pulmonary disease (TOPD) defined as post-tubercular airway obstruction with no significant TS or BMS exposure. The data were analyzed using Jamovi with ANOVA and Pearson chi-square tests; Kaplan–Meier survival analysis for impact of exposure on survival, and Cox proportional hazards regression to identify independent predictors of mortality.

Results: In this cohort of 717 patients, 38.1% had hypertension, 22.3% had diabetes, and 31.4% had heart disease. Non-survivors had a significantly higher prevalence of hypertension and heart disease ($p = 0.001$). Pulmonary hypertension (34.3%) and corpulmonale (27.8%) were common, with non-survivors showing a higher prevalence of pulmonary hypertension ($p = 0.001$). The prevalence of exposure phenotypes was 16.4% for tobacco-induced COPD (TOPD), 22.4% for biomass COPD, and 53.56% for combined tobacco and biomass exposure. 82.7% were from low-income categories. Mental health assessment revealed mild depressive symptoms (mean HAM-D: 7.0 ± 4.5) and minimal anxiety (mean HAM-A: 1.0 ± 0.1). Mechanical ventilation was required in 8.1% (invasive) and 24.4% (non-invasive); longer in BMS-exposed individuals ($p < 0.001$). In-hospital mortality was 12.7% for severe COPD and 15% for very severe COPD.

Kaplan–Meier survival analysis revealed that TOPD had the poorest survival (log-rank test, $p < 0.0001$) (Figure and Table 1). In a multivariable Cox model (Table 2), TOPD was associated with an increased mortality risk (HR 7.89, 95% CI 4.17–14.91, $p < 0.001$). BMS exposure alone had no significant mortality impact (HR 0.96, $p = 0.914$), and TS and BMS exposure showed intermediate mortality risk (HR 0.57, $p = 0.083$).

Conclusions: TOPD is associated with higher mortality compared to tobacco, biomass, and combined tobacco–biomass exposures. Comorbidities, such as pulmonary hypertension and corpulmonale independently increase in-hospital mortality.

Intensive Care Medicine Experimental 2025,* 13(1)*:001008

Introduction: In recent years, cytomegalovirus (CMV) reactivation has been reported in apparently non-immunosuppressed patients during their acute illness with worse clinical outcomes [1,2,3]. However, no prospective study is available in patients requiring prolonged mechanical ventilation (PMV).
Objectives: To study the prevalence of CMV reactivation and its viral load kinetics in apparently non-immunosuppressed patients requiring PMV (more than one week).
Methods: After ethics committee approval, this prospective study screened all consecutive adult ICU patients requiring PMV for the presence of CMV seropositivity (anti-CMV IgG antibodies). Exclusion criteria were: age < 18 years, use of antiviral agents within the preceding 7 days, known or suspected underlying immune deficiencies, and pregnant patients. Blood samples from the included patients were analyzed for CMV reactivation every week for a maximum of four weeks after the initiation of mechanical ventilation (MV). Further, in cases of CMV reactivation, 3 more samples (maximum) were collected on a weekly basis to assess the viral load kinetics. The real-time PCR reactions were performed in plasma samples, and the CMV DNA load expressed as copies/ml. CMV reactivation was defined as blood viral load > 1000 copies/ml.
Results: During the study period (Jul 2024-Feb 2025), 52 out of 210 patients met the eligibility criteria. At the time of ICU admission, the median age was 40.5 years (IQR 31–56), and 55.7% were male. At study inclusion, the median SOFA score was 7.5 (IQR 4–12.5). A total of 188 plasma samples were analyzed. CMV reactivation was observed in 22 out of 52 patients (42.30%), and more than half (13/22) of them were positive by two weeks after the initiation of MV (Fig. 1). The clinical characteristics of patients with CMV reactivation compared to those without reactivation were as follows: age 38 versus 41 years ($p = 0.44$), SOFA score at inclusion 8 versus 6.5 ($p = 0.40$). The bloodstream infection (BSI) in CMV reactivation group was 45.5% (10/22) in comparison to 13.3% (4/30) in non-CMV reactivation group. The mortality rate at ICU discharge for the CMV reactivation group was 72.72% (16/22) as compared to 33.35% (10/30) in the non-reactivation group ($p = 0.01$). Among patients with CMV reactivation, the maximum reactivation in survivors occurs at 1st and 2nd week, while in non-survivors at 3rd and 4th week. At the time of reactivation, the median copies (per ml) in survivors were 2850 (IQR 2387–14487) and in non-survivors 4050 (IQR 2216–8462); which decreased to median copies 2,240 (IQR 1,337–5,060) in survivors; while increased to 13,600 (IQR 2,900–48,230) in non-survivors in follow-up samples (Fig. 2).
Conclusions: CMV reactivation occurred in 42% of patients with PMV, with significantly higher mortality in comparison to patients without reactivation. Among CMV reactivation, non-survivors have higher median CMV copies which continued to rise in follow-up weeks in comparison to survivors.

Impact of the sulfide donor, diethyl-ammonium tetrathiomolybdate on healthy rats and in a model of haemorrhage–reperfusion

Introduction: Ischaemia–reperfusion injury (IRI) contributes to significant morbidity and mortality. The reperfusion injury component is largely driven by excessive production of reactive oxygen species (ROS), leading to cellular damage and death. Sulfide donors have shown promise by reversibly inhibiting the mitochondrial electron transport chain, reducing metabolic activity and ROS generation. We identified diethyl-ammonium tetrathiomolybdate (DEATTM) as a slow-release sulfide donor and tested its safety and therapeutic potential in mitigating IRI.
Objectives: To test the safety and pharmacokinetics/pharmacodynamics (PK/PD) in healthy rats, and the therapeutic efficacy of DEATTM in a non-recovery rat model of IRI.
Methods: Under isoflurane anaesthesia, Wistar rats (200–300 g, both sexes) underwent carotid and jugular cannulation, bladder catheterisation, and tracheostomy, and initiation of fluid administration (Ringer's lactate [RL], 10 ml/kg/h). (i) Safety and PK/PD studies: A dose–escalation study of DEATTM (1–100 mg/kg IV bolus) was performed, followed by a second study assessing a 30 mg/kg bolus dose followed by a 90 mg/kg 1-h infusion. Outcomes included survival, cardiorespiratory function, and lactate. Urine output and electrolytes were assessed hourly. Blood samples were collected for PK/PD analyses.
(ii) IRI study: Anaesthetised Wistar rats and following instrumentation (as described above). Ischaemia was induced by withdrawing 40% of circulating blood volume over 15 min, followed by a 90-min ischaemic period; background fluids were ceased during ischaemia. Rats (16 per group; 50% male) were randomised to receive either DEATTM (30 mg/kg bolus at the point of resuscitation) or RL as placebo. Both groups were then resuscitated with the shed blood. Treated animals received a 30-min DEATTM infusion (60 mg/kg, half dose was added with injected blood), while control animals received an equivalent volume of RL. Animals were monitored for 4 h post-intervention, and outcomes were assessed as per the safety studies. Data were analysed using repeated measures one-way or two-way ANOVA, as appropriate, with Dunnett's or Sidak's post hoc tests. Log-rank and Mann–Whitney U tests were also used where relevant. Survival was assessed using Kaplan–Meier analysis.
Results: The DEATTM dose escalation study performed in healthy rats was well tolerated. In the bolus + infusion safety study, a significantly greater diuresis, natriuresis, kaliuresis and chloruresis were observed with DEATTM compared with controls. (Fig. 1). In the IRI study, 4-h survival was higher in the DEATTM group (11/16, 69%) compared to controls (5/16, 31%) ($p = 0.04$) (Fig. 2A). Diuresis was also significantly greater with DEATTM over the first 2 h following reperfusion.
Conclusions: DEATTM was safe in short-term studies in healthy animals; the accompanying diuresis/natriuresis suggests inhibition of the renal tubular Na^+/K^+-ATPase. DEATTM conferred a survival benefit in the IRI model, with short-term diuretic/natriuretic effects.

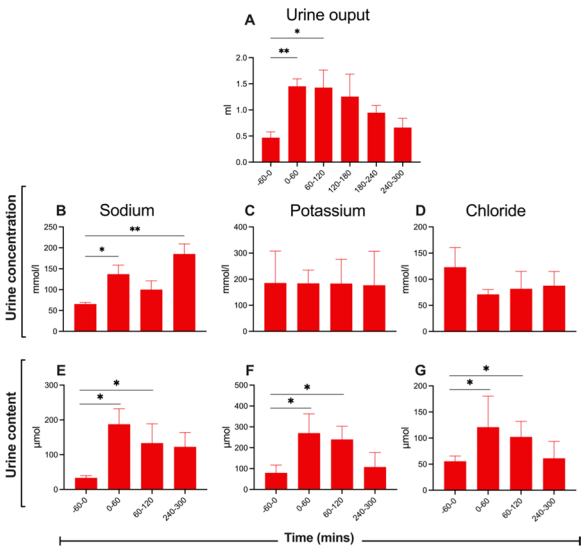

Fig. 1 (abstract 001009) Urine output (A), urinary electrolyte concentrations (B–D) and total excreted content (E–G) in healthy rats given a 30 mg/kg bolus of DEATTM followed by a 90 mg/kg infusion over 1-h (Study 2). Data are presented as mean ± SD. *$p < 0.05$ and 0 **$p < 0.01$ vs. baseline, analysed using repeated measures one-way ANOVA with Dunnett's post hoc test

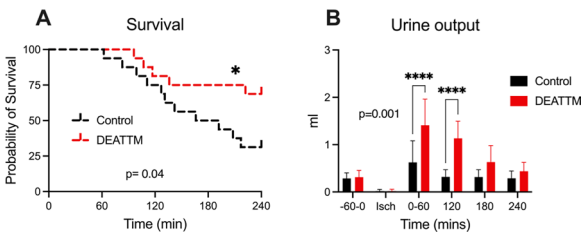

Fig. 2 (abstract 001009) Survival and urine output in the haemorrhage–reperfusion model. (A) Survival probability in control ($n = 16$) and DEATTM-treated ($n = 16$) groups, with equal sex distribution (50% male). Survival was significantly higher in the DEATTM group (69%) vs. control (31%) ($p = 0.04$; Log-rank test). (B) Urine output was significantly higher in the DEATTM group at 60 and 120 min. Data are presented as mean ± SD. *$p < 0.05$, ****$p < 0.001$

Efficacy and safety of cipepofol versus non-cipepofol sedation regimens in mechanically ventilated patients with severe pneumonia

J. Juan, Y. Li
Department of Respiratory Medicine, Xiangya Hospital, Central South University, Changsha, China
Correspondence: Y. Li
Intensive Care Medicine Experimental 2025,* 13(1)*:001010

Introduction: Patients with severe pneumonia often present with acute respiratory distress syndrome or serious hypoxemia, necessitating sedation strategies that prioritize maintaining synchrony with mechanical ventilation and reducing oxygen consumption. In addition, patients with sepsis or septic shock exhibit significantly reduced hemodynamic tolerance to sedative agents. So far, optimal sedation strategy remains controversial in mechanically ventilated patients with severe pneumonia.
Objectives: This study evaluated the efficacy and safety of cipepofol versus non-cipepofol sedation regimens in mechanically ventilated adults with severe pneumonia, focusing on clinical outcomes and hemodynamic stability.
Methods: In this single-center retrospective study, 230 patients with severe pneumonia admitted to the Respiratory ICU of Xiangya Hospital, Central South University from February 2023 to December 2024 were included. Patients were divided into the cipepofol (N = 110) and non-cipepofol (N = 120) groups. Baseline characteristics (age, sex, BMI) and sedation/analgesia durations were comparable between two groups, while the non-cipepofol group exhibited higher APACHE II scores than the cipepofol group. Primary endpoint was mechanical ventilation duration (time from intubation/ICU admission to extubation). Secondary endpoints included sedation success (defined as achieving the target sedation level of RASS-1 to -4 in more than 90% of recorded RASS assessments), length of ICU stay, 28-day mortality, and circulatory adverse events (hypotension: SBP < 90 mmHg, DBP < 60 mmHg, MAP < 70 mmHg, or > 30% drop from baseline; bradycardia: HR < 40 bpm or > 30% drop from baseline).
Results: No significant differences were observed in mechanical ventilation duration (67.16 ± 12.59 vs. 65.83 ± 13.36 h, $p = 0.310$), length of ICU stay (387.24 ± 361.10 vs. 367.88 ± 267.59 h, $p = 0.643$), or 28-day mortality (56.4% vs. 60.0%, $p = 0.595$) between the cipepofol and non-cipepofol groups. Sedation success rate and mean sedation compliance rate were comparable between the two groups. Cipepofol demonstrated superior safety profiles with a lower incidence of hypotension within the first hour of sedation (28.6% vs. 46.1%, $p = 0.008$) and reduced bradycardia events (23.8% vs. 38.3%, $p = 0.029$). Vasoactive drug requirements were significantly lower in the cipepofol group (total norepinephrine dose 174.02 ± 208.18 vs. 242.64 ± 229.06 mg, $p = 0.026$). The cipepofol group demonstrated no significant increases in serum lipid levels, total bilirubin, or creatinine concentrations as compared to the non-cipepofol group.
Conclusions: Although cipepofol and non-cipepofol regimens showed comparable efficacy in managing sedation and clinical outcomes for severe pneumonia, cipepofol was associated with enhanced hemodynamic stability and reduced vasopressor dependence. These findings position cipepofol as a safer alternative for ICU sedation in mechanically ventilated patients with severe pneumonia.

Peripheral blood leukocyte-based clusters in sepsis: phenotypic characterization and prognostic implications

L. Wang[1], X. Qiu[2], Y. Kang[1]

[1]Department of Critical Care Medicine, West China Hospital of Sichuan University, Chengdu, China; [2]Department of Neurosurgery, West China Hospital of Sichuan University, Chengdu, China

Intensive Care Medicine Experimental 2025,* 13(1)*:001011

Introduction: Sepsis is a life-threatening organ dysfunction caused by a dysregulated host response to infection, representing the leading cause of mortality in critically ill patients worldwide. It accounts for approximately 49 million cases and 11 million deaths annually, contributing to nearly 20% of global mortality [1,2]. Peripheral blood leukocytes, as key mediators of immune responses, exhibit phenotypic alterations that may reflect the pathological progression and prognosis of sepsis [3]. Recent studies have revealed significant heterogeneity in the distribution and functional characteristics of leukocyte subsets in septic patients, including increased myeloid-derived suppressor cell phenotypes [4] and lymphocyte exhaustion [5]. These alterations demonstrate potential correlations with disease severity and clinical outcomes. However, systematic investigations into the dynamic clustering patterns and phenotypic signatures of peripheral blood leukocytes in sepsis remain inadequate, particularly regarding their prognostic implications.

Objectives: This study aims to characterize the phenotypic clustering patterns of peripheral blood leukocytes in septic patients, evaluate the correlation between distinct clusters and clinical outcomes, and provide theoretical foundations for risk stratification and immunomodulatory interventions.

Methods: This study identified sepsis patients meeting diagnostic criteria from the Medical Information Mart for Intensive Care-IV (MIMIC-IV) database. Absolute counts of neutrophils, lymphocytes, monocytes, basophils, and eosinophils were obtained from the first peripheral blood test within 24 h of admission. Using expression levels of these five leukocyte subsets, we performed cluster analysis through an integrated approach combining the Elbow Method, Gap statistic, and Silhouette coefficient to determine the optimal number of clusters. The K-means algorithm was then employed for phenotypic stratification of sepsis patients. Prognostic differences among the identified sepsis subtypes were subsequently compared using Kaplan–Meier survival analysis.

Results: Our analysis identified 18,365 sepsis patients from MIMIC-IV who were stratified into three distinct clusters. The cohort distribution revealed: Cluster 1 comprised the majority of cases (n = 10,710; 58.32%), followed by Cluster 3 (n = 6,699; 36.47%), while Cluster 2 represented the smallest subgroup (n = 956; 5.21%). Kaplan–Meier analysis revealed significant inter-cluster survival differences, with Cluster 3 exhibiting the lowest 28-day survival (67%), Cluster 1 demonstrating optimal outcomes (82%), and Cluster 2 showing intermediate prognosis (78%).

Conclusions: We identified three sepsis subphenotypes characterized by varying inflammatory statuses and mortality risks, stratified by leukocyte counts. This stratification could enhance prognostic evaluation and guide tailored therapeutic strategies in sepsis care.

Introduction: Little is known about long-term survival of patients treated in the intensive care unit (ICU) during the years following ICU care.
Objectives: To investigate long-term survival of ICU patients compared to the general population.
Methods: We retrieved data on patients treated in ICUs in 2005–2022 from the Finnish national intensive care registry. We used the personal identity codes to link each patient to the Causes of Death Statistics, maintained by Statistics Finland, that include the date of death of every deceased Finnish resident. With permission from the Finnish Social and Health Data Permit Authority (Findata) and Statistics Finland, a control population was formed from the Finnish general population by randomly selecting five age, sex and region of birth-matched control subjects for each ICU patient. We compared the survival of ICU patients to that of the control population. The follow-up extended to the end of year 2022.
Results: The total number of ICU patients in the study population was 140,788; of whom 62.9% were male. The median age at the time of ICU admission was 63 years (interquartile range, 50–73 years). The control population included totally 694,271 persons. Among the ICU patients, the survival rates were 86.5% at 30 days, 73.5% at one year, 58.7% at five years, 45.3% at 10 years, and 35.3% at 15 years following ICU admission. After 15 years' follow-up, 66.5% of the control population were still alive. After seven years, the shape of the survival curve of ICU patients was comparable to that of the control group (Fig. 1).
The relative 15-year survival (i.e. the surviving proportion of a group of ICU patients divided by the surviving proportion of the respective control population) differed across diagnostic groups, being highest for the groups "non-operative trauma" (0.76), "intoxication" (0.73) and "post-operative trauma" (0.72), and lowest for the groups "non-operative cardiovascular" (0.38), "sepsis" (0.40) and "non-operative gastrointestinal" (0.41).
Conclusions: Even after the acute critical illness, patients treated in the ICU experienced excess mortality as compared to the age and sex-matched general population for at least seven years. 15 years after ICU admission, one third of the patients were still alive, as compared to two thirds of the control population.

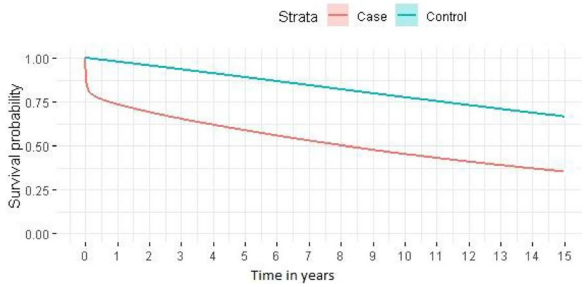

Fig. 1 (abstract 001013) Survival curves for ICU patients (case) and age, sex and place of birth-matched control persons that were randomly chosen from the Finnish general population. Time zero denotes time of ICU admission

Introduction: Deaths due to in-hospital cardiac arrest (CA) is a clinical indentity with high morbidity and mortality associated with a significant social, economic and health impact. Althoug there is not so much data available in our country, it is estimated around 370000–750000 in-hospital cardiac arrest in USA and 700000 in Europe. Survival from in-hospital CA is poor, but it could be possible to reduce mortality and moribidity if we improve the first response of assistance. For that purpose, we propose four steps in the cardiac chain of survival.
Objectives: The study includes the results of the operation of Cardiopulmonary Resuscitation (CPR) Hospital Plan along seventeen years. Also, the characteristics of those patients who suffer an in-hospital CA in units with non-monitored facilities (HU).
Methods: An observational, prospective study in a cohort of patients who presented in-hospital cardiac arrest along a decade period. HU of a general hospital as a province reference. Patients admitted to a HU from May 2007 until December 2024 after suffering in-hospital CA and treated according to a specific CPR Hospital Plan in order to: (a) decentralize CPR through de training iof the nurses as the first responder capable to perform CPR and early desfibirlation (DF) (less than four minutes); (b) having a specific phone number as hospital alarm of CA and (c) maintenance of the CPR maneuvers by an early intervention of the Resuscitation Team (RT) (less than eight minutes).
Results: A total of 642 patients were included with activation of CA alarma, 85 of them were false alarms, 63% of them were men with an average of 71 years. A total of 80% took place in the medical area, in patients with cardiac or respiratory failure. In 80% of the cases initial heart rhythm was asystolic or electromechanical dissociation and shockable rhythm in 18% of them. The first attending person was a nurse in 77% of the cases, CPR was always iniciated in less than one minute and RT arrive in less than eight minute in the 98% of cases. Finally, in terms of survivance, 52% of the patients survived and 31% of them were dicharged live from the hospital.
Conclusions: The CPR "Juan Ramón Jiménez" Hospital Program is an applicable and effective initiative in our setting. Although another performances related to prevention and security should be necessary to improve in-hospital CA surv¡val.

Introduction: Acute pulmonary embolism (PE) is thought to originate from distal thrombosis. However, in critically ill patients with hyperinflammatory conditions, such as Coronavirus disease 2019 (COVID-19), thrombosis in the lung vasculature may occur outside the context of peripheral thrombosis, denoted as microvascular- or in-situ thrombosis (IST). A hyperinflammatory response with not only upregulation of T helper 1 cells (Th1 cells) but also non-Th1 cell responses have been associated with severe COVID-19. We hypothesize that IST is a result of this immune dysregulation and can be distinguished from PE in the critically ill by specific histology, together with radiologic features and biomarkers of the host response. Therefore, the study aims were to explore differences in serum biomarkers and computer tomography (CT)-imaging between PE and IST, and to explore whether predictive modelling could be used to discriminate between PE and IST.
Methods: In this multicenter case series, critically ill patients who succumbed to COVID-19 and from whom histo-pathological examination of lung tissue was obtained were included. Patients with IST, based on histological characteristics, were compared to patients with proven PE and to control patients without histological proof of any pulmonary thrombosis. Serum biomarkers of inflammation, endothelial activity and hemostasis were selected, based on a thorough literature search, to investigate their potential to differentiate IST from PE. CT imaging and blood samples taken < 7 days before death were analyzed.
Results: 21 patients were included with a mean age of 69 years in the IST group ($n = 6$), 70 years in the PE group (n = 8) and 77 years in the control group of patients without any thrombosis ($n = 7$, NS). The majority in all groups was male. IST patients had higher mean levels of IL-17, IL-18, and IL-33 compared to those with PE and negative controls. A prediction model constructed with least absolute shrinkage

and selection operator (LASSO) followed by cross-validation showed excellent performance, using IL-17, IL-18 and von Willenbrand factor A2 as top three markers, with an area under the receiver-operating characteristic of 0.91 (95% CI 0,79–1.00). Features of IST were also able to be determined, with thrombosis along the vessel wall in smaller arteries and in proximity of pulmonary infiltrates.
Conclusions: Based on the differences in histology, radiology and immune biomarkers, we show that IST and PE are distinct forms of pulmonary thrombosis. IST is characterized by skewing from an effective immune response to upregulation of Th1, Th2 and Th17 cell pathways.

Introduction: Unregulated inflammation drives morbidity and mortality in COVID-19 ARDS. Although corticosteroids and IL-6 inhibitors, as standard of care (SoC), have improved survival, mortality remains high, suggesting inadequate control of inflammation and involvement of additional pathways. While several biomarkers have been associated with mortality, previous studies often ignore treatment effects and focus mainly on inflammatory biomarkers. This study compared biomarkers across multiple pathways between survivors and non-survivors receiving SoC to better understand COVID-19 ARDS and inform potential additional treatment strategies.
Methods: Patients with COVID-19 ARDS who received both dexamethasone and IL-6 inhibition as SoC prior to plasma sample collection were included. Baseline was defined as the time of the first plasma collection. Patients who had received high-dose corticosteroids before baseline were excluded. Sixty-one biomarkers across various pathways, including alveolar epithelial injury, coagulation, complement, endothelial integrity and inflammation, were measured using either Luminex or standard laboratory assays. Differences between survivors and non-survivors were assessed using the Mann–Whitney *U* test and Fisher's exact test, with significant biomarkers presented as normalized Z scores. Given the exploratory nature of this study, no corrections for multiple testing were made.
Results: Among the 32 patients, no differences in timing or dosage of anti-inflammatory treatment were observed between survivors and non-survivors (Table 1). Non-survivors showed significantly higher levels of CXCL8, CXCL10, IL-1 beta, IL-4, IL-6, NLR, SP-D and suPAR compared to survivors. Thrombocytes and vWF were lower in non-survivors compared to survivors (Fig. 1).

Table 1 (abstract 001017) Patient characteristics and outcomes under standard of care, stratified by survival

	All patients	Survivors	Non-survivors	*P* value*
N	32	25	7	
Sex—male	27 (84.4)	20 (80)	7 (100)	0.6
Age (years)	61 [52–67]	58 [50–67]	64 [62–71]	0.083
ICU day at first sample collection	5 [4–6]	5 [3–7]	4 [4–5]	0.4
APACHE IV predicted mortality score	0.15 [0.10–0.20]	0.15 [0.09–0.18]	0.22 [0.11–0.37]	0.4
SOFA score	5 [3–6]	3 [2–5]	5 [4–7]	0.2
PaO2/FIO2 (kPa)	33 [22–40]	34 [24–40]	29 [19–32]	0.2
Time between last dexamethasone dose and baseline	1 [0–1]	1 [0–1]	0 [0–1]	0.5
No. of dexamethasone dosages received prior to baseline	4 [3–5]	4 [3–5]	4 [3–5]	0.5
Time between last tocilizumab dose and baseline	5 [3–6]	5 [3–6]	4 [3–5]	0.8

All categorical variables are presented as counts and percentages and all continuous variables as median [IQR]. *Using Fisher's exact test for categorical variables and Mann–Whitney *U* test for continuous variables

Conclusions: Elevated inflammatory and epithelial injury biomarkers in non-survivors despite SoC suggest insufficient suppression of these pathways. This raises the question of whether higher corticosteroid doses, extended treatment duration or additional tocilizumab, might have been beneficial. Additionally, these findings raise the possibility that Anakinra or Imatinib may offer therapeutic benefit. Notably, significant biomarker differences were observed between survivors and non-survivors, whereas PF ratio and disease severity scores did not differentiate between the two groups.

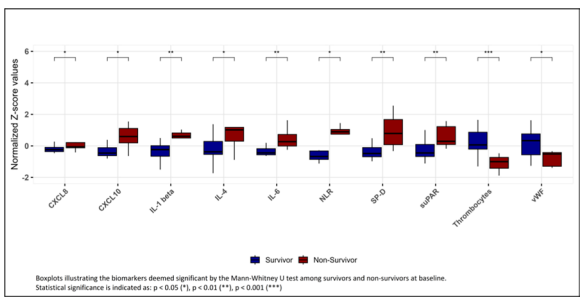

Fig. 1 (abstract 001017) Biomarker profiles in survivors and non-survivors in COVID-19 ARDS
Plasma levels of CXCL8, IL-6, SP-D, and suPAR were significantly higher in non-survivors compared to survivors, while thrombocyte counts and vWF levels were lower. Data are presented as normalized *Z* scores. Mann–Whitney *U* test was used for comparisons; $P < 0.05$ considered statistically significant.

Intensive Care Medicine Experimental 2025,* 13(1)*:001019

Introduction: Diastolic dysfunction is a possible sign of septic cardiomyopathy.1 Unlike systolic dysfunction, which shows high mortality in patients with ejection fraction < 35% or > 60%, the role of diastolic dysfunction as a mortality predictor remains unclear.2–5.
Objectives: To determine whether patients with diastolic dysfunction assessed through filling pressures by E/e' values in the setting of sepsis and septic shock is a predictor of mortality in a cohort of 134 patients in an intensive care unit (ICU) of a high complexity hospital in Argentina.
Methods: We conducted a cross-sectional analysis of 134 patients admitted to ICU to examine associations between diastolic dysfunction and clinical outcomes. Statistical methods included chi-squared and Wilcoxon rank-sum tests for categorical and non-normally distributed variables, t tests for continuous normally distributed variables, and multivariable logistic and linear regressions adjusting for age, sex, and APACHE score. We used Stata v15.
Results: A total of 134 patients admitted to ICU were included. Diastolic dysfunction was present in 45 (45.9%) patients. Sex distribution was similar between groups, with 45.8% of patients with diastolic dysfunction being female, compared to 54.2% among those without. Patients with diastolic dysfunction were significantly older than those without (mean age 72.8 vs. 62.5 years; mean difference − 10.2 years; 95% CI − 15.8 to − 4.7; $p = 0.0004$). ICU mortality was significantly higher in patients with diastolic dysfunction compared to those without (53.3% vs. 18.9%; $\chi^2(1) = 12.76$, $p < 0.001$). In a logistic regression model adjusting for age, sex, and APACHE score, diastolic dysfunction remained independently associated with increased odds of ICU mortality (OR = 3.53, 95% CI 1.35–9.23; $p = 0.010$). No significant association was found between diastolic dysfunction and length of ICU stay. Median ICU days were similar across groups (10.9 ± 11.1 vs. 13.3 ± 15.4 days, in patients with vs. without dysfunction), and neither unadjusted comparisons ($p = 0.39$, t test; $p = 0.66$, Wilcoxon rank-sum test) nor adjusted linear regression ($\beta = -1.10$, 95% CI − 6.96 to 4.77; $p = 0.71$) showed evidence of a relationship. Similarly, no significant association was observed between diastolic dysfunction and site of infection ($p > 0.05$), with intra-abdominal (38.9%) and pulmonary infections (30.2%) being the most common. Maximum troponin T levels were not significantly different between patients with and without diastolic dysfunction ($p = 0.12$, Wilcoxon rank sum test), although levels tended to be higher in the dysfunction group.
Conclusions: Diastolic dysfunction appears to be an independent predictor of ICU mortality but is not associated with length of stay, troponin T levels, or site of infection. These findings highlight the prognostic value of diastolic function assessment in critically ill patients.

Intensive Care Medicine Experimental 2025,* 13(1)*:001020

Introduction: Intradialytic hypotension (IDH) is a common and clinically significant complication in critically ill patients undergoing intermittent hemodialysis (IHD) for acute kidney injury (AKI). Identifying patients at risk before initiating dialysis remains a major clinical challenge. Simple bedside hemodynamic indices such as the systolic shock index (SSI = heart rate/systolic arterial pressure), diastolic shock index (DSI = heart rate/diastolic arterial pressure), and pulse pressure (PP = systolic – diastolic pressure) may reflect impaired cardiovascular reserve and guide risk stratification.
Objectives: To evaluate the predictive performance of SSI, DSI, and PP for the occurrence of IDH in critically ill patients undergoing their first IHD session.
Methods: In this prospective observational study, adult ICU patients with AKI (KDIGO stage 3) undergoing IHD with ultrafiltration were included. Hemodynamic parameters including heart rate, systolic and diastolic pressures were recorded prior to dialysis. SSI, DSI, and PP were calculated. IDH was defined as a mean arterial pressure (MAP) < 65 mmHg during the dialysis session. Receiver-operating characteristic (ROC) curves were used to assess the predictive accuracy of each index.
Results: Among 187 patients included, 51 (27.3%) developed IDH. Compared with those without IDH, affected patients had significantly higher SSI [0.85 (IQR 0.76–0.96) vs. 0.71 (0.64–0.80); $p < 0.001$], higher DSI [1.25 (1.10–1.40) vs. 1.02 (0.91–1.13); $p < 0.001$], and lower PP [35 mmHg (30–42) vs. 44 mmHg (38–52); $p < 0.001$]. ROC analysis demonstrated good predictive performance for DSI (AUC = 0.78; 95% CI 0.70–0.85), SSI (AUC = 0.74; 95% CI 0.66–0.82), and PP (AUC = 0.72; 95% CI 0.64–0.80). In multivariate analysis, elevated DSI, reduced PP, and preload dependency (via passive leg raising) were independent predictors of IDH. Ultrafiltration rate was not associated with hypotension.
Conclusions: Elevated diastolic and systolic shock indices, along with reduced pulse pressure, are independent and accurate predictors of IDH. These easily obtainable bedside parameters may support early risk stratification and inform individualized dialysis strategies in critically ill patients with AKI.

ROC curve for intradialytic hypotension prediction.

Introduction: Diastolic dysfunction (DD) is a critical factor to consider in patients undergoing major surgery, particularly liver transplantation (LT), owing to the high risk of bleeding, the need for aggressive fluid resuscitation, and frequent blood product transfusion. Cirrhotic cardiomyopathy (CCM) is characterized by systolic and/or DD in patients with advanced liver disease in the absence of pre-existing cardiac disease. CCM with DD is diagnosed when at least three echocardiographic criteria for DD are met.
Objectives: To characterize the prevalence of DD and evaluate its clinical impact during the perioperative period in patients undergoing liver transplantation.
Methods: This retrospective cohort study included 66 patients with advanced cirrhosis who underwent LT in 2023 at the Hospital Clínico Universidad Católica. All patients underwent preoperative echocardiographic evaluation. DD was defined according to the following criteria: tricuspid regurgitant velocity > 2.8 m/s, left atrial volume index (LAVI) > 34 cm^3/m^2, E/e' ratio > 15, and septal e' velocity < 7 cm/s. Clinical outcomes analyzed included acute kidney injury (AKI), days on mechanical ventilation (MV), and length of stay in the intensive care unit (ICU) to assess associations with DD.
Results: Of the 66 patients, 39 (59%) met at least one echocardiographic criterion for DD. Seventeen patients (26%) fulfilled two or more of the DD criteria. The distribution of echocardiographic findings was as follows: LAVI > 34 cm^3/m^2 in 27 patients (40%), tricuspid regurgitant velocity > 2.8 m/s in 28 (42%), septal e' < 7 cm/s in 1 patient (2%), and E/e' > 15 in 1 patient (2%). Patients with two or more DD criteria had significantly longer ICU stays and a trend toward prolonged mechanical ventilation. No significant association was observed with AKI incidence.

Table 1 (abstract 001021) ...

Tricuspid regurgitant gradient, mmHg	32 [28–35]	28 [24–30]	35 [30–40]	35 [34–40]*	0.159
Left atrial volume index, cm^3/m^2	40 [35–46]	32 [25–33]	38 [36–44]	45 [39–56]*	0.657
E/e' ratio	8.8 [7.5–10.0]	8.0 [6.6–9.0]	9.4 [8.5–10.5]	9.0 [7.8–11]	0.304

Conclusions: There was a high prevalence of echocardiographic markers of DD (59%) in patients undergoing LT. The presence of two or more DD criteria was significantly associated with an increased ICU length of stay, highlighting DD as a clinically relevant comorbidity. Further research is warranted to optimize perioperative hemodynamic and volume management in this high-risk population.

DD criteria.

Developing effective therapeutic music programs using patient outcome associated electroencephalogram markers developing effective therapeutic music programs using patient outcome associated electroencephalogram markers

A. Moe[1], A. Gururaja[2], R. Fitzpatrick[1], C. Sicard[1], L. Kim[1], R. Kleinpell[3], S. Williams Roberson[4], J. Schlesinger[1]

Intensive Care Medicine Experimental 2025,* 13(1)*:001023

Introduction: Therapeutic music enhances recovery environments and evokes positive emotions in patients while decreasing anxiety and delirium [1, 2]. The Vanderbilt Music in the Intensive Care Unit (ICU) program, implemented in 2019, connects student and community volunteer musicians with patients, families, and ICU staff to provide therapeutic music sessions. Our initial qualitative papers demonstrated the therapeutic program's feasibility and appropriateness, with 92% of ICU patients finding music to be a significant part of their lives [1, 2]. These findings indicate a larger scope for implementing therapeutic programs to improve the quality of stay and studying the modifiable physiological effects of therapeutic music.
Objectives: This study aims to identify how therapeutic music conditions influence electroencephalogram (EEG) markers associated with neurophysiological function. These findings may ultimately inform interventions designed to improve patient outcomes in diverse populations.
Methods: Data were collected from fifty adult hospital inpatients receiving at least two hours of EEG monitoring for clinical purposes. Therapeutic sessions consisted of randomized 3-min conditions of live music, recorded music, pink noise, and no music with 2-min "babble" washout periods in between each condition [3]. Live music consisted of jazz and classical genres played on piano, violin, viola, cello, or saxophone. Recorded music and pink noise were delivered through sterilized headphones. De-identified EEG clips were processed and analyzed using MATLAB(R) to determine frequency composition, frequency variability and complexity. The Kruskal–Wallis test was used to compare EEG metrics across music conditions.
Results: Relative alpha power (RAP), relative delta power (rDP), delta variability (SVD), and approximate entropy (ApEn) showed no significant differences across the four music conditions. However, the no music condition showed on average, higher RAP, ApEn, and SVD compared to conditions with auditory stimuli.
Conclusions: This study explored how different music conditions correlate with neurophysiological responses, using EEG markers associated with specific patient outcomes. While the data yielded no significant differences across music conditions for the EEG markers tested, average increases between music and no music conditions in markers associated with healthy brain states (RAP, ApEn, and SVD), suggest music may play a role in influencing these markers and associated outcomes such as delirium. Future studies can explore additional EEG markers and vary length of exposure in the auditory conditions.

Optimized intravenous heparin dosing in acute pulmonary embolism: a reinforcement learning approach

S. Rapuri[1], C. Harris[1], R. Stevens[2], S. Dias[3]
[1]Biomedical Engineering, Johns Hopkins University, Baltimore, United States of America; [2]Department of Anesthesiology and Critical Care Medicine, Johns Hopkins University School of Medicine, Baltimore, United States of America; [3]Unidade de Cuidados Intensivos Neurocríticos e Trauma, Unidade Local de Saúde São José, Lisboa, Portugal

Intensive Care Medicine Experimental 2025,* 13(1)*:001025

Introduction: Pulmonary embolism (PE) is frequent in critically ill patients and represents a leading cause of death in that setting. First-line treatment in acute PE is intravenous unfractionated heparin (IV-UFH), however, the therapeutic margin for IV-UFH is narrow, exposing patients to over- or under-treatment of PE, both of which compound risk [1].
Objectives: Evidence shows that current IV-UFH dose–adjustment protocols are imprecise. Here, we develop a novel approach which leverages reinforcement learning (RL), a type of artificial intelligence which optimizes choices in a defined decision space.
Methods: We identify adult patients with acute PE who were admitted to the ICU at Johns Hopkins from 2013 to 2024 [2]. Clinical variables, laboratory studies, and physiological data are used as inputs to an offline RL model (Q-learning) which is trained to make IV-UFH dose recommendation every 4 h (Fig. 1), with hospital survival as a model reward parameter. The model uses a clustering algorithm to assign patients to one of six latent states, then maps the state to an IV-UFH dosage. By applying this process repeatedly at each decision node, the algorithm optimizes dosages that minimize the risk of

hospital mortality with each new patient trajectory. The treatment gap between the recommendations of the RL policy and the dose that was implemented by the medical team (clinician policy) is then determined by computing the cumulative magnitude of RL policy–clinician policy dosage offset normalized by patient stay duration. The resulting distribution of normalized dosage differences (NDD) is then divided into three bins, and for each bin, and the corresponding 30-day mortality rate is calculated for each bin.
Results: In 757 adult ICU patients diagnosed with acute PE, the dosing policy trained using a static target aPTT range as the model reward showed no statistically significant difference in mortality across the NDD bins. The NDD between the AI and clinician policies correlated inversely with hospital survival, with patients in the lowest NDD bin having the highest survival rate (95.3%), whereas those in the highest NDD bin having the lowest survival 76.3% ($p = 0.006$).
Conclusions: These preliminary findings suggest that an RL algorithm for IV UFH dosing may be effective as an automated tool to personalize IV-UFH treatment in critically ill patients with PE.

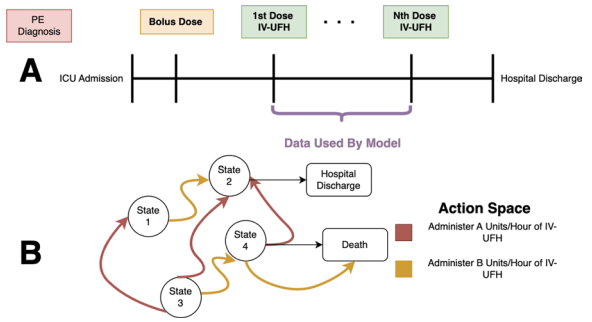

Fig. 1 (abstract 001025) **A** Observation window. **B** Example patient trajectories created through unsupervised clustering of patient data. The final AI policy learns from these trajectories and maps each underlying patient state to one IV-UFH dosage

Intensive Care Medicine Experimental 2025,* 13(1)*:001026

Introduction: Carbon monoxide (CO) is an odorless, tasteless, colorless, nonirritating gas formed by hydrocarbon combustion. CO binds to hemoglobin with much greater affinity than oxygen, forming carboxyhemoglobin (COHb) resulting in impaired oxygen transport. CO can precipitate an inflammatory cascade that results in central nervous system (CNS) lipid peroxidation and delayed neurologic sequelae (DNS).
Objectives: Review CO poisoning-related complications and posible neurological sequelae.
Methods: We have carried out a retrospective observational study in an 18-bed ICU of a second level centre. We are a reference centre for hyperbaric oxygen therapy (HOT) in the whole region of Catalonia.
Results: We reviewed patients who underwent HOT for acute CO poisoning between 2012 and 2025. HOT has been performed in a total of 1524 patients of which 41 were admitted to the ICU. 36.59% (15) were women and 63.41% (26) were males. The median age was 60 years. 90.24% (37) were admitted under mechanical ventilation, 100% (15) of women and 88.46% (23) of males. Intubation was used to protect the airway when the Glasgow Coma Scale was lower than 8 or in the presence of soot in the airway.
Reviewing the analytical data, we found that most of the patients had lactic metabolic acidosis with mean lactate levels of 3.117. Elevated cardiac markers have been detected in 46.34% (19) with an average of 105,68 ng/L, a mínimum value of 0.3 and maximum of 20083 ng/L.
The COHb levels ranged between 2.1 and 76% with a mean of 24.85. All were administered the standard adult dose of 5 g iv hydroxycobalamin.
HOT was carried out in all patients using pure oxygen at a pressure of 2,5-3 atmospheres during 60–120 min. Complications arising from therapy were observed in 24.39% (10) as otic barotrauma and 4.87% (2) developed bronchospasm.
The ICU lengh of stay was 5.7 days. The hospital lengh of stay was 11,97 days.
Major acute complications detected in our series were in one case acute respiratory failure caused by PTE and constrictive bronchiolitis, ARDS requiring ECMO and toxic myocarditis. Neurological sequelae included gait disturbance in one patient and basal ganglia leukoencephalopathy with parkinsonism (DNS) in another patient. Two patients developed anoxic coma as a fatal complication of CO.
Mortality in our case series was 7.31% (3).
Conclusions: After reviewing the series of patients admitted to the ICU for CO poisoning, we detected some serious pulmonary or cardiac complications, which have already been described in the literature. We found very few late neurological sequelae and a low mortality similar to that described.
Having reviewed our case series, although small, we believe that HOT performed within the first 24 h of the acute event could reduce short- and long-term sequelae.

Intensive Care Medicine Experimental 2025,* 13(1)*:001027

Introduction: Long-term physical disability, decreased health related quality of life (HRQOL), and high healthcare utilisation are common following critical illness (1). Disability can be characterised using the World Health Organisations International Classification of Functioning, Disability, and Health (ICF) framework (2). Return to paid employment or volunteering are important long-term post-ICU outcomes and can be situated within the participation domain of the ICF. Musculoskeletal (MSK) health problems are known to be severe and prevalent

following critical illness, negatively impacting long-term physical function (ref). MSK health problems sit within the body function and structure domain of the ICF, resulting in limitations at the activity and participation domains, including return to work or volunteering. However, return to work or volunteering readiness should also be evaluated considering both personal and environmental factors, which are likely to be richer when explored qualitatively. Therefore, understanding the MSK health problems and experiences of those hoping to return to work will contribute to the development of specific, impairment-focused rehabilitation following critical illness.
Objectives: To explore patients experiences of readiness to return to work and volunteering in patients with severe MSK health problems six month following admission to ICU.
Methods: This study received ethical approval (21/NS/0143) and represents a sub-analysis of a subset of a large UK multicentre observational study which prospectively evaluated MSK health following critical illness (2). Participants were followed-up by telephone six months following admission to ICU where their MSK health and HrQOL were evaluated and details of their return to employment explored. Participants reporting severe disability relating to MSK health were invited to share their experiences of living with MSK impairments during semi-structured interviews. These were audio recorded, transcribed verbatim and thematically analysed.
Results: Eleven participants with severe MSK health related disability were interviewed). Most participants ($n = 9$, 81.8%) presented with multisite MSK problems and poor HRQOL (median EQ5D 40, IQR 35–60). Seven participants were employed prior to their ICU admission, five (71.4%) of those were newly unemployed post-ICU, all of whom worked in manual jobs (4). From the interviews, exemplar quotes included: 'I am a mechanic by trade so with my hand not working, it's not really [possible]; and 'We have got a village studio full of community spirit…So to have you been involved with…I just don't feel able now…. From my back….' These suggest working themes of 'Physical losses impacting work' and 'Lack of self and contribution to community spirit'.
Conclusions: Six months following admission to ICU, of those employed preadmission 71.4% were newly unemployed and all were manual workers. Returning to work and volunteering were considered important milestones following critical illness, with experiences of MSK impairments reducing or preventing participation.

Intensive Care Medicine Experimental 2025,* 13(1)*:001028

Introduction: During acute brain injury (ABI) low PbtO2 was demonstrated to be independently associated with a significant improvement of brain oxygenation after red blood cells transfusion (RBCT).
Objectives: We aim to identify if BOx ratio (i.e. PbtO2/ PaO2 ratio) can be used as a predictor of this improvement.
Methods: We retrospectively analyzed a cohort study from 2012 to 2020 including three European Intensive Care Units of University Hospitals located in Belgium, Switzerland and Austria, including all patients with acute brain injury, who were monitored with brain tissue oxygenation (PbtO2) catheters and received at least one RBCT. We identified as responders the events associated with an increase > 20% from the baseline value of PbtO2 after transfusion. We collected the PbtO2 and PaO2 values at the time of transfusion and two hours after and calculated the corresponding BOx ratios.
Using a linear mixed model, we then identified the variables independently correlated with the response to transfusions.
Results: We included 69 patients receiving a total of 106 RBCTs. Baseline hemoglobin (Hb) and PbtO2 were 8.0 [7.4-8.7] g/dL and 23 [20–30] mmHg in the nonresponders group and 7.7 [7.1–8.6] g/dL (p 0.137) and 18 [13–22] mmHg (p 0.001) in the responder group; whereas the BOx ratio was, respectively 0.21 [0.15–0.28] in the nonresponders and 0.16 [0.1–0.21] in the responders group (p 0.004).
The generalized mixed model showed that high heart rate (HR) and low BOx ratio at baseline were independently associated with a 20% increase in PbtO2 after RBCT. The area under the receiver-operator curve for the ability of baseline BOx ratio in identifying responder was 0.72 (95% CI 0.61–0.82). The cutoff with the best compromise between sensitivity (80.3%) and specificity (60.3%) was a BOx ratio of 0.183. A BOx ratio of 0.183 had a positive predictive value of 45.5% and a negative predictive value of 90.6%.
Moreover, in the group of responders the BOx ratio showed a statistically significant increase from the baseline to 2 h after the transfusion, going from 0.16 [0.10–0.21] of the baseline to 0.21 [0.16–0.28] after transfusion ($p < 0.001$), while this increase was not found in the group of nonresponders.
Conclusions: Lower BOx ratio values at baseline could predict a significant increase in brain oxygenation after RBCT. Moreover, a significant improvement in BOx ratio values after transfusion was described in the responder group, suggesting a clinical value of this new parameter.

Receiver-operator curve for the ability of baseline BOx ratio in identifying an increase > 20% from the baseline value of PbtO2 after transfusion.

Introduction: Our study aimed to compare the efficacy of the two weaning modes VSV and PSV in terms of weaning success, defined as no requirement of ventilatory support after 48 h of weaning from mechanical ventilation.

Objectives: ·The primary outcome was to evaluate the efficacy of the weaning mode by achieving successful weaning with no requirement of ventilatory support after 48 h of weaning from the ventilator. The secondary outcomes were number of weaning trials given by using each mode and the number of weaning failures in each mode. Respiratory rate of the patient on each mode,evel of PaCo2 on each mode after two hours, four hours, eight hours, twelve hours, and twenty-four hours, comparison of hemodynamic changes in both the groups; and, evaluation of sedation requirement in both the groups to prevent patient ventilator asynchrony.

Methods: We conducted an open labelled randomized control trial with 82 patients and compared the efficacy of volume support ventilation and pressure support ventilation for weaning in mechanically ventilated patients admitted to the adult intensive care unit of our institute. The weaning mode was selected randomly using a sequentially numbered, opaque, sealed envelope method. Heart rate, systolic, diastolic, and mean blood pressure, respiratory rate, saturation of oxygen and serial ABG values of pH, PaO2, PaCO2, PaO2/FiO2, HCO3—were collected at two, four-, eight-, twelve-, and twenty-four-hour time intervals. The rate of successful weaning, duration of weaning, hemodynamic changes and sedation requirements were compared between the two weaning modes.

Results: The study included 41 patients in each PSV and VSV group. There was no difference in the duration of weaning [(62.34 ± 21.22 h) in PSV and 60.76 ± 23.05 h in VSV) in both the groups. The rate of successful weaning, reintubation, hemodynamic parameters, ABG parameters and sedation requirements were also comparable in both the groups.

Conclusions: Neither of the weaning modes—volume support ventilation or pressure support ventilation—proved to be superior to the other for weaning from mechanical ventilation.

Comparison of duration of weaning among the study population.

Barriers and opportunities in large-scale record linkage

B. van der Woude, O. Cremer, L. Derde, E. Sieswerda[2], H. J. De Grooth[1]
[1]Department of Intensive Care, University Medical Center Utrecht, Utrecht, Netherlands; [2]Department of Medical Microbiology, University Medical Center Utrecht, Utrecht, Netherlands

Intensive Care Medicine Experimental 2025,* 13(1)*:001030

Introduction: ICU cohort studies contain rich data, but follow-up often ends at discharge. Linking cohorts with national databases can

extend follow-up and enhance variable depth, creating more robust datasets. However, this requires a clear framework and regulatory guidance, as these data sources are often built for different purposes and created under different governance structures.
Objectives: To describe the feasibility of large-scale record linkage.
Methods: Our base cohort included all ICU admissions in two academic medical centers. This was linked to four national databases: population registry (PR), national cause of death registry (NCDR), Dutch hospital discharge registry (DHDR), and a bacterial culture database (ISIS-AR). Linkage occurred within a secure research environment provided by a governmental institute. For linkage, participants in external databases were assigned a record identification number (RIN) based on a combination of identifying characteristics.
Results: We linked 6,300 ICU patients to PR (27 M records), NCDR (4 M records), and DHDR (44 M) records. Linkage to ISIS-AR is ongoing. Time from applying for data use to successful linkage ranged from 1 to > 9 months.
We identified important barriers. Different institutions gave differing legal advice, despite all following the same privacy laws. Even in the face of the comprehensive GDPR, each institution interprets the law differently. Despite preference from the governmental statistic institute to use citizen service number (CSN) for the most accurate linkage, both academic medical centers did not approve this. We instead used gender, date of birth, postal code, and date of death.
Despite growing support for data sharing, we noticed hesitancy and mixed interpretations of data ownership agreements. For one database of patient data from different institutions, data sharing and linkage was straightforward. For another database with patient data (from partly the same institutions), several participating institutions wanted to re-review the ownership conditions of data that was already shared at the national level.
We also identified many opportunities. Many national databases live in the remote research environment, so participants already have RINs assigned based on CSN, and access to these databases is granted quickly. Uploading external databases to this centralized environment reduces the need to move sensitive data between institutions. While linkage of these external databases is difficult without approval to use CSN, we achieved 94% linkage using unique combinations of variables. To link ISIS-AR, we plan to also use bacterial culture date and hospital admission date.
Conclusions: Data linkage creates valuable datasets, leading to new collaborations and research possibilities. The most important barrier we identified is that each institution interprets the same laws in different ways and thereby puts up different barriers. A framework for data federation and clear regulatory guidelines would reduce the burden of record linkage.

Introduction: Mechanical thrombectomy has become the cornerstone in the management of acute ischemic stroke due to large vessel occlusion. Despite advances in care, many patients experience poor functional outcomes. Identifying predictors of outcome may support timely interventions and better patient selection.
Objectives: This study aims to identify early predictors of poor functional outcomes in stroke patients treated with mechanical thrombectomy (MT) via the emergency stroke pathway.
Methods: A retrospective cohort study included all patients admitted through the emergency room stroke pathway and treated with MT between January 2022 and December 2024. We included patients with a previous modified Rankin score (mRS) ≤ 2 and wake-up strokes or stroke onset within 4.5 h. The outcome was dichotomised as good (mRS 0–2) vs. poor (mRS 3–6) functional status at hospital discharge. Univariable logistic regression was first conducted to identify candidate predictors, followed by a multivariable model that included those with the strongest associations.
Results: A total of 190 patients were included, with 63% ($n = 121$) presenting poor functional outcomes at discharge (mRS 3–6), including death ($n = 35$).
In Table 1, we presented the variables studied and their association with poor outcomes.

Variable	Total ($n = 190$)	Poor outcome ($n = 121$)	Crude OR (95% CI)	Univariable *p* value
> 65 years old, n(%)	145 (76.3%)	98 (80.1%)	1.994	0.047
Male Gender, n(%)	87 (45.8%)	56 (46.3%)	1.056	0.875
HBP, n(%)	140 (73.7%)	93 (76.9%)	1.555	0.190
DM, n(%)	54 (28.8%)	37 (30.6%)	1.347	0.383
Obesity, n(%)	47 (24.7%)	28 (23.1%)	0.792	0.500
Tobacco use, n(%)	19 (10.0%)	12 (9.9%)	0.975	0.960
Wake-up stroke, n(%)	52 (27.4%)	36 (29.8%)	1.403	0.330
Thrombolysis, n(%)	89 (46.8%)	52 (43.0%)	0.652	0.158
Time to MT, median (IQR)	158 (129–191)	152 (127–191)	0.999	0.828
Previous mRankin, median (IQR)	0 (0–0)	0 (0–1)	2.051 per point	< 0.001
NIHSS, median (IQR)	11 (7–16)	19 (15–22)	1.187 per point	< 0.001

HBP high blood pressure, *DM* diabetes mellitus, *IQR* interquartile range

Variables retained in the final model were higher NIHSS on admission with an adjusted OR = 1.191 (95% CI 1.122–1.264, $p \leq 0.001$) per point and pre-stroke functional status (mRankin) with an adjusted OR = 2.051 (95% CI 1.294–3.254, $p = 0.002$).
The final model performed significantly better than the null model ($p < 0.001$), with a Nagelkerke R^2 of 0.362. It demonstrated good discrimination (AUC = 0.815) and accurate classification overall (76.8%). Sensitivity was 86.8%, and specificity was 59.4%.
Conclusions: Baseline neurological severity and pre-stroke functional status are strong, independent predictors of poor functional outcomes following mechanical thrombectomy. These results underscore the importance of incorporating NIHSS and pre-stroke mRS into early triage and decision-making tools. Future protocols and predictive models should systematically include these variables to better guide patient selection, tailor post-acute care strategies, and optimise resource allocation.

Intensive Care Medicine Experimental 2025,* 13(1)*:001033

Introduction: Status epilepticus is a medical emergency with an incidence of approximately 20–40 per 100,000 and a global mortality rate of 10–20%, which can rise to 80% after anoxic events.
Objectives: To analyse the morbidity and length of hospital stay in patients admitted to a Neurocritical Care Unit with status epilepticus.
Methods: Longitudinal, retrospective study in a Neurocritical care unit for adult patients performed from January 2014 to January 2020. Demographic variables, type of seizure, GCS at admission, etiology, clinical presentation, modified Status Epilepticus Severity Score (mSTESS), administered treatment, duration of invasive mechanical ventilation (IMV), length of stay in the intensive care unit (ICU) and hospital, and major complications during admission were collected (acute renal failure, arrhythmias, metabolic acidosis,haemodynamic complications, infections, critical illness polyneuromyopathy, rhabdomyolysis and cerebral edema). Poor outcome was defined as death or Glasgow Coma Scale (GCS) score $\leq$ 13 at hospital discharge**.**
Categorical variables are expressed as frequencies and percentages and continuous variables as mean and standard deviation (SD) when the data followed a normal distribution, or as median and interquartile range (IQR = 25th—75th percentile) when the distribution deviated from normality. Percentages were compared, as appropriate, by the Chi-square test or Fisher's exact test, means by the *t* test and medians by the Wilcoxon test for independent data. Statistical significance was set at $p < 0.05$. The data were analyzed with the R package, version 4.2.1 (R Development Core Team, 2022).
Results: Out of the 47 patients, 32 exhibited a good outcome (68%). Mortality was 19% (9 patients). The mean age was 50 years ($\pm$ 23.1), with 66% of patients being male. No significant differences were found in demographic variables or etiology of status epilepticus between the two groups. Univariate analysis revealed significant differences in haemodynamic complications; 9 patients (60%) in the poor outcome group vs 6 patients (18.8%) in the good outcome group. In addition, statistical differences were found in the duration of IMV, with a median of 14 days (5; 36) in the poor outcome group compared to 3.5 days (1.8; 16.5) in the good outcome group. Finally, the poor outcome group had a statistically significant higher score on the mSTESS prognostic scale, with a median of 4 (3; 5) points as compared to a median of 3 (2; 3.2) points in the good outcome group.

Table 1 (abstract 001033) Results

	Overall (*N* = 47)	Good outcome (*N* = 32)	Poor outcome (*N* = 15)	*p* value
Age (years)	50.0 ± 23.1	51.7 ± 16.6	46.4 ± 33.5	0.47
Sex male	31 (66.0)	24 (75.0)	7 (46.7)	0.056
Death	9 (19.1)	0	9 (60.0)	–
Arrhythmias	5 (10.6)	2 (6.2)	3 (20.0)	0.309
Haemodynamic complications	15 (31.9)	6 (18.8)	9 (60.0)	0.008
Infections	24 (51.1)	17 (53.1)	7 (46.7)	0.68
mSTESS	3 (2; 4)	3 (2; 3.2)	4 (3; 5)	0.039
IMV duration (days)	5 (2.5; 25.5)	3.5 (1.8; 16.5)	14 (5; 36)	0.01

Data are means ± SD, frequencies (%) and medians (IQR)

Table 2 (abstract 001033) Multivariate logistic regression for bad prognosis

	p value	Odd ratio (95% CI)
Haemodynamic complications	0.005	6.500 (1.665–25.376)

Conclusions: Haemodynamic complications was identified as an independent risk factor for developing a poor outcome.

Can one question reflect it all? Correlation between FS-ICU 24R and a single-item satisfaction score

R. Fumis[1], G. André[1], E. Queiroz[1], L. Mesquita[1], L. Pastore Junior[2], E. L. V. Costa[3], F. Ramos[1]
[1]Intensive Care Unit, Hospital Sirio Libanes, São Paulo, Brazil; [2]Icu, Hospital Sirio Libanes, São Paulo, Brazil; [3]Research and education institute, Hospital Sirio Libanes, São Paulo, Brazil
Correspondence: R. Fumis
Intensive Care Medicine Experimental 2025,* 13(1)*:001034

Introduction: Family satisfaction is a key indicator of quality in intensive care units (ICUs), especially after the discharge of critically ill patients. The FS-ICU 24R questionnaire is one of the most widely used tools to assess family satisfaction with care and involvement in decision-making. Understanding how family members perceive the care received can guide improvements in patient-centered and family-centered care models. Moreover, the use of simpler measures, such as a single-item question on the likelihood of recommending the ICU, may represent a practical alternative for overall satisfaction assessment.
Objectives: To evaluate family satisfaction after ICU discharge using the FS-ICU 24R questionnaire and to verify the correlation between its overall satisfaction score and a single-item question on the likelihood of recommending the ICU.
Methods: This longitudinal study included family members of patients who stayed $\geq$ 48 h in the ICU of a tertiary hospital in São Paulo, Brazil. Data were collected after the patient's ICU discharge while they remained hospitalized. Family satisfaction was measured using the FS-ICU 24R includes 24 items and generates three scores: satisfaction with care, satisfaction with decision making, and overall satisfaction (combining both domains). Scores range from 1 to 5 and were rescaled to 0–100 scale for comparability ([raw score-1) $\times$ 25]). A single-item question, based on the Net Promoter Score (NPS) methodology, assessed the likelihood of recommending the ICU (0 = not at all likely to 10 = extremely likely). Sociodemographic data were also collected.
Results: We evaluated 62 family members, median age was 59 [47.5–70.5] years, 69.4% were females. Most were spouses (45.2%) or children (33.9%) of the patients; and most 61.3% lived with the patient and 38.7% lived in a different city. A university-level education was

reported by 74.2%. Mean rescaled satisfaction scores were: 85.3 for care, 84.3 for decision making, and 84.0 for overall satisfaction. Sociodemographic variables, such as relationship to the patient and education level showed no significant association with overall satisfaction, suggesting others factors may play a larger role in family perceptions. The single-question score about the likelihood of recommending the ICU to others had a median of 10 [9–10]. This score showed a moderate and significant correlation with the FS-ICU24R overall score, with Spearman's test ($r = 0.516$; $p < 0.01$).
Conclusions: Family satisfaction with care and decision-making after ICU discharge was high in this cohort. The moderate correlation between the FS-ICU 24R overall score and a single-item question suggests that simplified tools may be valid and useful for assessing general satisfaction in critical care settings.

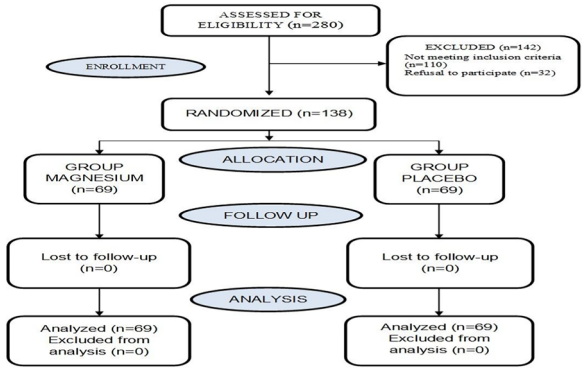
Intensive Care Medicine Experimental 2025,* 13(1):*001037



Introduction: The development of spontaneous intracerebral hematomas is a condition with increasing frequency in our setting and a growing reason for ICU admission. The therapeutic management of these patients and their prognosis have been changing in recent years, leading to an increase in the number of patients in critical care.
Objectives: To analyze the mortality of patients admitted to the ICU due to spontaneous intracerebral hematomas between the years 2019 and 2024 based on different prognostic variables.
Methods: A retrospective and analytical study was conducted with patients who developed spontaneous intracerebral hematomas and required ICU admission between January 2019 and June 2024. Demographic variables, therapeutic approach, and final clinical outcomes were collected. Descriptive statistics were performed using measures of central tendency and dispersion for quantitative variables, and frequency analysis for qualitative ones. Statistical analysis was conducted using the independent samples Student's t test. Statistical significance was established at $p < 0.05$.
Results: A total of 215 patients were included between January 2019 and June 2024. Of these patients, 69 died in the ICU or during hospitalization (32%), and 146 survived (67.9%). The average age of the surviving patients was 57 years, while that of the deceased was 62 years. The average APACHE II score of deceased patients was 21, compared to 15 in surviving patients. The average ICU stay for deceased patients was 3.9 days, compared to 20.71 days for survivors. Among the deceased patients, 7 underwent emergency surgery, while 60 of the survivors underwent surgery.Statistically significant differences were found regarding APACHE II score on admission ($p < 0.0001$), ICU length of stay ($p < 0.0001$), and age ($p < 0.01$). Significant differences were also found regarding the performance of emergency surgery in relation to mortality, with an odds ratio (OR) of 0.16.
Conclusions: The analysis of these patients shows that those who died had greater severity upon admission, were older, and had a shorter average ICU stay. Undergoing emergency surgery appears to be a protective factor regarding patient mortality. Further studies are needed to assess outcomes in larger samples.

Intensive Care Medicine Experimental 2025,* 13(1):*001039

Introduction: We investigated the impact of magnesium on the clearance of lactate in patients who were diagnosed with sepsis in the emergency department.
Methods: In this randomized trial, 138 adult patients with sepsis with serum lactate levels > 2 mmol/L presented to the emergency department were randomized into the magnesium (M) group and placebo (P) group. The individuals in group M were administered 2 g of magnesium sulphate infusion diluted in 50 ml of normal saline over 2 h for three days. The individuals in group P were administered an identical volume of normal saline for three days. We compared time to 20% lactate clearance, changes in lactate clearance, intensive care unit (ICU) duration, hospital stay and 28-day mortality in both groups.
Results: Time to 20% lactate clearance was considerably lower in the M group (5.73 ± 2.19 h) when compared with the P group (8.54 ± 2.72 h), $p < 0.001$. The mean increase in lactate clearance was markedly more significant in the M group than the P group on day 1 (18.88 ± 1.80% vs 12.61 ± 1.94% respectively, $p < 0.001$), on day 2 (30.02 ± 4.30% vs 23.34 ± 4.76% respectively, $p < 0.001$) and day 3 (50.74 ± 6.06% vs 37.94 ± 4.53% respectively, $p < 0.001$). The M group also had a significantly shorter length of ICU and hospital stay and a lower 28-day mortality than the P group.
Conclusions: Adding magnesium decreases the time required for lactate clearance, shortens the length of ICU and hospital stays, and lowers 28-day mortality rates in patients presented to emergency department with sepsis.

Predictors of permanent pacemaker implantation in a TAVI program at a secondary-level hospital

A. Martinez Cabezas, R. Garcia Martínez, S. Mariño Guerreiro, M. E. Poyatos Aguilera, P. Fernandez Morales
Intensive care unit, Hospital Universitario Clínico San Cecilio, Granada, Spain
Correspondence: R. Garcia Martínez
Intensive Care Medicine Experimental 2025,* 13(1)*:001040

Introduction: Severe aortic stenosis (AS) is a prevalent condition in the elderly population and is associated with significant morbidity and mortality when left untreated. Transcatheter aortic valve implantation (TAVI) has emerged as the preferred therapeutic option for patients at increased surgical risk, offering a less invasive alternative to surgical valve replacement. Despite its clinical benefits, TAVI is frequently complicated by conduction disturbances, often leading to the requirement for permanent pacemaker implantation (PPMI), which may impact both short- and long-term outcomes.
Several baseline electrocardiographic abnormalities, such as right bundle branch block (RBBB) and atrial fibrillation (AF), have been reported as potential predictors of post-TAVI PPMI, although the findings have been inconsistent across studies. Moreover, the need for pacemaker implantation following TAVI varies widely between centers, influenced by patient characteristics, procedural factors, and device type.
In this single-center prospective study, we aimed to identify pre- and post-procedural predictors of PPMI in patients undergoing TAVI. We also evaluated the clinical profile and outcomes of extremely elderly patients in this cohort, with the goal of improving risk stratification and guiding clinical decisions in this increasingly common intervention.
Objectives: The primary objectives were to identify the predictors of new permanent pacemaker implantation in patients with aortic stenosis (AS) undergoing transcatheter aortic valve implantation (TAVI). The secundary objectives were to study the characteristics, and outcomes of transcatheter aortic valve implantation (TAVI) among extreme elderly.
Methods: We conducted a prospective observational cohort study at a secondary-level in Granada (Southern Spain) between 2021 and 2024. A total of 160 consecutive patients with severe aortic stenosis (AS) who underwent transcatheter aortic valve implantation (TAVI) were evaluated. Patients with a prior permanent pacemaker ($n = 15$) and those with missing data for key variables ($n = 5$) were excluded, resulting in a final cohort of 140 patients for the primary analysis.
Baseline clinical characteristics, laboratory tests, 12-lead ECG, and transthoracic echocardiography were recorded. Variables assessed included left ventricular ejection fraction (LVEF), atrial fibrillation (AF), right bundle branch block (RBBB), atrioventricular block (AVB), prior coronary artery disease, and previous valvuloplasty. Postprocedural ECG findings such as new RBBB and complete AV block were also analyzed.
The primary outcome was the need for permanent pacemaker implantation within 30 days after TAVI. Statistical analysis was performed using multivariate logistic regression. Two models were built: one including only preprocedural variables and a second incorporating postprocedural ECG changes. Age and baseline creatinine were excluded due to lack of statistical significance. The results were expressed as odds ratios (OR) with 95% confidence intervals (CI), and a p value < 0.05 was considered significant.
Results: The mean age was 82 years, and 54,4% were females. 80.2% had LVEF > 50%, 71.2% did not have coronary disease. Among the 140 eligible patients, 31 (22,1%) underwent pacemaker implantation ≤ 30 days following TAVI. 7 (4,8%) died during hospital admission and 13 (8,9%) during 1 year follow up. On multivariable analysis, right bundle branch block (OR 6,456, 95% CI 2,316–17,991) and atrial fibrillation at baseline (OR 3,185, 95% CI 1,226–8,272) were predictors of pacemaker implantation. Female sex protected (OR 0,403, 95% CI 0,164–0,99) against pacemaker implantation. Right after the TAVI implantation, complete atrioventricular block (OR 4,097, 95% CI 1,391–12,069) and right bundle branch block (OR 4,384, 95% CI 1,552–12,384) were strong predictors of pacemaker implantation.
Conclusions: In our current study, atrial fibrillation and right bundle branch block have shown to be pre procedure predictors of pacemaker implantation, as right bundle branch block and atrioventricular block after the procedure. Female sex protects against pacemaker implantation.

Variable	OR (Exp B)	95% CI Lower	95% CI Upper	p-value
Female sex	0.403	0.164	0.990	0.047
Atrial fibrillation	3.185	1.226	8.272	0.017
Right bundle branch block (RBBB)	6.456	2.316	17.991	<0.001

Interpretation: Female sex was associated with a decreased risk of permanent pacemaker (PPM) implantation. Atrial fibrillation and pre-procedural RBBB significantly increased the risk of PPM implantation.

Female sex was associated with a decreased risk of permanent pacemaker (PPM) implantation. Atrial fibrillation and pre-procedural RBBB significantly increased the risk of PPM implantation.

Variable	OR (Exp B)	95% CI Lower	95% CI Upper	p-value
Right bundle branch block (RBBB)	4.384	1.552	12.384	0.005
Complete AV block post-TAVI	4.097	1.391	12.069	0.011

Interpretation: Both pre-procedural RBBB and post-procedural complete AV block were strong predictors of the need for a permanent pacemaker after TAVI.

Both preprocedural RBBB and postprocedural complete AV block were strong predictors of the need for a permanent pacemaker after TAVI.

Variable	Category	Frequency	Coding
LVEF <40%		12	1.000
LVEF 40–50%		14	1.000
LVEF >50%		114	0.000
Previous valvuloplasty	Yes	16	1.000
Previous valvuloplasty	No	124	0.000
Previous CAD	Yes	43	1.000
Previous CAD	No	97	0.000
Pre-intervention ECG rhythm	AF	35	1.000
Pre-intervention ECG rhythm	Sinus	105	0.000
Pre-intervention RBBB	Yes	22	1.000
Pre-intervention RBBB	No	118	0.000
Pre-intervention AV block	Yes	22	1.000
Pre-intervention AV block	No	118	0.000
Sex	Female	78	1.000
Sex	Male	62	0.000

Categorical predictive variables with their coding and frequency. Note: In addition to these categorical variables, continuous variables such as age and baseline creatinine were also included, but were excluded from the models due to lack of statistical significance.

Intensive Care Medicine Experimental 2025,* 13(1)*:001041

Introduction: Epileptic disorders, are neurological emergencies defined by prolonged or recurrent seizures without full recovery, often requiring intensive care unit (ICU) admission due to its life-threatening nature [1]. Management is time-sensitive and involves multiple drugs including anesthetics and a continuous monitoring [2–3]. Despite advances, these disorders remain a major cause of ICU resource use and mortality [4].
Objectives: To describe the clinical and demographic characteristics, therapeutic strategies, type of EEG monitoring, and outcomes of patients admitted to an ICU with epilepsy disorder over a 3-year period.
Methods: This retrospective cohort study included all adult patients admitted to our ICU between January 2021 and December 2023 with a diagnosis of epileptic disorders at admission or during their ICU stay. Collected data included demographic, severity scores (SAPS II), EEG modality, therapeutic interventions, mechanical ventilation, length of stay, Clinical Frailty Score (CFS) at discharge, and mortality (ICU, 30-day, 60-day).
Results: A total of 112 patients (70 men, 42 women) were included, with a mean age of 59.3 years (range 26–86). Mean SAPS II was 49.3. Mechanical ventilation was required in 92 patients (82.1%), with a mean duration of 11.7 days. Average ICU stay was 15.3 days (range 1–99). Among the cohort, 9 patients (8%) were classified as NORSE. In terms of treatment strategy, 36% of patients received benzodiazepines antiepileptic drugs (AEDs) and 64% nonbenzodiazepine antiepileptic drugs as first-line therapy. In second-line therapy, 21.95% were administered benzodiazepines AEDs and 78.05% nonbenzodiazepine AEDs. Third-line regimens involved benzodiazepines AEDs in 26.92% and nonbenzodiazepine AEDs in 73.08% of cases. Anesthesic drugs were required in 47 patients (42%) for seizure control or to facilitate mechanical ventilation. Continuous EEG monitoring was performed in 27 patients (24.1%), and intermittent EEG in 85 (75.9%). ICU mortality was 31 patients (27.7%). In addition, 7 patients (6.25%) died within 30 days of ICU discharge, and 7 (6.25%) within 60 days. The median CFS at discharge was 4(range 2–8).
Conclusions: The identification of NORSE cases in 8% of patients and the use of sedative drugs in 42% reflect the high clinical complexity of seizure management in the ICU setting.The meadian moderate-low level of dependency observed in most patients after ICU discharge can be interpreted as a favorable prognosis.
This study contributes real data on our epileptic disorders ICU population management and outcomes, reinforcing the need for a multidisciplinary approach. This investigation is a beginning for future studies aimed, for example, at identifying prognostic markers to improve care for these patients.

Introduction: SeptiLoop is a new in vitro diagnostic test that uses a lipopolysaccharide antigen to stimulate cells in heparinised whole blood. The detection of tumour necrosis factor-alpha (TNF-α) by lateral flow assay (LFA) is used to identify in vitro responses to the antigen that are associated with bloodstream infection and sepsis. This phenomenon when inhibited is known as endotoxin tolerance (ET).

Objectives: The aim of this study was to describe the postoperative ET rate (Septiloop levels 0 or 1) and TNF-α levels after exogenous stimulation in the first 4 days after postoperative major abdominal surgery. As a secondary objective, we compared the rate of postoperative infection in patients with lower vs higher levels of TNF-α.
Methods: We designed a prospective observational study.
All patients scheduled for abdominal surgery with a high risk of intra-abdominal infection (IAI) who gave informed consent for the study were consecutively selected.
To interpret the test results, it should be noted that the lateral flow strip developed by Loop Diagnostics is designed to detect the presence of TNF-α in a blood sample after stimulation with LPS. Detection of this biomarker is indicative of the endotoxin tolerance (ET) status of the patient's immune cells. To illustrate the results of TNF-α detection in the sample, the strip has two positions where a red band may appear upon contact with the sample: a control position, indicated by a letter 'C', and a test position, indicated by a letter 'T'. A scoring table on a scale of 0 to 5 of the possible intensities that the test line could show was included. The intensity of the strip is proportional to the TNF-α levels.
The test was performed once a day during the first 4 postoperative days. Variables related to the patient, the surgical intervention and the postoperative evolution were collected. The diagnosis of postoperative infection was considered according to international criteria (CDC.gov).
For descriptive analysis, quantitative variables were expressed by mean and standard deviation if they follow a normal distribution, otherwise by median and interquartile ranges. Qualitative variables were expressed by absolute number and percentage. For comparative analysis between populations (Septiloop negative and positive) Student's *t* test (for quantitative variables) or its corresponding parametric and Chi-square (for qualitative variables) were used.
Results: 120 postoperative major abdominal surgery patients (colorectal surgery (77.6%), pancreatectomy (9.2%) and gastrectomy (13.2%)) were collected.
The median Septiloop value was 2 on the first two postoperative days and 3 on the third and fourth day. 53.5% patients had ET defined as Septiloop of 0 or 1.
The overall postoperative infection rate was 15.8%. 64.4% had IAI, 36.8% had surgical site infection and 10.5% had urinary tract infection. Regarding severity of infection, 52.6% had local infection as compared to 47.4% who developed sepsis, septic shock or multiorgan dysfunction syndrome.
The infection rate in patients with Septiloop values 0–1 on any of the first 4 postoperative days was 28.13% versus 1.79% in patients with values > 1 ($p < 0.001$).
Conclusions: Postoperative high-risk major abdominal surgery was associated with alterations in immune response the first 4 postoperative days. Patients with lower TNF-α levels after exogenous toxin exposure had a higher postoperative infection rate.
Septiloop is a simple, noninvasive test with a high potential to predict the risk of infection in the postoperative period after abdominal surgery.

Evolution of postoperative septiloop values.

Introduction: Intracranial hypertension (ICH) worsens TBI prognosis and may require barbiturates or decompressive craniectomy (DC) when refractory to medical therapy1-4. Although DC reduces ICP and improves cerebral perfusion5,6, its prognostic value remains controversial, especially in the absence of a mass lesion7–13. Trials such as DECRA14 and RESCUEicp15 report reduced mortality, but with greater functional disability. Most studies do not distinguish between primary and secondary DC10,13,16–27. The timing may influence outcomes 10, 12, 28, although evidence remains inconsistent 11,12,17,26,28–30.
Objectives: To compare clinical and epidemiological characteristics of TBI patients undergoing primary vs secondary DC in a single-center cohort.
To develop a prognostic scoring system based on these variables to identify candidates for primary DC without the need for invasive confirmation of refractory ICH.
Methods: This was a single-center retrospective observational study including TBI patients admitted to the ICU at Hospital Clínico San Carlos (2014–2024), who underwent primary(prophylactic) or secondary(therapeutic) DC. Cases requiring secondary DC after a prior primary procedure were excluded. Clinical, epidemiological, and radiological variables were collected. Statistical analysis included univariate tests (Kolmogorov–Smirnov, Chi-square, Student's *t* test or Mann–Whitney *U*), survival analysis (Log-Rank test), binary logistic regression, and ROC curve analysis performed using SPSS v15.0.
Results: Of the 312 patients, 72 required DC: 45 primary and 33 secondary. Patients undergoing primary DC showed greater clinical severity at admission (GCS 3vs10; APACHEII 22vs18; $p < 0.0001$), higher mydriasis (55.6%vs22.2%; $p = 0.006$), hemodynamic instability (31.1%vs7.4%;p = 0.019), and mortality (ICU 42.2%vs14.8%; in-hospital 46.7%vs22.2%). Radiological findings in the primary DC group included more frequent midline shift (86.7%vs44.4%), ventricular collapse (68.8%vs29.6%), and perimesencephalic cistern compression (68.2%vs22.2%) (all $p < 0.0001$). Subdural hematomas were larger in primary DC (10 mm vs 5 mm; $p = 0.006$) In contrast, cerebral contusions were more common in secondary DC (81.5% vs 48.9%; $p = 0.006$). Secondary DC was performed at a median of 35 h from admission (range 1–312 h).A logistic regression model was developed to predict the indication for primary DC. Independent predictors included perimesencephalic cistern compression (OR4.73; 95% CI 1.39–17.1), midline shift (OR4.7; 95% CI 1.25–17.6), and hemodynamic instability (OR4.89; 95% CI 0.89–26.7). The model showed good discriminatory capacity (AUC 0.821; 95% CI 0.72–0.92; $p < 0.0001$) (Fig. 1).

Conclusions: Primary DC patients showed more severe clinical and radiological findings at admission, which may justify earlier intervention despite higher mortality, likely reflecting initial injury severity. The predictive model showed strong discriminatory power and may help identify candidates for primary DC without requiring invasive ICP monitoring.

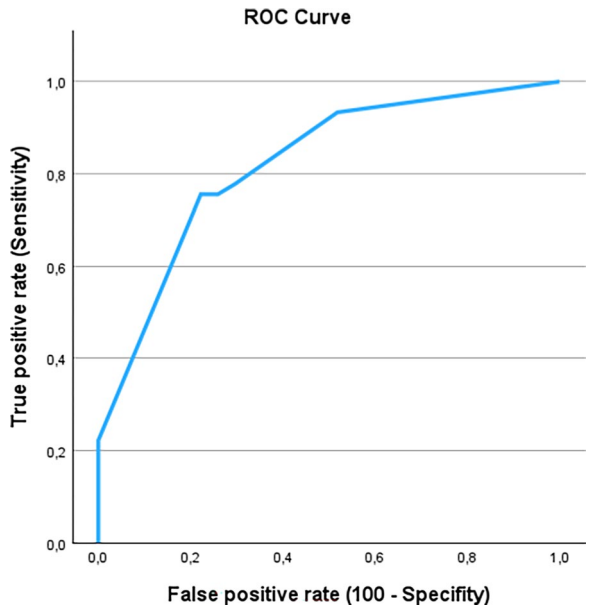

Fig. 1 (abstract 001043) ROC curve used to evaluate the discriminatory performance of the predictive model

Introduction: Acute brain injury (ABI) is associated with high mortality and long-term disability. Cerebral ischemia is an important mechanism of secondary brain injury, resulting from impaired oxygen delivery due to reduced cerebral blood flow, low arterial oxygen content, or metabolic uncoupling (1). The aim of this study was to evaluate predictors of cerebral ischemia in ABI patients and whether a liberal transfusion strategy would influence the occurrence of such event.

Methods: This is a post hoc analysis of the TRAIN study (2). Cerebral ischemia was reported by local investigators according the presence

of a new (e.g. occurring after randomization) ischemic lesion visible on brain imaging (e.g. either CT-scan or MRI). The primary outcome was to identify the predictors of cerebral ischemia. Secondary outcomes included the association of transfusion strategy (liberal vs. restrictive) on its occurrence and the impact of cerebral ischemia on functional outcome at 6 months, assessed by the Glasgow Outcome Scale–Extended (GOSE, unfavorable outcome = GOSE 1–5).
Results: Out of the 820 included patients, 92 (11.2%) developed cerebral ischemia after randomization. Patients with ischemia were more frequently female (75% vs. 42%, $p = 0.001$) and had more often a subarachnoid hemorrhage as initial ABI (70% vs. 17%, $p = 0.001$). Cerebral ischemia occurred more frequently in patients randomized to the restrictive strategy (62% vs. 50%, $p = 0.04$) compared to liberal one. In an unadjusted analysis, liberal transfusion was associated with a reduced risk of ischemia (OR 0.62, 95% CI 0.40–0.97); however, in a multivariable logistic regression analysis adjusted for age, ABI, GCS at randomization, hemoglobin at randomization, and elevated ICP requiring second-tier therapy, liberal strategy was not significantly associated with a reduced risk of cerebral ischemia (adjusted OR 0.65, 95% CI 0.41–1.03). Patients with cerebral ischemia had significantly higher rates of unfavourable functional outcome (85% vs. 65%, $p = 0.001$) than others. In a multivariable analysis, cerebral ischemia was independently associated with unfavorable functional outcome (adjusted OR 2.65, 95% CI 1.39–5.07).
Conclusions: In this post hoc analysis of the TRAIN study, cerebral ischemia occurred in 11% of patients with ABI and was independently associated with worse functional outcome. Although a liberal transfusion strategy was associated with a reduced incidence of cerebral ischemia in univariate analysis, this association could be influenced by other confounders.

Intensive Care Medicine Experimental 2025,* 13(1)*:001045

Introduction: Sepsis is the most severe form of infections. It is both frequent and severe. Awareness regarding long-term consequences of sepsis, after ICU discharge, is rising. Sepsis survivors face an increased risk of developing organ failure, such as chronic kidney disease or heart failure. Although numerous studies investigated the early immune mechanisms involved during sepsis, the pathophysiology of those long-term phenomenon has been poorly investigated.
Methods: We developed a mouse model of sublethal sepsis using cecal ligature punction (CLP) model. Multiparametric Flow cytometry, FateMapping experiments and scRNAseq were used together with spatial transcriptomic analyses to unravel the origin, kinetic and profile of intrarenal and intracardiac macrophages following sepsis and relation with long-term outcome. We later used a two-hit model combining CLP and angiotensin-2 infusion to test cardiorenal resilience to subsequent immune chalenge.
Results: Our results showed that sublethal sepsis causes transient and reversible renal and heart failure but induces a durable increase in tissue resident macrophages. Fate mapping study showed that the rise in macrophages numbers was mainly due to recruited monocyte-derived macrophages. scRNAseq and spatial transcriptomics analyses of heart and kidney showed that monocyte-derived macrophages had a distinct transcriptomic signature with pro-inflammatory and pro-fibrotic features that is associated with proinflammatory environment. This change in tissue macrophage landscape is associated with poor resilience to secondary hits with an increase in mortality and tissue fibrosis observed when septic mice are undergoing an angiotensin-2 challenge.
Conclusions: Our findings suggest that macrophages stem sepsis-induced altered organ repair and could represent a therapeutic target to improve septic patient long-term outcomes.

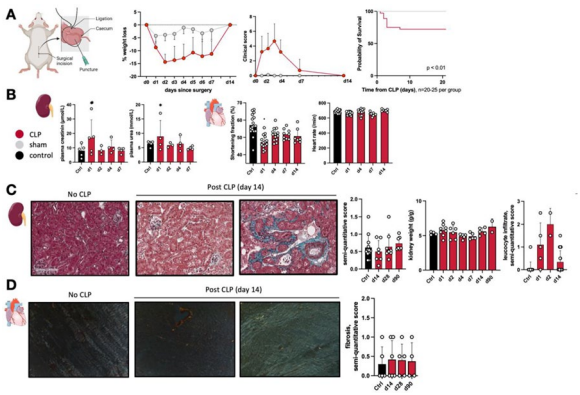

Fig. 1 (abstract 001045) Sepsis is associated with transient and reversible organ dysfunction. **A**Diagram of sub-lethal cecal ligature punction model. Weight loss and behavioral changes were returned to normal values among survivors by day 14. Survival curves confirmed the sub-lethal nature of our model **B** Diagram of plasma urea and creatinine following sepsis as well as echocardiographic constatations. **C** Histology analyses (Masson Trichrome) of kidney after CLP, fibrosis was assessed using semi-quantitative score by blinded physician, tubular atrophy was assessed by monitoring kidney weights at various time-points. **D** Histology analyses (Sirius red) of cardiac fibrosis after sepsis, fibrosis was assessed using semi-quantitative score by blinded physician. *$p < 0.05$; $n = 2–10$, 1-way
ANOVA followed by Tukey's multiple comparisons test. The data are mean ± SEM.

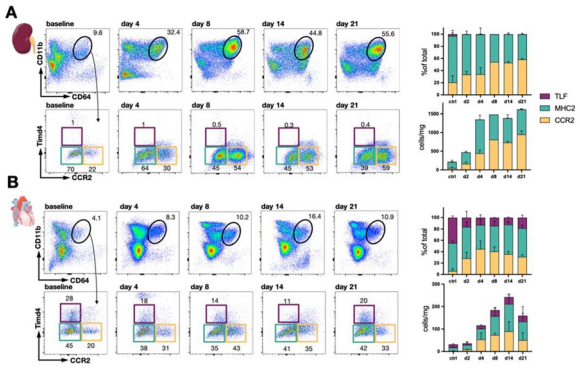

Fig. 2 (abstract 001045) Sepsis induces profound and durable alterations of intra-organ macrophages number and subsets. Heart **A** and kidney **B** tissues were isolated from adult wild-type mice and single-cell suspensions were prepared for flow cytometry. Macrophages were identified as live + lin-CD45 + CD64 + CD11b + later stratified based on expression of TIMD4 and CCR2. For complete gating strategy see Supplementary Figure S1. *$p < 0.05$; $n = 2–6$; the data are mean ± SEM

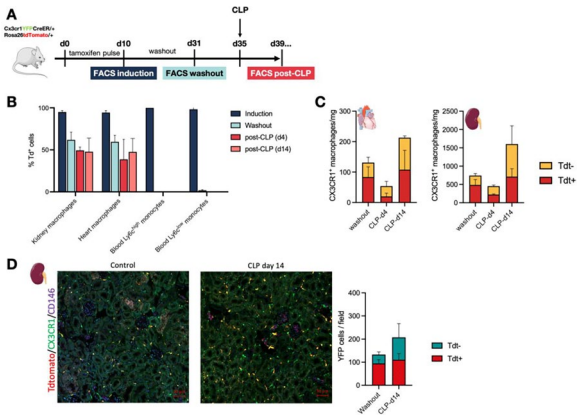

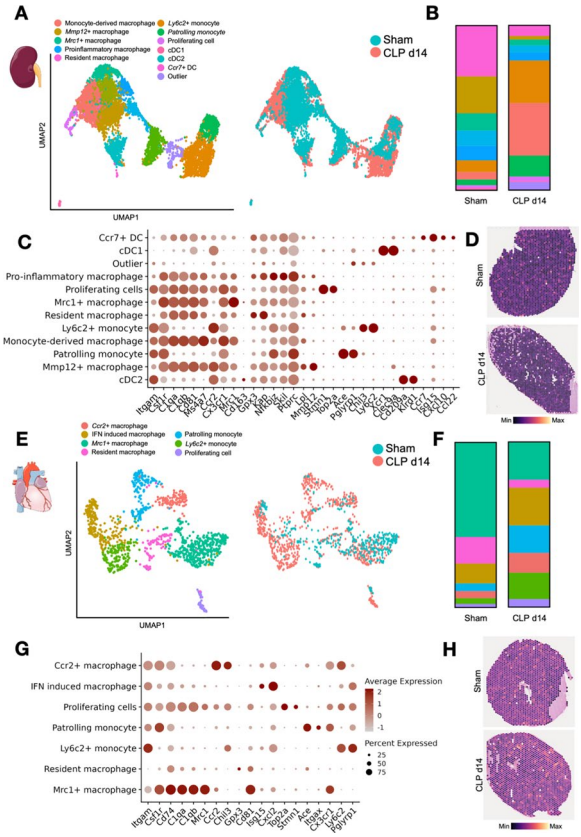

Fig. 3 (abstract 001045) Fate mapping analysis identifies monocytes-derived macrophages as the main source of tissue macrophages expansion during sepsis. **A** 6–10-week-old c57Bl6 Cx3Cr1YFP-CreER/ + Rosa26Tdtomato/ + mice were fed with tamoxifen-containing chow for 10 days. By day 10, we confirmed by flow-cytometry the complete induction of Cre Recombinase. After a period of washout of 21 days (confirmed by flow cytometry), mice were subjected to cecal ligature punction. Flow cytometry was used at different timepoints to assess abundance and Tdt + retention of intra-organ macrophages. **B** Percentage of Td + cells in tLy6Chi monocytes, Ly6Clo monocytes, kidney and heart after induction, after washout or at different timepoints following sepsis. **C** For each timepoints, total number of intra-organ macrophages was assessed and Tdt + retention was computed. **D** Representative immunofluorescence staining of EYFP (green), Tdtomato (red) and CD146 (violet) in of adult Cx3Cr1YFPCreER/ + Rosa26Tdtomato/ + mice at day 14 after sham or CLP, × 20 magnification, Quantification of the proportion of Tdt + in macrophages was performed by blinded physician ($n = 2–3$)

(abstract 001045) Single cell characterization of myeloid cells in the septic organs. scRNA-seq analysis of identifies seven heart monocyte and macrophages cell types, with dynamic changes in the proportion and transcriptome of each cell type observed across the septic model. **A** tSNE plot of 7642 pooled myeloid cells from kidney from each time point, annotated by cell type and condition. ($n = 3$ per time point). **B** Relative proportions of each cell type at each time point. **C** Dotplots showing the expression levels of selected marker genes in each cluster. **D** Spatial transcriptomic analyses revealed few kidney spots containing macrophages based on canonical markers **E** tSNE plot of 943 pooled myeloid cells from heart for each time point, annotated by cell type and condition. ($n = 3$ per time point). **F** Relative proportions of each cell type at each time point. **G** Dotplots showing the expression levels of selected marker genes in each cluster. **H** Spatial transcriptomic analyses revealed few kidney spots containing macrophages based on the canonical markers

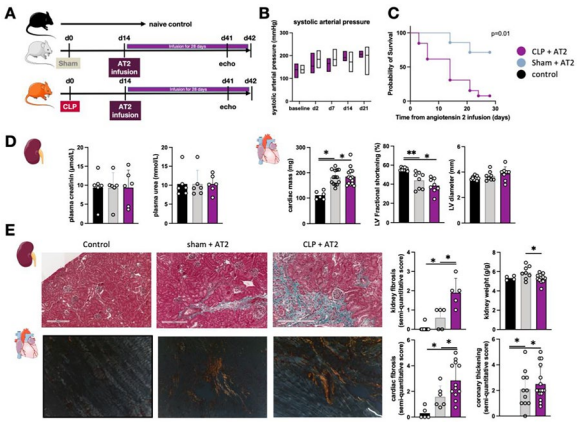

Fig. 7 (abstract 001045) Sepsis causes altered organ repair after second hit. **A** C57bl6 WT mice were randomly assigned to receiver either CLP or sham operation. After complete recovery from the septic episode (day 14), sepsis-surviving mice and sham operated mice were subjected to continuous angiotensin (AT) 2 infusion (800 ng/kg/min) combined with salty drinking water (NaCl 0.2%) for 28 days. Echocardiographic evaluation was performed by blinded physician just before sacrifice. **B** AT 2 infusion induced hypertension as confirmed by arterial pressure monitoring, appearing from day 2 **C** Survival curves of WT mice when exposed to AT2 demonstrates an important mortality among sepsis survivor mice when exposed to AT 2 as compared to sham operated mice **D** Plasma urea and creatinine did not differ with baseline after AT 2 infusion. Echocardiography revealed increased cardiac mass and reduction of fractional shortening consistent with AT 2 induced cardiac hypertrophy **E** Weighting of kidney was in favor of tubular atrophy in CLP mice after AT2 infusion. Histological analyses of kidney (Masson trichrome) revealed fibrosis in both conditions, with a strong increase among sepsis-surviving mice. Heart analyzes (Sirius red) revealed coronary thickening, consistent with intense sheer stress induced by AT 2 infusion. Fibrosis was present in both conditions; it was more important in sepsis survivors as compared with sham operated mice. Coronary thickening and fibrosis were assessed using semi-quantitative score by a blinded physician; *t* test was performed; *$p < 0.05$; **$p < 0.01$; data are mean ± SEM

Intensive Care Medicine Experimental 2025,* 13(1):*001048

Introduction: Midodrine, an oral alpha-1 agonist, has been increasingly used as an adjunct to reduce the need for intravenous vasopressors in critically ill patients. However, its application in neurocritical care remains underexplored.
Objectives: This study aimed to describe the trends in midodrine use at a high-complexity neurocritical care center, including its impact on blood pressure and vasopressor requirements.
Methods: We conducted a retrospective observational study reviewing medical records of adult patients who received midodrine between January 1, 2013, and July 31, 2024, at a neurocritical care unit (NCCU). Data collection included demographic characteristics, hospitalization details, midodrine indications, hemodynamic parameters, vasopressor use, and adverse events. Statistical analysis included paired *t* tests, Wilcoxon signed-rank tests, and logistic regression, with significance set at $p \leq 0.05$.
Results: A total of 84 patients were included, with a mean age of 57.3 years (SD ± 20.2), and 52.4% ($n = 44$) were male. The primary indications for midodrine were dysautonomia (50%, $n = 42$) and stroke-related conditions (36.9%, $n = 31$). The median time to midodrine initiation was 4 days (IQR: 1.0–11.25). Mean arterial pressure (MAP) increased from 80 mmHg (± 18) to 86 mmHg (± 15) at 24 h post-initiation ($p = 0.25$), while norepinephrine dose decreased from 0.025 ± 0.07 µg/kg/min to 0.01 ± 0.01 µg/kg/min ($p = 0.023$). One patient required discontinuation due to symptomatic bradycardia. The median length of NCCU stay was 7 days (IQR: 2–17.5), and total hospital stay was 13.5 days (IQR: 6–29). No significant correlation was found between midodrine dose and vasopressor reduction ($p = 0.383$).
Conclusions: Midodrine was associated with reduced vasopressor requirements and stable hemodynamic parameters in neurocritical ill and neurovascular patients, supporting its role as a potential adjunct for blood pressure management. The low incidence of adverse events reinforces its safety profile in our population.

Introduction: Sepsis is a clinical syndrome, triggered by a systemic infection and often resulting into successive organ failure and lethal outcome. Early diagnosis and identifying of patients with sepsis is therefore crucial as, early treatment and therapeutic interventions likely to improve it. The need for the hour is to have an inflammatory marker that predicts sepsis rapidly and effectively in order to initiate appropriate treatment as soon as possible. Although procalcitonin is found to be better than the inflammatory markers used earlier, reliability is still an issue. Hence, there is considerable space for searching new sepsis markers such as pentraxine 3 and presepsin. These biomarkers have shown significant potential of early diagnosis of sepsis in various studies worldwide. In the only study done on the Indian population, presepsin was found superior over procalcitonin in diagnosing sepsis. There have been no prior studies observing the relationship between Pentraxin-3 and sepsis in an Indian population.
Methods: In this prospective cohort study, adult patients (≥ 18 years age) having clinical features suggestive of sepsis as defined by Sepsis-3 definition (2016) at the time of ICU admission were enrolled. Blood sample was taken from the patient for the purpose of serum procalcitonin estimation at this time (day 1-D1). The test for presepsin and pentraxin-3 were done from the same sample. These tests were repeated on day 3 (D3), day 7 (D7) and at the time of discharge from Intensive care unit/death (Dd). We studied changes in pentraxin-3 and presepsin levels in patients with sepsis during first week of ICU admission. We also correlated levels of these markers with prognosis of patients.
Results: The study comprised 60 patients who satisfied the inclusion criteria. There was a serial decrease in all the 3 biomarkers values in patients who were discharged from the ICU and serial increase in the values in patients who died. On day 1, prentaxin-3 was the only marker found to have a significant predictive ability for ICU deaths [AUC 0.702; 95% CI 0.569–0.836, $p = 0.008$]. Using Youden's index method, the ideal cutoff is found to be 2.36 ng/mL, where the sensitivity was found to be 97.1% and specificity is 38.5%.
Conclusions: The use of procalcitonin, presepsin and pentraxin is good for screening of sepsis in intensive care unit. These can improve the outcome of sepsis by early institution of aggressive therapy in patients with high values of these markers thus potentially improving the mortality rates in sepsis. Out of all these 3 sepsis biomarkers, pentraxin has a high sensitivity for prediction of ICU mortality which shows that it is a significant marker of mortality is sepsis.

ROC curve of PCT, presepsin and pentraxin values on Day 1 against outcome to prognosticate 28 day mortality.

Angiotensin II and platelet count in patients with septic shock: a case series

A. Vujević, S. Šundalić, C. K. Ela, A. Vujaklija Brajković
Department of Internal Medicine, University Hospital Centre Zagreb, Zagreb, Croatia
Correspondence: A. Vujević
Intensive Care Medicine Experimental 2025,* 13(1)*:001051

Introduction: Thrombocytopenia is frequently observed in patients with sepsis. Angiotensin II (Ang II) is increasingly used in patients with septic shock. However, concerns exist regarding Ang II-associated thrombocytopenia and the increased potential for bleeding and thrombotic complications (1, 2).

Objectives: To investigate platelet count trajectories and possible adverse reactions associated with Ang II administration in patients with septic shock.
Methods: Adult patients with septic shock admitted to the medical intensive care unit (ICU) of the University Hospital Centre Zagreb were included in the study. We analyzed data from patients who required Ang II application for the treatment of septic shock regardless of platelet count. Patients signed informed consent at the beginning of the study. At admission, we recorded demographic data, comorbidities, SOFA score, and platelet count. We analyzed platelet trends and associated clinically significant bleeding and thrombotic events.
Results: Six patients were included (age: 71 ± 10 years, SOFA score: 13.3 ± 2.66). Patient data are presented in Table 1. Notably, 5 out of 6 patients had active malignant disease, and 4 out of 6 had ongoing therapy for these conditions. Platelet counts were recorded on the first, second, and third day. Patients that died within the first two days ($n = 2$) were excluded from the third day calculations. The one patient who received platelet transfusions was excluded from general platelet change calculation, but was observed individually for platelet dynamics. The mean platelet count decreased from 73.0 on Day 1 to 58.7 × 10^9/mL on Day 2. For the patients with Day 3 data available ($n = 3$), the mean platelet count change from Day 1 to Day 3 was -39.7 × 10^9/mL. While a decrease in platelet count was observed in most patients during the study period, with the majority (5/6 patients) progressing to severe thrombocytopenia (< 50 × 10^9/mL), none experienced clinically significant bleeding. In one patient receiving platelet transfusions during the study, we observed an adequate increase in platelet values without any thrombotic or other adverse effects. No thrombotic events were noted in this patient series. Patient outcomes differed with two patients (patients 2 and 6) being discharged alive from the ICU, while four patients died.
Conclusions: Thrombocytopenia in these patients is likely due to a combination of factors, including sepsis, malignant disease, and potentially vasopressor therapy. Despite observed platelet changes with Ang II use in refractory septic shock, this small case series suggests that clinically significant bleeding and thrombotic events may be uncommon in this specific cohort, even in the context of an underlying malignant disease. These findings warrant further investigation in larger, prospective studies to fully assess the safety profile of Ang II and to identify potential risk factors for thrombotic and bleeding complications.

Lactate as a predictor of citrate accumulation in patients undergoing continuous renal replacement therapy?

U. W. Iepsen[1], J. Ulrichsen[2], R. Plovsing[3], N. Foss Bang[2], R. Berg[4]

Intensive Care Medicine Experimental 2025,* 13(1)*:001052

Introduction: Regional citrate anticoagulation (RCA) is the preferred strategy for continuous renal replacement therapy (CRRT). However, impaired citrate metabolism, observed in patients with liver failure, mitochondrial dysfunction, and/or shock, can result in potentially lethal citrate accumulation (CA). We aimed to evaluate the ability of elevated lactate levels to predict CA in critically ill patients undergoing RCA-CRRT.
Methods: We performed a comprehensive search in PubMed and Embase databases for studies involving adult critically ill patients who underwent RCA-CRRT, where both CA and lactate levels were assessed. The primary outcome was lactate levels in relation to patients with and without CA. The certainty of the effect estimates for each outcome and the quality of the included studies was assessed.
Results: We included seven observational studies comprising 1,573 critically ill patients undergoing RCA-CRRT. Five were deemed good quality evidence and two poor to answer the research question. We found a significant mean difference (MD) in baseline lactate levels (MD: 0.87, 95% CI [0.04; 1.70] $p = 0.04$, six studies, 1485 patients) between the CA and the non-CA group with very low confidence in the estimate. This difference was persistent between the two groups when using peak lactate levels (MD: 6.05, 95% CI [0.06; 12.03], $p = 0.05$, three studies, 271 patients), and the CA group had an overall higher mortality risk (OR: 5.24, 95% CI [1.05; 26.25], $p = 0.04$, five studies 1438 patients).
Conclusions: The evidence is very uncertain but elevated lactate may be associated with an increased risk of CA in critically ill patients undergoing RCA-CRRT.

Hypothesized mechanism of lactate in prediction of citrate accumulation. The whole-body lactate metabolism during exercise in healthy humans. Left side illustrates the intracellular pathway of lactate metabolism in muscle cells. Here lactate may be the end product of glycolysis and is either transported into the mitochondria where it is converted to pyruvate which is a substrate in tricarboxylic acid cycle or out of the cell. If lactate is transported out of the muscle cell, it can be used as a substrate for mitochondrial respiration in the brain and heart or transported to the liver and kidney for gluconeogenesis. Therefore, lactate can be considered as a surrogate marker of mitochondrial function and if mitochondrial function is impaired due to critical illness, citrate cannot be metabolized and will accumulate. *Acetyl CoA* acetyl coenzyme A, *mLDH* mitochondrial lactate dehydrogenase, *TCA cycle* tricarboxylic acid cycle. Optimising sedation practice in a Scottish tertiary intensive care unit using a quality improvement approach

R. Brunner[1], D. Buchanan[1], S. Davis[1], J. Gordon[1], P. Richards[1], G. Mackinnon[1], A. Rocas[1], K. Quinn[2], Z. Jiwaji[1]

Intensive Care Medicine Experimental 2025,* 13(1)*:001053

Introduction: Background: Sedation is widely used in intensive care units (ICUs). However, inappropriate sedation is associated with adverse outcomes including prolonging mechanical ventilation and delirium. Therefore, national quality recommendations (1) advocate for daily sedation holds (SH) to optimise patient sedation.
Problem: Post-COVID-19, we observed issues implementing daily SHs in our 42-bed mixed level-2 and level-3 tertiary combined medical and surgical ICU; the largest ICU in Edinburgh. This led to low off-sedation neurological assessment rates and became an issue highlighted by national quality surveillance processes.
Objectives: Identify reasons for suboptimal sedation management and implement measures to improve sedation holds and off-sedation neurological status assessment rates.
Methods: Led by an Advanced Critical Care Practitioner (ACCP), a Quality Improvement (QI) project was designed using the Model for Improvement approach and implemented over several PDSA (Plan, Do, Study, Act) cycles. The project team assembled includes all identified MDT stakeholders (nurses, doctors, physiotherapists and a former ICU patient). The current sedation practice and barriers were identified through questionnaires. The results were fed back via pareto and fishbone charts. Discussions within the nursing team informed an empathy map. A data analyst helped support automated data extraction via the electronic patient record to allow evaluation of changes to sedation practice via an XmR chart.
Results: 1. Barriers Identified: Questionnaires and staff interviews identified uncertainty in decision-making, organisational factors and education gaps as the main themes obstructing optimum sedation management in our unit (Fig. 1).
2. Implementing Improvement Interventions: Identifying drivers to the above factors (Fig. 2) allowed implementation of targeted improvement measures over several PDSA cycles. Improvement measures included: 1) A tailored sedation hold guideline; 2) Improved medical staff induction; 3) Targeted nursing education including simulation and 'World Delirium Day' teaching.
3. Tracking Consequences of Interventions: An XmR chart (Fig. 3) continuously evaluated effects of interventions. Accounting for nonrandom variations after medical-staff turnover, we identified a sustained post-stabilisation shift after improvement interventions (run > 12 points above previous system mean) in off-sedation neurological assessment from a mean of 74.6% to a new sustained mean of 93.5%; establishing a 'New Standard System'.

Key Learning Points and Challenges:

- A multidisciplinary and motivated team to drive quality improvement is paramount.
- Presenting data visually and encouraging feedback and discussions from all staff groups is vital for buy-in.
- Data collection challenges during implementation of a new ICU electronic patient record system were managed with data-analyst support.

Conclusions: We demonstrated that an ACCP-led project, using robust QI methodology and involving several PDSA cycles, with involvement of the whole MDT, improves awareness of sedation practice and leads to a positive sustained shift in off-sedation neurological assessment.
Next Steps: The project continues with ongoing focus now on: (i) improving senior staff support and; (ii) increasing relative and patient involvement.

Intensive Care Medicine Experimental 2025,* 13(1)*:001054

Introduction: Invasive mechanical ventilation (IMV) is one of the most common therapies in intensive care units (ICU), its objective is to partially and transiently replace respiratory function (1) Acute respiratory distress syndrome (ARDS) is a theoretical and practical challenge for IMV. Ventilatory strategies, such as tidal volume limitation, plateau pressure control and driving pressure in safe ranges have evidence for improving clinical outcomes in ARDS. However, evidence is limited for positive end-expiratory pressure (PEEP) titration, one of the ubiquitous components during IMV (2) The emergence in the last decade of electrical impedance tomography (EIT), introduced a new method for titrating PEEP and thus a new uncertainty (3).
Objectives: To identify differences in mortality in critically ill patients under IMV when PEEP is titrated by EIT compared with other titration methods.
Methods: A living systematic review of the literature was performed in the following databases: PubMed/Medline, Embase, Google Scholar and Cochrane following PRISMA 2020 guidelines. The search was restricted in time from the start of operation of the databases until April 1, 2025. The search focused on randomized controlled clinical trials (RCTs), with three reviewers. A thematic advisor and a methodological advisor accompanied the conduct of the review. RCTs were included that evaluated EIT as a method for PEEP titration and compared it with other techniques: pressure–volume curve, PEEP/FiO2 chart, esophageal manometry and distensibility. Complete texts in English and Spanish about humans were included. (Fig. 1) The authors were not contacted. The importance of the outcomes was defined according to the GRADE methodology by a panel of three subject matter experts. Bias analysis was performed with the ROB 2.0 tool (Fig. 2).
Results: The summary of the included studies is shown in Table 1. After the search, 125 studies were identified, of which 119 were discarded due to title and abstract. Six full texts were evaluated, from which four RCTs were selected that met the eligibility criteria, with low risk of bias and good GRADE quality. These trials evaluated mortality although for Hui-Ju Hsu et al. (4) it was a secondary outcome limiting the estimation of the effect and dose response, in addition the sample calculated for the protocol was not reached, however, the result was favorable for the EIT. The study by Huaiwu He et al. (5) did not identify significant differences between the two groups for 28-day mortality. In turn, the studies by Yuan et al. (2023) (6) and Wong et al. (2024) (7) are ongoing trials evaluating 28-day mortality as the primary outcome with better sample sizes ($N = 376$ and $N = 680$ respectively) (summary of results in Table 1).
Conclusions: This systematic review has found a clear trend in favor of PEEP titration by EIT since it seems to be associated with an improvement in outcomes such as 28-day mortality, (without sufficient power to establish significance), this is consistent with the available evidence in favor of EIT for physiological outcomes (respiratory mechanics and oxygenation). Owing to the fact that two studies with a larger sample power are being carried out, we have decided to leave the review alive and when the outcomes are available, we will propose a meta-analysis with their respective sequential analysis of clinical trials.

Thyroid dysfunction in critically ill patients with sepsis and septic shock: a prognostic study

Q. Sudani[1], A. Chaari[2], V. Malhotra[1], A. M. Wasif[1], O. Abusedera[1]
[1]Critical Care Department, Royal College of Surgeon in Ireland—Bahrain, Al Sayh, Bahrain, Muharaq, Bahrain; [2]Critical Care Department, King Hamad University Hospital, Al Sayh, Bahrain
Correspondence: A. Chaari
Intensive Care Medicine Experimental 2025,* 13(1):*001055

Introduction: In addition to the macrocirculation and microcirculation consequences, sepsis and septic shock are associated with endocrine dysfunction(s) that may affect the outcome of critically ill patients. The literature data investigating the prognostic impact of thyroid dysfunction in critically ill patients with severe infection are scarce.
Objectives: To evaluate the impact of thyroid dysfunction on the 28-day mortality in critically-ill patients with sepsis and septic shock.
Methods: Retrospective study conducted between 01.01.24 and 31.03.25 in the intensive care units (ICUs) of two tertiary hospitals. All patients admitted with sepsis or septic shock and who had a thyroid function test collected within the first 48 h of admission were screened for inclusion. We excluded all patients with known thyroid disease, pregnancy and those with an underlying malignancy and an expected survival $\leq$ 30 days. Two groups were compared: 28-day survivors and 28-day nonsurvivors.
Results: Ninety-five patients were included. Median [Quartiles] age was 69 [59–79] years. Sex ratio (M/F) was 1.5. Diabetes and hypertension were the main recorded comorbidities (62.1% and 64.2%, respectively). SAPSII score calculated within the first 24 h of admission was 50 [36–64] and SOFA score was 11 [8–13]. Median [Quartiles] FT3, FT4 and TSH levels were 1.8 [1.4–2.4] pg/ml, 0.98 [0.83–1.3] ng/dl, and 1.8 [0.98–3.1] uIU/ml, respectively. Vasopressors were initiated for 72 (75.8%) patients and 61 (64.2%) patients required mechanical ventilation for 1- [3–22] days. Twenty-four (25.3%) patients developed acute kidney injury requiring renal replacement therapy. The source of sepsis was community or hospital acquired pneumonia in 45 (47.4%) patients, urinary tract infection in 23 (24.2%) patients, abdominal

sepsis in 9 (9.5%) patients, wound infection in 8 (8.4%) patients, and catheter-related blood stream infection in 6 (6.3%) patients. The sepsis was related to Gram negative bacilli in 59 (62.1%) patients. Twenty-eight patients (29.5%0 died by day-28.
Nonsurvivors had significantly lower FT3 serum levels (1.3 [1.1–2.4] pg/ml vs 1.9 [1.7–2.4] pg/ml; $p = 0.014$) whereas Ft4 and TSH were comparable between survivors and nonsurvivors (0.9 [0.8–1.2] ng/dl vs 1 [0.9–1.3] ng/dl; $p = 0.065$, and 2.1 [1–4.1] uIU/ml vs 1.6 [0.9–3] uIU/ml; $p = 396$, respectively). Nonsurvivors had also significantly higher SAPSII (57 [49–68] vs 42 [33–63]; $p = 0.002$) and higher SOFA score (13 [10–17] vs 10 [7–13]; $p = 0.001$). There were significantly more patients requiring mechanical ventilation (85.7% vs 55.2%; $p = 0.005$) and renal replacement therapy (42.9% vs 17.9%; $p = 0.011$) in the nonsurvivors group.
In multivariate analysis, only SOFA score on admission was identified as an independent factor predicting 28-day mortality (OR = 1.3 95% CI [1.1–1.5]; $p = 0.001$).
Conclusions: Sepsis and septic shock are associated with deranged thyroid function tests in critically ill patients. Low FT3 serum level was associated with higher 28-day mortality in the univariate analysis but not in the multivariate analysis.

Topic: Metabolism, endocrinology, liver failure and nutrition

Performance of general and specific prognostic scores in acute decompensation of liver cirrhosis admitted to intensive care

M. Ferreira, P. Baptista, T. Cardoso, G. Cabral-Campello
Intensive Care Department, Unidade Local de Saúde do Tâmega e Sousa, E.P.E., Guilhufe, Portugal
Correspondence: M. Ferreira
***Intensive Care Medicine Experimental 2025,* 13(1)**:001056

Introduction: In Portugal, liver cirrhosis accounts for nearly 6 000 annual hospitalizations and 1 000 annual deaths (1). Acute decompensation events are responsible for 2,3–4,5% of all intensive care units (ICUs) admissions and are associated with high rates of short-term mortality (2). Prognostic assessment of these patients is essential to guide therapeutic decisions, prioritize resources, and discuss prognosis within the healthcare team and with the patient/relatives.
Objectives: To describe acute decompensation events in liver cirrhosis admitted to an ICU and evaluate the performance of general and specific prognostic scores in this population.
Methods: Retrospective cohort study of all cases of acute decompensation of liver cirrhosis without criteria for acute-on-chronic liver failure (ACLF) admitted to the ICU of a secondary care hospital between January 2022 and December 2023. The discriminative power of the prognostic scores [Child–Pugh (CP), Model for End-Stage Liver Disease Sodium Score (MELD NA), Acute Physiology and Chronic Health Evaluation (APACHE II), Simplified Acute Physiology Score (SAPS 2) and Chronic Liver Failure Consortium Decompensation Score (CLIF-C AD)] was evaluated by receiver-operator characteristics (ROC) curve analysis.
Results: A total of 99 patients with liver cirrhosis were evaluated, of whom 61% ($n = 60$) presented with acute decompensation of liver cirrhosis. This group had a mean ± SD age of 55 ± 8 years, 78% were males ($n = 47$), and alcohol was the most common etiology (93%, $n = 56$). The most frequent decompensating factor was hypertensive gastrointestinal bleeding (70%, $n = 42$). In 40% of patients ($n = 24$), the current episode was their first decompensation. Stratification through the CP score revealed, 35% ($n = 21$) of patients in CP class A, 43% ($n = 26$) in class B, and 22% ($n = 13$) in class C. The median (IQR) MELD NA score was 15 (11–19), the median (IQR) SAPS II score was 25 (18–37), the median (IQR) APACHE II score was 14 (9–18), and the median (IQR) CLIF-C AD score at admission was 53 (49–61).
Mortality in ICU, in hospital, at 28-days and at 1-year was 10% ($n = 6$), 17% ($n = 10$), 17% ($n = 10$) and 28% ($n = 17$), respectively. The overall performance of the scores is showed in Table 1.

Table 1 (abstract 001056) Overall performance of prognostic scores

AUROC curve (95% CI)				
Score	**ICU mortality**	**Hospital mortality**	**28-days mortality**	**1-year mortality**
Child–Pugh	0.500 (0.255–0.745)	0.681 (0.485–0.877)	0.681 (0.485–0.877)	0.657 (0.504–0.809)
MELD-NA	0.846 (0.643–1.000)	0.758 (0.559–0.957)	0.758 (0.559–0.957)	0.770 (0.627–0.914)
SAPS II	0.937 (0.874–0.999)	0.848 (0.666–1.000)	0.848 (0.666–1.000)	0.776 (0.624–0.928)
APACHE II	0.921 (0.830–1.000)	0.805 (0.645–0.965)	0.805 (0.645–0.965)	0.765 (0.627–0.902)
CLIF-C AD	0.765 (0.534–0.997)	0.500 (0.302–0.698)	0.500 (0.302–0.698)	0.500 (0.337–0.663)

Conclusions: In our population, SAPS II, APACHE II and MELD NA showed a better discrimination power in predicting short and long-term mortality. The more specific scores like Child–Pugh and CLIF-C AD were not useful in that prediction.

Predictors and clinical outcomes in patients undergoing TAVI at a secondary level hospital: a descriptive study

A. Martinez Cabezas, R. Garcia Martínez, S. Mariño Guerreiro, M. E. Poyatos Aguilera, P. Fernandez Morales
Intensive care unit, Hospital Universitario Clínico San Cecilio, Granada, Spain
Correspondence: R. Garcia Martínez
Intensive Care Medicine Experimental 2025,* 13(1)*:001057

Introduction: Transcatheter aortic valve implantation (TAVI) has become a widely accepted alternative to surgical aortic valve replacement, particularly in elderly and high-risk patients. As the indication for TAVI extends to intermediate- and high-risk populations, understanding the real-world characteristics and outcomes of patients undergoing this procedure is crucial. This study presents a descriptive analysis of a TAVI program initiated in 2021 at a secondary-level hospital, focusing specifically on patients admitted to the intensive care unit (ICU).
Objectives: To evaluate the anesthetic conditions under which TAVI was performed and to characterize the clinical profiles and short- and mid-term outcomes in this setting.
Methods: We conducted a retrospective observational study including all patients with severe aortic stenosis who underwent transcatheter aortic valve implantation (TAVI) between 2021 and 2024 in a secondary-level hospital in southern Spain.

Patients were not stratified by post-procedure conduction outcomes; instead, the entire cohort was considered as a single descriptive population. Data collected included demographics (age, sex), comorbidities (baseline creatinine, coronary artery disease), echocardiographic parameters (left ventricular ejection fraction), procedural sedation and anesthesic strategies, and the occurrence of peri- and postprocedural complications.

Complications were classified into vascular access-related, infectious, hemorrhagic, and others. Mortality was recorded both in-hospital and at one-year follow-up. Statistical analysis included descriptive measures.

Anesthetic strategies evolved from deep sedation and intubation in 2021, with routine use of central venous and radial access and bladder catheterization, to high-flow nasal oxygen and conscious sedation from 2022 onward. This transition marks a step forward toward minimally invasive procedural standards in our hospital.

Results: A total of 150 patients underwent TAVI between 2021 and 2024. The mean age was 78.9 years, and 67 patients (44.7%) were male. The mean baseline creatinine was 1.09 mg/dL. Regarding cardiac function, 122 patients (81.3%) had a preserved left ventricular ejection fraction (LVEF > 50%), while 12 (8.0%) had moderately reduced function (LVEF 40–50%), and 13 (8.7%) had severely reduced LVEF (< 40%). Coronary artery disease was documented in 40 patients (26.7%).

As for complications, 30 patients (20%) experienced vascular access-related issues. Infectious complications related to bladder catheterization were observed in 10 patients (6.7%), including 6 urinary tract infections and 4 cases of hematuria. Three patients (2.0%) had pericardial effusion as a hemorrhagic complication. Moderate to severe post-TAVI aortic regurgitation was found in 2 patients (1.3%), severe post-TAVI aortic regurgitation was found in 2 patients (1.3%).

Anesthetic management varied over time. Initially, all procedures in 2021 were performed under deep sedation with orotracheal intubation (17 patients, 11.3%). From 2022 onwards, most patients (141, 94.0%) received high-flow nasal oxygen therapy with conscious sedation. The most commonly used sedatives were propofol (n = 9), remifentanil (n = 38), and dexmedetomidine (n = 101), with 3 cases (2.0%) of bradycardia associated with the latter.

In terms of outcomes, in-hospital mortality was 4.7% (7 patients), while one-year mortality reached 8.7% (13 patients). There were also 4 intra-procedural cardiac arrests (2.7%), one of which resulted in death.

Conclusions: TAVI is a feasible and safe therapeutic strategy in secondary-level hospitals. Our experience confirms that most patients present with preserved LVEF and moderate comorbidity. Over time, we observed a clear trend toward minimally invasive strategies in anesthesia, vascular access, and avoidance of urinary catheterization, improving patient outcomes. Complication rates, particularly infections and bleeding, were relatively low. Based on our findings, institutional protocols were updated to eliminate routine bladder catheterization, orotracheal intubation and radial artery catheterization, reducing the risk of associated adverse events.

Integrated Summary Table - TAVI Program

Section	Variable / Item	n (%)
Section	Variable / Item	n (%)
Baseline Characteristics	Age (mean)	78.9
	Creatinine (mean)	1.09
	Male sex	67 (44.7%)
	LVEF >50%	122 (81.3%)
	LVEF 40–50%	12 (8.0%)
	LVEF <40%	13 (8.7%)
	Coronary artery disease	40 (26.7%)
Complications	Vascular access-related	30 (20.0%)
	UTI (related to catheter)	6 (4.0%)
	Hematuria (related to catheter)	4 (2.7%)
	Pericardial effusion	3 (2.0%)
	Moderate-severe aortic regurgitation	2 (1.3%)
Management & Outcomes	Orotracheal intubation (2021)	17 (11.3%)
	HFNO (2022 onward)	141 (94.0%)
	Propofol	9 (6.0%)
	Remifentanil	38 (25.3%)
	Dexmedetomidine	101 (67.3%)
	Bradycardia (Dexmedetomidine)	3 (2.0%)
	In-hospital mortality	7 (4.7%)
	1-year mortality	13 (8.7%)
	Intra-procedural cardiac arrest	4 (2.7%)

This table summarizes the main clinical and procedural characteristics of patients undergoing transcatheter aortic valve implantation (TAVI) in a secondary-level hospital. It includes baseline variables, complication rates, and management strategies used during the study period. Notably, the shift toward high-flow nasal oxygen (HFNO) and conscious sedation from 2022 onward is reflected in the procedural data. Outcomes, such as in-hospital and one-year mortality, as well as anesthesia-related events, are also detailed.

The effect of a sleep-promoting protocol on sleep and delirium in ICU patients

K. Brečko[1], P. Radšel[2]

[1]Faculty of Medicine, University of Ljubljana, Ljubljana, Slovenia;

[2]Department of Intensive Internal Medicine, University Medical Centre Ljubljana, Ljubljana, Slovenia

Correspondence: K. Brečko

Intensive Care Medicine Experimental 2025,* 13(1)*:001058

Introduction: Poor sleep quality in intensive care units (ICU) is an important contributor to prolonged length of stay, higher incidence of delirium and mortality and is often the result of environmental, medical and psychological factors. The Society of Critical Care Medicine Clinical Practice Guidelines for Management of Pain, Agitation, Delirium, Immobility, and Sleep (PADIS) recommend implementing a sleep-promoting protocol of pharmacological and non-pharmacological interventions for sleep quality improvement in critically ill patients. The purpose of this study was to assess the quality of sleep and incidence of delirium in ICU before and after the implementation of a sleep-promoting protocol.

Methods: A prospective cohort study was conducted at Intensive Care Medicine Unit at University Medical Centre Ljubljana over 1-year period from July 2023 to July 2024, in which the sleep quality of admitted patients was assessed using a Richards–Campbell Sleep Questionnaire (RCSQ) and the incidence of delirium using CAM–ICU. The study period was divided into two parts: before and after the implementation of a sleep-promoting protocol, comprised of pharmacological and non-pharmacological interventions.

Results: 1043 questionnaires were obtained from 420 patients, 145 (34.5%) were female. The median RCSQ score was 55.0 mm. Higher noise levels had significant effect on sleep, with decreased sleep quality across all five categories of RCSQ (depth, latency, awakenings from sleep, ability to return to sleep and quality). Patients with delirium (143/880, 16.3%) had inferior sleep quality as compared to nondelirious patients (p < 0.001). After the implementation of protocol, reported noise levels were significantly reduced and sleep quality improved in all five categories (p < 0.001). There was no difference in the incidence of delirium. Before the introduction of the

protocol, fewer patients received at least one sleep-promoting agent (421/728, 57.8%) versus after (225/315, 71.4%). The most prescribed sleep-promoting agents were melatonin (265/1043, 25.4%) and dexmedetomidine (290/1043, 27.8%), with higher melatonin prescription after the implementation of the protocol (20.3% vs. 37.1%). Melatonin improved sleep latency, awakenings from sleep, and ability to return to sleep as compared to patients receiving no sleep-promoting agent ($p < 0.05$), but had no effect on the incidence of delirium.
Conclusions: Implementation of a sleep-promoting protocol, comprising of pharmacological and nonpharmacological interventions, was associated with significantly improved sleep quality in our ICU patients, further reinforcing the importance of sleep quality interventions in the ICU. Noise reduction, especially, presents an efficient and cost-effective intervention, emphasising the need for a structured approach to nonpharmacological sleep-promoting protocol.

Impact of a clinical pharmacist on the achievement of PK/PD targets in ICU: significant results of a comparative study on ceftazidime

N. Dulac, M. Launay, G. Thiery, S. Perinel Ragey
[1]Réanimation G, University Hospital of Saint-Etienne, Saint-Priest-en-Jarez, France
Correspondence: S. Perinel Ragey
Intensive Care Medicine Experimental 2025,* 13(1)*:001059

Introduction: The European Society of Intensive Care Medicine (ESICM) is devoting more and more attention to the clinical pharmacist (1) in the intensive care unit (ICU). Indeed, their presence is associated with a reduction in mortality and length of stay, in particular due to their expertise in pharmacovigilance and pharmacological optimization, including in multiorgan failure (1).
Objectives: From 2023, a pharmacist was present in our ICU 3 days a week. We wanted to assess the impact of this change in practice on the achievement of ceftazidime PK/PD targets compared with other ICUs in the same time periods.
Methods: This was a retrospective study comparing the achievement of PK/PD targets for ceftazidime in a ward where a pharmacist was present (test unit) with 5 other ICUs (control units). This study also compared the achievement of targets before/after the arrival of the pharmacist (period 1: historical cohort between November 2019 and November 2021/period 2: January 2023 to August 2024). Doses were performed in the same laboratory as part of routine therapeutic drug monitoring in all ICUs (target values: 35–80 mg/L).
Results: A total of 136 patients were included, 86 in the control units (64 and 26, respectively for periods 1 and 2) and 46 in the test unit (26 and 20, respectively). There were no significant differences in CKD-EPI at baseline, age, weight, body mass index, SOFA score, mortality, length of stay and ceftazidime doses between test and control units for each time period. Between periods 1 and 2, target achievement in the test unit increased significantly to 85% at the last measurement compared to 34,6% in period 1 ($p < 0.01$) (Fig. 1A). In period 2, target achievement in the test unit increased significantly to 85% at the last measurement as compared to 38.5% in the control units ($p < 0.01$) (Fig. 1B).
Conclusions: Before the intervention, target achievement was similar in the test and control units. Daily exchange between pharmacists and intensivists was associated with a significant improvement in achievement of PK/PD targets for ceftazidime at last measurement, regardless of comparison (historical data or other comparable ICUs in the same time period). However, the clinical impact remains to be assessed, particularly in terms of improvement in SOFA score and length of stay. An opposite trend was observed in the control units: In our recent multicenter study involving all ICUs, it was suggested to increase the ceftazidime dose in overweight patients (2), which may explain this trend. The introduction of an individualized dosing tool available to all could help to improve global practices and an increase in the number of clinical pharmacists in ICUs also seems essential.

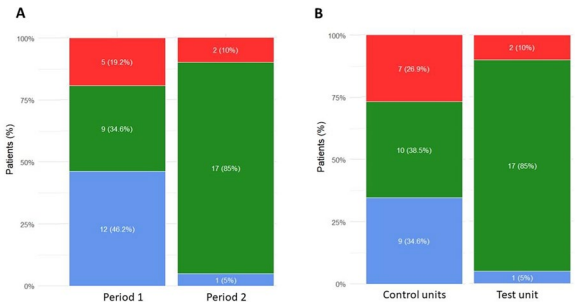

Fig. 1 (abstract 001059) **A** Percentage target achievement in previous standard practice (period 1) and with a clinical pharmacist (period 2) for test unit at last measurement. **B** Percentage target achievement in the test unit (with a clinical pharmacist) and in the control units for the same period at last measurement
Underdosing (concentration below 35 mg/L) in blue, on target in green and overdosing (concentration above 80 mg/L) in red.

Implementation of nursing rounds in an intensive care unit: a pilot project

H. Eugenio Barbosa[1], P. Nydahl[2]
[1]Nurse in Cardiac Surgery ICU, Universitätsklinikum Schleswig–Holstein, Campus Kiel, Kiel, Germany; [2]Nursing Research, Universitätsklinikum Schleswig–Holstein, Campus Kiel, Kiel, Germany
Correspondence: H. Eugenio Barbosa
Intensive Care Medicine Experimental 2025,* 13(1)*:001060

Introduction: Nursing rounds represent a structured, patient-centered approach aimed at improving communication, safety, and the quality of nursing care. Although widely practiced internationally, their systematic implementation in German intensive care units (ICU) remains limited (Kußmaul, 2018). Evidence suggests that structured nursing rounds can enhance clinical outcomes, reduce hospital-acquired conditions (HACs), and improve interdisciplinary communication (Kannappan et al., 2023; Shalman et al., 2024). Furthermore,

the recent research highlights that nursing rounds have a statistically significant effect on improving care quality and planning for process-responsible care in ICU settings (Johnen et al., 2024).
Objectives: The primary goal was to integrate nursing rounds into daily ICU routines during a 3-month pilot phase. Specific aims included enhancing communication among nurses, patients, and families, improving documentation practices, and fostering individualized care planning. Active participation of bedside nurses, patients, and relatives was emphasized to ensure a person-centered approach.
Methods: A working group of five experienced ICU nurses developed criteria for patient selection (e.g., stay ≥ 72 h, no planned discharge within 24 h, complex therapy) and designed a documentation tool. Over 3 months, 12 nursing rounds were planned. Each round involved bedside nurses, working group members, patients, and relatives (when possible), focusing on identifying key nursing problems (e.g., skin integrity, psychological state) and setting individualized care goals. The rounds also facilitated procedural clarifications. Similar approaches have been shown to improve patient safety and communication in ICU settings (Kannappan et al., 2023).
Results: Seven nursing rounds were conducted due to staff shortages and time constraints. Nine patients (2 female, 7 male; aged 46–66 years) participated, with some receiving multiple rounds. A total of 28 nurses were involved in the process. Across all rounds, 53 nursing problems were identified, leading to 74 care goals. Of these goals, 48 were fully achieved, while others showed partial or no progress. Each round lasted approximately 2–3 h and enabled patients to actively contribute to their care planning.
Conclusions: The pilot phase demonstrated that structured nursing rounds can enhance reflective practice and interdisciplinary communication. Common nursing problems identified during the rounds will be mapped to standardized nursing diagnoses (e.g., NANDA-I) to improve care comparability and planning (Herdman et al., 2024). Patient and family inclusion proved effective in promoting a person-centered approach. Furthermore, evidence from Kannappan et al. (2023) highlights the potential of structured nurse rounds to reduce hospital-acquired complications such as pressure injuries and infections. Additional findings reinforce their broader impact, including shortened ICU stays and improved patient outcomes (Shalman et al., 2024).

Introduction: Prone positioning is a cornerstone of ARDS management, but optimal duration and efficacy remain unclear, with inconsistent mortality prediction based on oxygenation response during proning; however, the clinical significance of resupination parameters remains largely unknown(1). This study uses machine learning to predict survival in mechanically ventilated proned ARDS patients by analyzing respiratory mechanics and oxygenation after resupination, aiming to clarify the clinical relevance of sustained improvements following return to supine position.
Methods: Data were extracted from the COVID-Predict Dutch Data Warehouse, containing full-admission records of 3,464 critically ill COVID-19 patients across 25 Dutch hospitals. Mechanically ventilated ARDS patients who underwent a first supine-prone-supine sequence were selected, and ventilatory variables no more than 4 h from resupination were extracted. Machine learning models, logistic regression, and grid-search optimized XGBoost classifier and decision tree, were then trained on LASSO-selected features to predict 28-day mortality, with performance evaluated using AUC–ROC, precision-recall and F1 scores.
Results: The final cohort included 522 patients, of whom 365 (69.9%) survived and 157 (30.1%) died (Fig. 1, Table 1). The predictive performance of individual clinical parameters for 28-day mortality was generally modest. FiO_2 (AUC 0.681) and physiological dead space (AUC 0.640) showed the best discrimination for 28-day mortality (Fig. 2). In model comparisons, XGBoost, demonstrated the best recall (0.732) and F1 score (0.500) for predicting 28-day mortality, despite lower precision (0.380), and maintained the highest AUC (0.719). Logistic regression had the highest accuracy (0.771) and precision (0.619). Decision tree showed the lowest overall performance (Fig. 3).

Variable	Data availability (%)	Survived (*n* = 365)	Died (*n* = 157)	*P* value
Age, years	100.0	63 [14.0]	70.0 [10.0]	< 0.001
Weight, kg	65.0	90.0 [23.0]	82.1 [20.0]	0.044
Height, m	98.5	1.76 [0.13]	1.73 [0.14]	0.001
BMI, kg/m2	64.5	27.8 [6.3]	27.4 [5.0]	0.309
Gender [male]	99.6	277 (75.9)	118 (75.2)	0.865
Diabetes mellitus, n [%)	69.2	69 (26.2)	22 (22.5)	0.594
Cardiovascular insufficiency, n [%)	66.1	5 (2.0)	3 (3.2)	0.797
Chronic renal insufficiency, n [%)	65.9	12 (4.8)	7 (7.5)	0.448
COPD, n [%)	66.3	24 (9.5)	9 (9.6)	0.999
Cirrhosis, n [%)	66.1	0 (0.0)	0 (0.0)	0.999
Neoplasm, n [%)	66.1	0 (0.0)	2 (2.1)	0.128
Immunodeficiency, n [%)	66.5	16 (6.4)	11 (11.6)	0.162
SOFA score	45.1	6.0 [3.0]	7.0 [5.0]	0.632

COPD—chronic obstructive pulmonary disease. Values are median [IQR] or *n* (%).

Conclusions: This study is the first to use resupination values to predict mortality in prone-positioned patients. To improve patient outcomes and minimize unnecessary interventions, early identification of nonresponders is crucial. Analyzing post-resupination indicators

demonstrates a potential for refined patient selection, offering an alternative to current reliance on intra-proning oxygenation changes (1). Our results suggest this approach may improve patient selection for continued prone therapy. Further optimization of this model is possible.

Intensive Care Medicine Experimental 2025,* 13(1)*:001063

Introduction: Flow-controlled ventilation (FCV) is a novel ventilator mode where the expiratory phase is actively controlled as opposed to the passive expiration in conventional mechanical ventilation. Compared with volume-controlled ventilation (VCV), it has been shown to improve gas exchange while using lower peak inspiratory pressure in healthy lungs (1).
Objectives: To assess any difference between FCV and VCV as to distribution of lung ventilation (V) and perfusion (Q) at the same minute volume ventilation in a model of acute lung injury (ALI).
Methods: Nine anesthetized and paralyzed pigs (29–31 kg) were subjected to either lung lavage injury (30 mL/kg; $n = 2$) or oleic acid injury (0.1 mL/kg; $n = 7$). Optimal PEEP was titrated for the highest compliance then lowest degree of collapse and overdistension, assessed by electrical impedance tomography (Enlight 1800, Timpel Medical, São Paolo, Brazil). Tidal volume (TV) was set to 6–8 mL/kg and respiratory rate (RR) adjusted to normoventilation in VCV (Servo-i, Maquet/Getinge, Sweden) with *I*:*E* ratio 1:2. Tidal volume and RR were kept for FCV (Evone, Ventinova Medical, Eindhoven, The Netherlands). Both VCV and FCV were applied at baseline (BL) and in the computed tomography (CT) laboratory after ALI had been established.
Dual-energy CT (DECT; 80 + 140 kV, SOMATOM Definition Flash, Siemens, Fochheim, Germany) was performed with a fixed table position at the juxtadiaphragmatic level during 20 s of uninterrupted ventilation, (5 mm thick slices). Iodine maps and virtual noncontrast (VNC) images were reconstructed for manual segmentation and quantitative voxel-based analysis in MATLAB (v 2024b, MathWorks, Natick, MA, USA) (Fig. 1).

$\dot{V}$ was calculated from the difference in gas volume (Vgas) between end-inspiration and end-expiration on VNC images. Q, defined as mean pulmonary blood volume (Vb), was estimated from iodine maps by normalizing voxel attenuation to that of aortic blood. To assess spatial distribution, these ventilation and perfusion measures were quantified across ten ventrodorsally distributed lung regions.

Results: At BL, the median PaO_2 was 15.9 kPa for FCV and 17.0 kPa for VCV. Following induction of ALI, values were 14.6 and 15.1 kPa, respectively. Median $PaCO_2$ at BL was 6.4 kPa for FCV and 5.6 kPa for VCV, and after ALI 6.7 respective 5.8 kPa. Hemodynamics and respiratory mechanics, except expiratory flow, did not differ between FCV and VCV. DECT image derived $\dot{V}$, Q and $\dot{V}$/Q in the entire slice of the lung or in the ventrodorsal segments did not differ between the ventilator modes (Table 1, Fig. 2).

Table 1 (abstract 001063) DECT derived variables (expressed as Median [IQR])

	VCV	FCV
Vgas exp (mL)	39.8 [36.6–42.5]	42.4 [40.4–42.9]
Vgas insp (mL)	45.6 [43.2–48.0]	47.7 [46.1–48.9]
$\dot{V}$ = Vgas (insp-exp) (mL)	5.8 [5.0–8.5]	5.6 [5.2–6.4]
Q = Vb (mL)	14.2 [13.0–16.3]	14.2 [13.3–20.8]
$\dot{V}/Q$ ratio	0.42 [0.33–0.50]	0.32 [0.26–0.40]

Conclusions: In this experimental series with lung injury, FCV did not alter total or regional (ventrodorsal) DECT-derived $\dot{V}/Q$ compared to VCV.

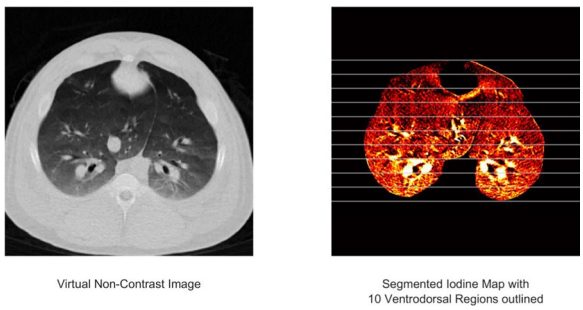

Fig. 1 (abstract 001063) Example of VNC and Iodine Map after post-processing and segmentation

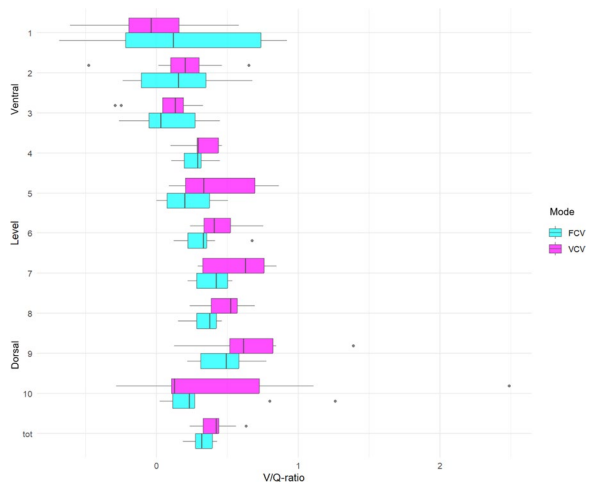

Fig. 2 (abstract 001063) Boxplots representing $\dot{V}/Q$ ratio for 10 superimposed ventrodorsal sections of the lung

No code digital transformation of intensive care unit (ICU) induction: a feasibility study

C. Lau, R. Folley, A. Myers, T. Samuels
Critical Care Department, East Surrey Hospital, Redhill, United Kingdom
Correspondence: C. Lau
Intensive Care Medicine Experimental 2025,* 13(1)*:001065

Introduction: Resident doctors in the UK frequently rotate between specialties, often finding themselves in unfamiliar environments. Increasingly doctors without a background in critical care are rotating into the high-stakes, high-pressure setting of the ICU. Timely, accessible and up to date induction is vital. Often, local induction is delivered by specialty trainees, as there is evidence to suggest that near-peer induction is effective and preferred over consultant-led induction (1). In our UK Hospital Trust, ICU induction is supported by a small paper-based guide covering clinical tips and orientation. However, this format contributes to cognitive overload during induction. There is growing evidence that digital resources, such as web-based mobile applications (apps) are emerging as effective tools in medical education. They offer flexible, self-directed learning (2) and are well aligned with the technology-enhanced education preferences of today's medical workforce.

Objectives: To assess the feasibility and benefits of digitalising an existing paper-based ICU induction guide into a smartphone app. This project aimed to reduce reliance on printed material, improve ease of access and enhance usability. It also sought to assess whether the app enhances confidence, preparedness and the overall ICU experience for resident doctors.

Methods: A URL-based app was developed using Glide (3), a free no-code platform, allowing rapid deployment without specialist coding knowledge or app store hosting costs (Figs. 1–3). This development took roughly 16 person hours. Retrospective surveys were conducted amongst doctors who had previously used the paper guide to evaluate its usefulness, accessibility and openness to a digital alternative. Prospective surveys were distributed to doctors currently using the app to assess usability, confidence before ICU shifts and impact on their ICU experience.

Results: Retrospective data revealed that several doctors (n = 8) had an outdated copy, had lost or never received the paper guide. Many relied heavily on it early in their rotation and supported the idea of a digital format. Initial prospective survey results indicate that users (n = 8) found the app intuitive, reported feeling more prepared for ICU shifts and would recommend it to peers. Feedback also suggested it served as a useful on-the-go reference.

Conclusions: This project demonstrates the feasibility and impact of leveraging existing digital tools for medical education. A mobile app is a practical and effective tool for ICU induction, offering flexible, on-demand support that complements traditional teaching. Although not a replacement for clinical judgement or textbook learning, it enhances orientation and encourages active, self-directed learning. The limitations of free no-code platforms include restricted customisation. Future directions could include coding a bespoke platform to enable all critical care departments to make an induction guide based on a template, negating requirements for programming knowledge.

Intensive Care Medicine Experimental 2025,* 13(1):*001067

Introduction: Accurate and accessible clinical records are essential in medical practice, particularly in intensive care units (ICUs) where patients are in critical condition. Detailed records of procedures such as intubation and extubation are critical to ensure continuity of care, prevent complications, and support clinical decision making. Lack of adequate documentation can compromise patient safety and quality of care.
Objectives: This audit aimed to assess the quality and integrity of electronic medical records related to airway management, particularly intubation and extubation procedures, in critically ill patients admitted to an intensive care unit (ICU) between January and June 2024.
Methods: The audit included 374 patients, of whom 174 required intubation and mechanical ventilation. The main parameters assessed for intubation records included endotracheal tube (ETT) size, type of laryngoscope and blade used, grade of Cormack–Lehane laryngoscopy, medications administered, and any complications or difficulties encountered. Regarding extubation, medical records were evaluated according to the mention of planned or accidental extubation, complications, and respiratory support used after extubation.
Results: The results revealed significant gaps in documentation: 42.9 percent of intubated ICU patients had no records/descriptions of the approach to airway management and less than half of the records provided minimal or insufficient details. In addition, 28.6 percent of extubation records lacked detailed information on post-extubation support, and 30 percent of reintubation events were not adequately documented. Despite these missing data, records of tracheostomy procedures were complete in all cases.
Conclusions: The results highlight the need for improved documentation practices, emphasizing the application of standardized checklists and targeted training for the ICU team. Detailed documentation will not only improve patient safety and continuity of care, but also support continuous quality improvement efforts in ICUs.

Intensive Care Medicine Experimental 2025,* 13(1)*:001070

Introduction: Targeted physiologic resuscitation to prevent secondary brain insults is a treatment priority in the early management of patients with severe traumatic brain injury (TBI). Evidence indicates that optimizing cerebral perfusion pressure (CPP) can lead to improved clinical outcomes; however, hemodynamic strategies used for CPP-targeted therapy present considerable risk and are not uniformly effective. Here, we implement unsupervised and causal machine learning methods in a large ICU dataset to explore treatment effects in TBI patients receiving norepinephrine (NE) to achieve a CPP target. We hypothesize that distinct TBI subphenotypes can be identified and that the latter exhibit heterogeneous treatment effects (HTE) as shown by differentiable outcomes when administered NE.
Methods: Adult patients admitted to the ICU with TBI were identified in the MIMIC-IV critical care database. Demographics, physiological time-series data including ICP and CPP, and medication administration details were preprocessed with a comprehensive pipeline involving outlier removal, scaling, time-series imputation, and transformation into a day-wise longitudinal dataframe. The primary outcome variable was in-hospital mortality. To identify candidate clusters, K-means was applied on data accrued in the first 24 h and the 7 days following ICU admission. Cox models were used to stratify 7-day ICU mortality risk and assign cluster weights based on hazard ratios. Dimensionality reduction techniques and Kaplan–Meier survival analysis were used to visualize the subgroups spatially and in their clinical trajectories, respectively.
Results: Of 3,503 ICU-admitted TBI patients, 1809 (51.6%) received NE during their ICU stay (mean infusion duration: 18.4 h). Clustering on 24-h and 7-day averaged physiological data (e.g., heart rate, oxygen saturation, mean arterial pressure, temperature, serum sodium, glucose, and GCS scores) revealed four distinct groups. The 24-h mortality rates for clusters 0 through 3 were 4.8%, 26.9%, 3.4%, and 27.4%, respectively; the corresponding 7-day mortality rates were 5.9%, 50.5%, 3.6%, and 100%, respectively." Hazard ratio-weighted clustering further stratified mortality risk with final in-hospital mortality rates of 21.5%, 75.7%, 2.7%, and 100% (log-rank $p < 0.05$). High-mortality clusters were characterized by elevated ICP and lower GCS motor/verbal scores. Cluster 3—with the highest mortality (7-day: 100%)–had the lowest average day 1 CPP (44.1 $\pm$ 27.7 mmHg), despite having the highest proportion of patients receiving NE (42.4%).
Conclusions: Using a data-driven ML modeling framework, we identified discrete severe TBI subphenotypes that may have differentiable clinical features, clinical trajectories, CPP, outcome, and responses to NE administration. Ongoing work is evaluating the causal impact of interventions, such as NE on CPP and outcomes. With validation, such a framework could guide clinicians in the early management of patients with severe TBI.

Sepsis-induced acute respiratory distress syndrome after major surgery

R. A. Ibadov, S. Ibragimov
Intensive Care Unit, Vakhidov Republican Center of Surgery, Tashkent, Uzbekistan
Correspondence: S. Ibragimov
Intensive Care Medicine Experimental 2025,* 13(1)*:001072

Introduction: Sepsis-induced acute respiratory distress syndrome (ARDS) is a severe and often fatal complication in surgical patients. It frequently develops after major operations complicated by postoperative sepsis and is associated with high rates of mechanical ventilation, multiorgan failure, and mortality. Despite modern intensive care approaches, outcomes remain poor, with mortality exceeding 50% in some cases. Early identification of patients at risk is essential, yet data on specific predictors of ARDS in the postoperative setting are limited.
Objectives: To assess the impact of postoperative sepsis-induced ARDS on mortality in patients undergoing extensive surgical interventions and to identify the most significant risk factors.
Methods: This secondary analysis included 428 adult patients ($\geq$ 18 years) admitted to the surgical ICU between December 2009 and February 2025 after major surgery. All met SEPSIS-3 criteria for postoperative sepsis or septic shock and were evaluated for ARDS based on the Berlin definition (2012). Inclusion required microbiologically confirmed sepsis and $\geq$ 24 h of invasive ventilation; patients without microbiological confirmation or with shorter ventilation were excluded. All patients received lung-protective ventilation (tidal volume 6–8 ml/kg, PEEP 6–8 cm H_2O, recruitment maneuvers as needed) and were managed according to international ICU protocols: early pathogen identification, targeted antibiotics, individualized fluid resuscitation, norepinephrine for MAP < 65 mmHg, hemoglobin targets of 7–10 g/dL, sedation, analgesia, and stress ulcer prophylaxis (IV omeprazole 20 mg). Decisions on tracheostomy and weaning were made clinically. Severity was assessed by SOFA and APACHE II scores within 24 h of ICU admission. Biomarkers (lactate, procalcitonin, LDH, creatinine), cultures, and arterial blood gases were measured serially. The data were analyzed using medians and interquartile ranges for continuous variables, and percentages for categorical data. Group comparisons used Mann–Whitney U and χ^2 tests. Risk factors were identified via multivariate logistic regression (Wald method), and survival was assessed with Kaplan–Meier curves and log-rank tests.
Results: ARDS predominantly developed in 56 (13.1%) patients with more severe illness. The ARDS group had significantly higher rates of septic shock (92.9% vs 69.1%; $p = 0.0041$), elevated SOFA scores (median 9.2 vs 8.3; $p = 0.0052$), higher APACHE II scores (17 vs 15; $p < 0.001$), and increased levels of lactate (6.4 vs 2.8 mmol/L; $p < 0.001$) and procalcitonin (25.7 vs 8.6 ng/mL; $p < 0.001$). Pneumonia (44.6% vs 22.0%; $p < 0.001$) and abdominal infections (76.8% vs 58.1%; $p = 0.002$) were more frequently diagnosed in this group. ARDS was associated with significantly prolonged mechanical ventilation (12.5 vs 4.3 day; $p < 0.001$), longer ICU stays (19.6 vs 9.2 days; $p < 0.001$), and higher 60-day mortality (62.5% vs 32.0%; $p < 0.001$). Independent risk factors for ARDS identified in multivariate analysis included higher SOFA score (OR = 1.2; 95% CI 1.1–1.3; $p = 0.021$) and elevated lactate levels (OR = 2.0; 95% CI 1.3–2.8; $p = 0.003$). Independent predictors of 60-day mortality included the presence of ARDS (OR = 2.8; 95% CI 1.2–6.4; $p = 0.023$), chronic kidney disease (OR = 4.1; 95% CI 1.3–13.8; $p = 0.025$), increased LDH levels (OR = 1.8; 95% CI 1.2–2.8; $p = 0.014$), and APACHE II score > 16 (OR = 2.8; 95% CI 1.4–5.5; $p = 0.005$).
Conclusions: The development of ARDS in patients with postoperative sepsis markedly elevates 60-day mortality and demands heightened vigilance from intensive care teams. Major risk factors include elevated severity scores (SOFA, APACHE II), increased lactate levels, and the presence of pneumonia or abdominal infections. Introducing early risk prediction tools and strengthening postoperative monitoring in septic patients may help lower the incidence of ARDS and enhance clinical outcomes.

Intensive Care Medicine Experimental 2025,* 13(1)*:001074

Introduction: Catheter directed intervention (CDI) should be considered in high-risk pulmonary embolism (PE) when first-line treatment with systemic thrombolysis (ST) is contraindicated or has failed, as well as in select cases of intermediate-high risk PE [1]. Mechanical thrombectomy (MT) using the FlowTriever® System (FT) was introduced in Sweden in 2021 and has since then been the predominant CDI technique. This study aimed to assess the outcome among patients treated with MT and patients treated with ST during the recent years in Sweden.
Objectives: The aim of this retrospective national multicenter study was to evaluate the effectiveness and safety of MT in acute PE with comparison to ST.
Methods: We included all adult patients with verified PE treated with FT in Sweden from January the year FT was introduced in the respective hospitals until December 2023. A comparison group was comprised of patients treated with ST from the same hospitals. The primary outcome was a composite of death within 30 days or severe bleeding within 7 days. Secondary outcomes included incidence and time to all-cause mortality within 30 days, severe bleeding within 7 days, intracranial bleeding, change in RV/LV ratio, cardiac arrest, and length of stay in the intensive care unit or intermediate care unit, as well as in the hospital.
Results: Among 132 patients included in 7 hospitals, 61 patients were treated with FT only (FT group) and 61 with ST only (ST group); 10 patients received both treatments. The two groups were similar with respect to patient characteristics and clinical presentation. The mean age was 66.8 (SD 15.0) in the FT group and 67.5 (SD 14.0) in the ST group, with 57% and 51% females, respectively. High-risk PE was present in 32 (52%) patients in the FT group and 38 (62%) in the ST group. The other patients all had intermediate-high risk PE. Cardiac arrest before treatment occurred in 9 (15%) patients in the FT group and 12 (20%) patients in the ST group. The number of primary outcome events was significantly lower following Bonferroni–Holm adjustment in the FT group compared with the ST group (Fig. 1), 6 (10%) vs. 17 (28%), adjusted OR 0.19 (95% CI 0.05–0.69). Five (8%) patients in the FT group and 13 (21%) in the ST group died within 30 days (OR 0.33; 95% CI 0.11–0.99). Among the patients with high-risk PE and the patients with intermediate-high risk PE in the FT group, 4/32 (12%) and 1/29 (3%) were deceased after 30 days. For the patients treated with ST, the corresponding numbers were 11/38 (29%) and 2/23 (9%). One severe bleeding occurred after FT and 7 after ST (OR 0.18; 95% CI 0.03–1.10), including 5 intracranial hemorrhages of which one fatal. The right to left ventricular diameter before treatment was 1.7 ± 0.5 in both groups and decreased by 0.63 ± 0.47 after FT and 0.69 ± 0.47 after ST. No statistically significant differences were observed for any secondary outcome.
Conclusions: Mechanical thrombectomy using the FlowTriever system, for intermediate-high and high-risk pulmonary embolism seemed effective and possibly safer than treatment with systemic thrombolysis as it was associated with a lower composite endpoint of early death or severe bleeding.

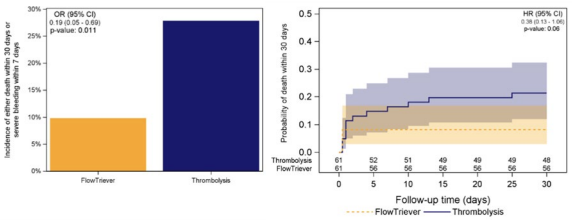

Fig. 1 (abstract 001074) Left panel illustrates proportional incidence of the composite primary endpoint in the two groups. Right panel describes survival over time until 30 days for the two groups. *OR* odds ratio, *HR* hazard ratio

Intensive Care Medicine Experimental 2025,* 13(1)*:001075

Introduction: The study, prevalence and concern about knowledge of neurological assessment has allowed us to improve the identification of the neurological status of our patients after a fatal event, highlighting cardiorespiratory arrest. This advance will allow us to improve the care necessary for a better recovery, even to reduce the rate of the

greatest negative event such as the death of this type of patient and to be able to balance the pessimistic prognosis. The main cause of death in these patients is due to the decision to limit or adapt life-sustaining treatment (ALST). The current guidelines recommend a strategy of combining several predictors of poor prognosis included in the examination and complementary tests (EEG, neuroimaging and biomarkers).
Objectives: Analyze neuro-prognosis taking the Glasgow Outcome Score as a reference (3–5: good, 1–2: bad).
Analyze the role of enolase as a predictor of neurological prognosis.
Methods: Observational, retrospective, single-center study. Patients admitted: recovered CRP since January of 2019, > 18 years are included. We excluded patients with head trauma.
Results: N 122 patients (31.1% women and 68.9% men), mean age 61.98 years (minimum age 21 and maximum age 87). 49.6% occurred in the hospital and 50.4% out-of-hospital settings. Cause: 32.0% due to ACS, 22.1% due to respiratory causes, 4.9% poisoning, 32.8% arrhythmia, 5.7% hemorrhage and 2.5% surgical complication. 32.2% had a good neurological prognosis, with recovery, with the remaining 67.8% having a poor prognosis (of these, 54.5% died performed in the ICU, 5.0% died in the ward and the rest had sequelae: 6.6% had mild sequelae and 1.7% severe sequelae). We analyzed enolase in 65 of those 122 patients, 29 had a good prognostic and 36 had a bad prognostic (death, mild sequelae or severe sequelae). In those 36 with bad prognosis 25 had ALTS for neurological involvement and 11 died due to multiple organ failure. Average limitation time was 3.64 days. To make this decision, different predictors of poor prognosis were combined, without being able to establish a clear pattern. We analyzed the maximum determination recorded in all patients during their evolution, with a general mean of 64.48, this mean being 92.76 in patients with a poor prognosis and 29.37 in patients with a good evolution. We performed ROC Curve with area under the curve of 0.784 (CI 95% 0.671–0.896) so we can conclude that high enolase values can be used to evaluate neurological involvement (Fig. 1).
Conclusions: Enolase can be a good predictor of poor neurological outcome, so together with the clinical examination (GOS) and other complementary tests such as EEG, N20 and neuroimaging, it can facilitate the decision making of ALST in patients with poor outcome.

Introduction: Postoperative delirium frequently complicates cardiac surgery and leads to adverse outcomes. Although iron homeostasis is crucial for cognitive function, its role in postcardiac surgery delirium remains poorly understood.
Objectives: This study aims to compare iron metabolism trajectories between patients who develop postoperative delirium and those who do not, from the preoperative period through the postoperative phase, potentially offering new insights for prevention and clinical intervention strategies.
Methods: This single-center retrospective study of 193 cardiac surgery patients examined perioperative iron metabolism profiles and their association with postoperative delirium. Iron metabolism parameters were measured preoperatively and on postoperative days 1, 3, and 7. Trajectory analysis, logistic regression, and mediation analyses were performed.
Results: Twenty-seven patients (14.0%) developed delirium. The delirium group showed higher preoperative ferritin (391 vs. 156 ng/mL, $p = 0.001$) and transferrin saturation, with lower iron binding capacity, along with elevated inflammatory markers (hs-CRP: 20 vs. 1 mg/L, $p < 0.001$; NSE: 44 vs. 26 ng/ml, $p = 0.001$) and decreased lymphocyte counts. These disturbances persisted postoperatively. Trajectory analysis identified two distinct ferritin patterns—a persistently high trajectory and a relatively lower trajectory with gradual postoperative increase—the former being associated with higher delirium risk (25.4% vs. 7.4%, $p = 0.001$) and worse clinical outcomes, including longer hospital stays and increased tracheostomy rates and 28-day mortality. Mediation analyses revealed ferritin's influence through direct effects (62.2%) and indirect pathways via inflammatory (CRP, 21.8%) and neuronal injury (NSE, 16.0%) markers. Preoperative ferritin > 325 µg/L emerged as a significant risk threshold for delirium development.
Conclusions: Perioperative iron metabolism disturbances, characterized by elevated preoperative ferritin levels and persistent postoperative trajectories, are associated with post-cardiac surgery delirium through direct and inflammatory-immune mediated pathways.

ICU readmission or in-hospital mortality of patients discharged from ICU: risk factors and validation of a new prediction model, the Worse outcome score

E. Papadakis[1], A. Proklou[1], G. Prinianakis[1], I. Papakitsou[1], E. Petrakis[1], C. Pappas[1], I. Konstantinou[1], S. Kokkini[1], E. Kondyli[2]

Intensive Care Medicine Experimental 2025,* 13(1)*:001077

Introduction: Intensive Care Unit (ICU) readmission and in-hospital mortality are critical indicators of patient outcomes following ICU discharge. Patients readmitted to the ICU often experience worse prognoses, increased healthcare costs, and prolonged hospital stays. Various risk factors, including patient demographics, comorbidities, illness severity, and ICU complications, contribute to these adverse outcomes.
Objectives: To indentify the risk factors for ICU readmission and in-hospital mortality, develop a predictive model for worse outcomes, and validate its clinical utility and reliability.
Methods: The study consists of two phases: (1) a retrospective observational study conducted in a mixed medical-surgical ICU to identify risk factors associated with ICU readmission and in-hospital mortality, and (2) a prospective validation phase assessing the predictive performance of a newly developed predictive score the Worse Outcome Score (WOScore). The data were collected from electronic hospital records, including patient demographics, ICU admission characteristics, severity scores (SAPS II, SAPS III, APACHE II, SOFA), interventions, and discharge conditions. Logistic regression was used to determine independent predictors of ICU readmission and in-hospital mortality. The predictive model was validated prospectively on ICU survivors to assess its accuracy.
Results: Among 1.190 ICU survivors analyzed, 126 (10.6%) were readmitted to the ICU, and 192 (16.1%) died in the hospital after ICU discharge. The key risk factors for ICU readmission included diabetes mellitus, SAPS III at admission, and ICU-acquired infections (ventilator-associated pneumonia VAP and catheter-related blood stream infections, CRBSI). As predictors of in-hospital mortality were indentified, the medical admission, high SAPS III and high lactate level at ICU admission, tracheostomy and reduced GCS at discharge, and blood transfusion, and AKI during ICU stay. The WOScore, based on the the above analysis, demonstrated a strong predictive ability (AUC: 0.886), with a cut off of 20 distinguishing high-risk patients (sensitivity: 88.1%, specificity: 73.0%).
Conclusions: ICU readmission and in-hospital mortality after ICU discharge are influenced by patient severity, underlying comorbidities, and ICU-related complications. The WOScore provides an effective risk stratification tool for identifying high-risk patients and guiding post-ICU interventions. Implementing structured ICU discharge protocols and targeted follow-up for high-risk patients may improve outcomes and optimize resource allocation. Further multicenter studies are needed to validate the model in diverse healthcare settings.

Correspondence: K.M. Scheffer-Wesdorp
Intensive Care Medicine Experimental 2025,* 13(1)*:001078

Introduction: Esophagectomy is a high risk procedure, 1 with pulmonary complications in up to 60% of cases and contributing significantly to morbidity and mortality.2,3 Although spirometry may help detection of pulmonary complications, the current guidelines advise against its use due to concerns regarding safety and feasibility.4 A recent systematic review conducted by our group (manuscript not yet published) revealed a lack of scientific evidence supporting this standpoint.
Objectives: To assess the feasibility and safety of spirometry in the first week after esophagectomy.
Methods: We conducted a prospective cohort study of adults undergoing elective esophagectomy at our hospital. Handheld spirometry was performed preoperatively and on postoperative day (POD) 2 and 7. Predicted values were based on the age, sex and height. Feasibility was assessed by comparing handheld to outpatient laboratory spirometry and measuring test duration. Safety was evaluated by monitoring vital signs (saturation and heart rate), pain scores (Numeric Rating Scale), and spirometry-related adverse events.
Results: In our prospective study, preliminary data from 21 patients showed good agreement between preoperative laboratory and handheld spirometry measurements (median vital capacity (VC) 92% versus 97% and Forced Expiratory Volume in 1 s (FEV1) 102% and 90% of predicted, respectively). Median spirometry test duration was 13.3 (10–15) minutes. During spirometry, oxygen saturation and heart rate demonstrated stable trends, with only minor fluctuations of 1% (0.5–3.0) and 3 beats per minute (0.5–7.0). One patient developed a pneumothorax with subcutaneous emphysema, first noted immediately after surgery prior to spirometry measurements, and worsening during the first postoperative week. Patients reported no change in their NRS (median change 0 [IQR 0–0]). Lung function declined substantially from baseline by POD2 (median VC 57% and FEV1 50% of predicted) and showed partial recovery by POD7 (median VC 85% and FEV1 73% of predicted) (Figs. 1 and 2).
Conclusions: Spirometry after esophagectomy appears feasible, and no evidence was found to support current recommendations discouraging its use following surgery. Our ongoing study aims to confirm these findings and to explore possible usefulness of spirometry in prediction and early diagnosis of postoperative pulmonary complications.

Intensive Care Medicine Experimental 2025,* 13(1)*:001079

Introduction: Solid organ transplant (SOT) recipients with acute respiratory failure (ARF) face poor outcomes and complex decisions regarding respiratory support. Given the preference for noninvasive respiratory support in this population, we compared high-flow nasal cannula (HFNC) versus noninvasive ventilation (NIV) as initial strategies to evaluate their impact on intubation-free survival.
Methods: In this single-center, randomized controlled trial, we enrolled 60 SOT recipients with acute respiratory failure. Patients were randomly assigned to receive either HFNC or NIV. The predefined primary outcome was days alive before intubation or death within 28 days (DABID-28), defined as the time interval from randomization until intubation or death, whichever came first. Secondary outcomes included 28-day mortality, intubation rate, and duration of respiratory support.

Results: Sixty patients were randomized (30 per group). The mean DABID-28 was 24 ± 9 days in the HFNC group versus 19 ± 12 days in the NIV group (difference, 5 days [95% CI −1 to 10]; $P = 0.085$). The 28-day mortality was significantly lower in the HFNC group (10% vs 40%; relative risk 0.25 [95% CI 0.08–0.80]; $P = 0.015$). The duration of allocated respiratory support was longer in the HFNC group (median 6 vs 3 days; $P = 0.013$). No significant differences were found in intubation rates or length of stay.
Conclusions: Among SOT recipients with acute respiratory failure, HFNC was associated with lower 28-day mortality as compared to NIV, although the difference in intubation-free alive days did not reach statistical significance. These findings require validation in larger multicenter trials.

Trauma in secondary care hospital: insights from the emergency department and intensive care unit admissions

S. Costa, C. Cunha, M. Magno, S. Mexia, E. Gisca, C. Santos, A. Araujo, L. Pereira
Intensive Care, Hospital Santo André—Hospital Distrital de Leiria, Leiria, Portugal
Correspondence: S. Costa
Intensive Care Medicine Experimental 2025,* 13(1)*:001080

Introduction: Trauma remains a leading cause of morbidity and mortality worldwide, placing a significant burden on emergency healthcare systems (1). Understanding the characteristics of trauma patients arriving at secondary care hospitals is essential to optimize resource allocation and improve clinical outcomes (2). The need for intensive care unit (ICU) admission among some of those patients reflects the complexity and severity of their condition (3). Although much of the literature focuses on the data from tertiary care centers, there is a relative paucity of information regarding trauma cases managed in secondary care settings.
Objectives: This study aims to characterize the trauma population admitted to the emergency department of a secondary hospital, with a particular focus on those requiring ICU care.
Methods: This was a retrospective study including all consecutive patients admitted to the emergency department of a secondary care hospital due to traumatic injury, between November 1, 2022, and July 31, 2023. Patients were characterized based on the baseline demographics, relevant medical history, type of traumatic injury, need for ICU admission, and clinical course during ICU stay. In-hospital mortality was also assessed. Descriptive and inferential statistical analyses were performed as appropriate.
Results: A total of 42 trauma patients were included; 69% were male, with a mean age of 61 ± 20 years. The mean Charlson Comorbidity Index was 2.57 ± 2.4. The average Revised Trauma Score (RTS) was 7 ± 1.27 (range: 2.63–7.84), the mean Injury Severity Score (ISS) was 18.17 ± 13, and the mean Trauma and Injury Severity Score (TRISS) probability of survival was 86%.
The most common injury type was thoracic trauma (47.6%), followed by traumatic brain injury (TBI) (28.6%). Among TBI cases, subdural hematoma was the most frequent finding (14.3%).
Most injuries resulted from blunt trauma (88.1%, $n = 37$), with burns accounting for 9.5% ($n = 4$). Road traffic accidents were the leading cause of trauma (35.7%).
Overall, 35.7% of patients required invasive mechanical ventilation and ICU admission. Among ICU patients, thoracic trauma (84%) and TBI (54%) were the predominant injuries. Nearly half (47.6%) of ICU patients were transferred to tertiary care centers. The most common complication was nosocomial pneumonia (9.5%). In-hospital mortality among the study population was 21.4%.
Conclusions: This study highlights the high mortality rate (21.4%) among trauma patients admitted to a secondary care emergency department, with the most severe cases requiring ICU admission. Thoracic and traumatic brain injuries were the predominant causes of critical illness, with a notable proportion of ICU patients requiring transfer to tertiary care hospitals. These findings emphasize the need for targeted interventions to reduce mortality, improve early identification of high-risk patients, and enhance resource allocation in secondary care settings.

Impaired mitochondrial respiratory capacity and exacerbated lactate release in response to exercise with experimentally induced sepsis in humans

H. G. Caldwell[1], J. Hartmann[2], M. Mohammad[2], J. Ulrichsen[3], S. Mortensen[4], K. Møller[5], R. Berg[2], R. Plovsing[3], L. Gliemann[1], UW. Iepsen[3]

Correspondence: H.G. Caldwell
Intensive Care Medicine Experimental 2025,* 13(1)*:001081

Introduction: In sepsis-induced multiorgan failure hyperlactatemia is prognostic for mortality and related to disease severity [1]; yet, lactate release plays an integral role in healthy exercise metabolism, where it is recognized as a substrate for oxidative phosphorylation [2]. Experimentally induced sepsis via purified lipopolysaccharide (LPS) from *E. coli* endotoxin provokes lactate release from the muscle at rest [3], although not reflective of the systemic catabolic response in clinical sepsis. Skeletal muscle mitochondrial respiratory chain enzyme activity and ATP content are reduced in critically ill septic patients [4,5]; whether this explains hyperlactatemia is unknown.
Objectives: 1. Investigate the influence of hyperlactatemia on mitochondrial respiratory capacity in the context of the acute pathophysiologic response to early sepsis (via LPS infusion) in healthy volunteers; and 2. utilize exercise to exacerbate skeletal muscle lactate release in the context of LPS.
Methods: $n = 8$ healthy adults (6/2 male/female, respectively) completed this placebo-controlled crossover study involving two experimental trials separated by > 8 weeks: 1. LPS (2 ng × kg-1); and 2. saline infusion (0.9%; PLACEBO). Following a resting biopsy (*m. vastus lateralis*) and insertion of catheters (brachial artery, femoral vein, muscle interstitial microdialysis) (PRE), LPS or saline was infused via an antecubital I.V. At peak lactate release (3 h) [3] a biopsy was taken (LPS). Thereafter, subjects completed two intensities of single leg knee extension exercise (4-min stages at 50% and 60% of max) with a biopsy taken immediately postexercise (EX). Mitochondrial respiratory capacity in permeabilized muscle fibers was measured via high-resolution respirometry (Oroboros Instruments, Austria).
Results: Interstitial lactate was threefold higher at 3-h post-LPS infusion at rest (Δ 1.1 mmol × l-1, 95% CI [0.4, 1.8], $p = 0.017$). The lactate/pyruvate ratio—a marker of impaired oxygen utilization—was increased by 28%, [−15, 71] ($p = 0.078$) at 1-h post-LPS infusion versus PRE. The venous-arterial lactate difference during the last stage of exercise was 1.5-fold higher during LPS (LPS vs. PLACEBO: Δ 0.7 mmol × l-1, [0.5, 0.9], $p < 0.001$). There was no effect of acute LPS per se on mitochondrial respiration at rest. As expected, complex-II respiration was increased at EX by 16%, [6, 27] ($p = 0.019$) versus PRE during the placebo trial. Complex-II respiration was *reduced* post-exercise by 18%, [−22, −14] ($p = 0.003$) during LPS. Maximal electron transport system (ETS) respiratory capacity showed the same impairment with LPS exercise (PLACEBO: + 25% [6, 43], $p = 0.029$; LPS: −15% [−27, -3], $p = 0.032$).
Conclusions: These data indicate that LPS-induced sepsis provokes impaired skeletal muscle respiratory capacity during exercise which coincides with exacerbated lactate release. Whether mitochondrial impairment precedes hyperlactatemia in established sepsis remains to be elucidated.

Introduction: Pancreatic stone protein (PSP) is a new pro-inflammatory biomarker used in the detection of sepsis. Identifying infections after trauma is challenging, as conventional pro-inflammatory markers are typically elevated due to resulting sterile inflammatory processes.1 Although previous studies suggest that PSP levels remain unchanged after trauma, PSP levels increase in patients who develop infections.2,3 This suggests that PSP may differentiate infection from sterile inflammation.
Objectives: This study evaluates PSP's diagnostic performance in critically ill trauma patients with and without ICU-acquired infections.

Methods: Using incidence density sampling, this nested case–control study matched ICU-acquired clinician-diagnosed infectious episodes (cases) to episodes without suspected infection (controls) (Fig. 1). PSP levels were compared between cases and controls, with procalcitonin (PCT) measured at infection onset (T0) as a proxy for infection. PSP concentrations were measured at 72 h before (T-72) and at T0. An exploratory analysis was performed to investigate the diagnostic performance of PSP to differentiate between three post hoc defined groups of patients suspected of infection (cases): those with microbiologically confirmed infection, those with unconfirmed infection, and those in whom infection was ruled out.
Results: We included 100 case- and 200 control-episodes from 202 patients. PSP and PCT levels in cases and controls showed no differences on T-72 or T0 (Fig. 2 and 3) Delta PSP levels between T-72 and T0 were 20 (−13 to 98) for cases and 11 (9–23 – 60) ng/ml for controls ($p = 0.09$). PSP levels at T0 for microbiologically confirmed infections as compared to controls with never suspected infection, unconfirmed and ruled-out infections were 291 (148–487), 174 (107–288), 171 (121–320) and 143 (98–216) ng/ml, respectively ($P = 0.002$). Using a PSP cut off of 100 ng/ml to distinguish between microbiologically confirmed infection and unconfirmed and ruled-out infection, sensitivity was 86% (95% CI 68–96%) and specificity was 20% (95% CI 12–31%).
Conclusions: Despite showing no signal in clinician-diagnosed cases versus control periods that were not suspected of infection, PSP may help distinguish microbiologically confirmed infection from sterile inflammation. These findings should be validated in a prospective cohort study to assess clinical utility.

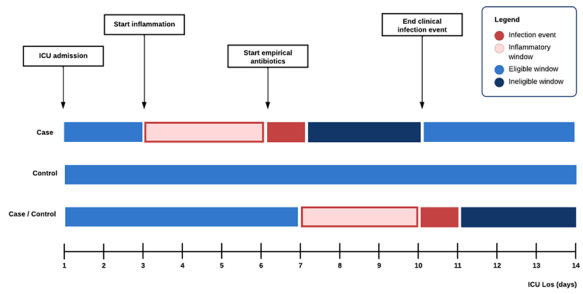

Fig. 1 (abstract 001083) Case/control matching scheme. Infection event: date of onset infection, i.e. day of start therapeutical antimicrobial therapy (T0). Inflammatory window: 3-day assessment period for clinical inflammation criteria starting at T-72 h to onset of infection. Eligible window: eligible as control event. Ineligible window: ineligible as control. ICU: Intensive Care Unit. Los: length of stay

A prospective observational study to evaluate the efficacy of HACOR SCORE in predicting NIV failure in ICU setting of a tertiary care centre

N. Jasmine, A. Sarath, V. Pillai[1]
Critical care medicine, PRS Hospital, Thiruvananthapuram, India

Intensive Care Medicine Experimental 2025,* 13(1):*001084

Introduction: The use of noninvasive ventilation (NIV) in critically ill patients reduces the work of breathing in acute respiratory failure, thereby reducing the need for intubation and associated complications.
Although NIV is frequently used in patients with respiratory failure, its failure rate remains high (25–59%) indicating that not all patients benefit from this treatment. And delayed intubation is associated with increased hospital mortality.
Previous studies have reported that patients who experience NIV failure have a higher heart rate, lower pH, Lower Glasgow Coma Scale (GCS) score, lower oxygenation, and higher respiratory rate. However, the predictive Power of NIV failure is low when based only on a single Variable. Hypothesizing that a combination of these variables has

to potential to increase the predictive HACOR score combined several variables that were easily obtained by simple bedside measurements in patients with acute respiratory failure to develop a scale for the prediction of NIV failure.

Objectives: The primary objective of the study is to determine whether HACOR score can help identify patients at risk of NIV failure and to compare the effectiveness of HACOR score at 1 h and 6 h in predicting NIV failure. The secondary objective of the study is also to determine the association of a higher HACOR score and length of hospital stay.

Methods: This prospective observational study which was conducted for a period of one year from April1, 2023 to Mar 31, 2024. Sample size of 130 patients has been calculated based on an earlier study.

•Inclusion criteria: Patients age > 18yrs requiring NIV patients initiated on NIV in our hospital.

•Exclusion criteria: Patients on home CPAP/NIV patients in DNR (EOLC) status.

Appropriate NIV settings for the patient were initiated based on the patient characteristics and the etiology of acute respiratory failure.

Patient were reevaluted after 1st hour of keeping NIV and after 6 h of initiating NIV and by recording the variables like heart rate, pH, GCS, PaO_2/FiO_2 and respiratory. HACOR score was calculated at these hours. These patients were then be followed up till discharge and outcomes were recorded. The outcome of NIV failure was defined as need for intubation and mechanical ventilation and NIV success when patient improved with NIV and was discharged.

The HACOR score and NIV success or failure was then correlated by statistical analysis.For continuous variables, we shall report median value with interquartile range (IQR) or mean value and standard deviation (SD) when appropriate. For categorical variables, we shall report numbers and percentage. Unpaired Student's *t* test was used to analyze the normally distributed continuous variables and Mann–Whitney *U* test was used to analyze the non-normally distributed continuous variables. Chi-square test or Fisher's exact test will be used to analyze the categorical variables when appropriate. All statistical analysis for the study was performed using statistical software Statistical Package for the Social Sciences (SPSS).

Results: At 1 h, HACOR score had a good predictive accuracy with a cutoff value of >5 having a sensitivity of 72.88% and specificity of 76.16%. At 6 h, HACOR score with a cutoff of >3, showed a sensitivity of 66.67% and specificity of 88.74%.

There is a strong positive correlation between the HACOR score (at both 1 and 6 h) and the length of ICU stay ($r = 0.568$ at 1 h and $r = 0.641$ at 6 h, $P < 0.001$). This suggests that higher HACOR scores are associated with longer ICU stays.

Conclusions: Higher HACOR score is strongly associated with NIV failure and worse ICU outcomes.

Incidence of sepsis and antimicrobial resistance in critically ill children with cancer and outcomes: a prospective observational study

S. Sharma[1], R. Mahale[1], S. Bhosale[2], A. Kulkarni[3], C. Dhamne[4]
[1]Department of Anesthesiology critical care and pain, TATA MEMORIAL HOSPITAL, Homi Bhabha Block, Mumbai, India; [2]Department of Anesthesia, Critical Care and Pain, Tata Memorial Centre, Mumbai, India; [3]Department of Anesthesia, Critical Care and Pain, Tata Memorial Hospital, Mumbai, India; [4]Department of Paediatric Oncology, Tata Memorial Hospital, Mumbai, India
Correspondence: S. SHARMA
Intensive Care Medicine Experimental 2025,* 13(1):*001085

Introduction: Intensive cancer therapies are associated with greater risk of life-threatening complications, of which sepsis continues to be the commonest cause of admission and death in intensive care. Along with sepsis burden, antimicrobial resistance (AMR) pattern has direct implication on the number of ICU admissions, hospital length of stay, and healthcare costs and mortality. A recent systematic analysis of the global burden of antimicrobial resistance (AMR) identified the six leading bacterial pathogens associated with the highest number of deaths, in descending order: *Escherichia coli*, *Staphylococcus aureus*, *Klebsiella pneumoniae*, *Streptococcus pneumoniae*, *Acinetobacter baumannii*, and *Pseudomonas aeruginosa.* This demands focus on tailoring research to improve outcomes in this patient population.

Objectives: Primary objective: Incidence of sepsis and sepsis related mortality in pediatric cancer patients.

Secondary objective: Site and cause of infection, prevalence and pattern of antimicrobial resistance, organ support, predictors of mortality, patient outcomes.

Methods: This is a prospective observational study in critically ill children with cancer (0–18 years). This study aimed to review the mortality in this cohort with focus on sepsis, causative microorganisms, site of

infection, antimicrobial resistance and clinical response. This study was started after ethical approval from Institutional ethics Committee and CTRI registration CTRI/2023/11/059572 and due consent from patients who were eligible.
Electronic Medical records of all consenting participants admitted in our ICU over 15 months were screened. Baseline and outcome information were collected on trial-specific electronic case report forms (eCRFs) and follow up was performed after 90 days of ICU admission.
Results: We have enrolled 176 children under 18 years over last 15 months with 110 children with suspected sepsis. These included 22 children with solid and 88 with hematological malignancies. Seventy-one children were neutropenic out of 110 children. The ICU mortality was 30/110 (27.3%) in suspected sepsis cases. The commonest site of infections were lungs (74), gastrointestinal focus (46), bloodstream infections (32), skin and soft tissue (13), central nervous system (13), endocarditis (4), urinary tract (4). The commonest isolate was *E. coli* in lung, bloodstream and gastrointestinal tract infections. The incidence of gram-positive infections was low. The carbapenem resistance was high in gram negative infections. Low yield of culture, lack of confirmatory methods to detect viral and fungal infections, low sensitivity of biomarkers result in excess coverage or coverage defect in antimicrobial use.
Conclusions: Sepsis is associated with one-third ICU mortality with lower respiratory tract being the most common site of infection. There is high prevalence of carbapenem-resistant gram-negative infections in children with cancer.

Intensive Care Medicine Experimental 2025,* 13(1)*:001086

Introduction: *Streptococcus pyogenes* (group A beta-hemolytic streptococcus, GAS) is a major cause of invasive infections that can lead to severe complications, including septic shock, renal failure and coagulopathies. Over the recent years, a growing incidence of GAS infections has been observed. Despite advances in antimicrobial therapy and critical care, mortality remains substantial.
Objectives: To describe the clinical features, sources of infection, complications, antimicrobial resistance patterns, and management strategies in ICU patients with confirmed GAS infections.
Methods: A retrospective cohort study of 29 ICU patients with microbiologically confirmed GAS infections admitted to the ICU of a tertiary hospital in Spain from 2010 to 2024.
Results: The median age was 45.7 years (IQR 37.3–59.5), and 62.1% were male. The most frequent sources of infection were skin and soft tissue (58.6%), respiratory (24.1%), and puerperal (17.2%). Common complications included septic shock (82.8%), acute kidney injury (72.4%), coagulopathy (72.4%), and respiratory failure (62.1%). Empirical antibiotic therapy included clindamycin, linezolid, and carbapenems in 51.7% of cases. Intravenous immunoglobulin was administered in 44.8%. Source control was achieved in 72.4% of patients. GAS isolates were 100% susceptible to penicillin and clindamycin, while resistance was observed in 19.2% to macrolides and 3.4% to quinolones. The mean ICU stay was 12.9 ± 6.5 days, and mean hospital stay was 38.6 days. The overall ICU mortality was 13.8%.
Conclusions: ICU patients with invasive GAS infections present with significant clinical severity, frequently developing septic shock and multiorgan failure. The relatively low mortality observed in this cohort compared to similar populations may reflect the benefits of early source control and the use of adjunctive therapies such as immunoglobulin. Nonetheless, the presence of macrolide resistance underscores the importance of prudent antibiotic use.

Intensive Care Medicine Experimental 2025,* 13(1)*:001087

Introduction: Group A beta-hemolytic streptococcus (*Streptococcus pyogenes*, GAS) is a highly virulent pathogen associated with

life-threatening invasive infections. Despite modern critical care practices, mortality remains high in ICU patients with GAS infections. Understanding the clinical factors associated with mortality could help improve management strategies and outcomes.
Objectives: To analyze mortality and associated risk factors in ICU patients with invasive GAS infections, with a specific focus on the role of infection source control.
Methods: This was a retrospective cohort study of 29 microbiologically confirmed GAS infections in patients admitted to the ICU of a tertiary care hospital in Spain between 2010 and 2024.
Results: Median age was 45.7 years (IQR 37.3–59.5), and 62.1% were male. The overall ICU mortality rate was 20.7%. Deceased patients were older (median age 58.6 vs. 45.4 years among survivors). Respiratory infections had the highest mortality rate (42.9%), compared to skin/soft tissue infections (17.6%), while no deaths occurred in puerperal infections. Although not statistically significant ($p = 0.13$), respiratory infections were also associated with longer ICU stays (18.9 vs. 10.4 days). Multiorgan failure (MOF) was present in 79.3% of cases; 24.1% developed failure of four or more organs. Infection source control was achieved in 72.4% of patients and was strongly correlated with survival ($r = 0.88$, $p < 0.001$). Median ICU and hospital stays were 7 (IQR 4–10) and 22 days (IQR 10–45), respectively.
Conclusions: Invasive GAS infections in the ICU are associated with a high burden of organ dysfunction and notable mortality. Respiratory infections tend to have worse outcomes and longer ICU stays, although statistical significance was not reached. The strong positive correlation between source control and survival highlights the critical importance of early and effective source management in improving outcomes for this patient population.

Table 1 (abstract 001087) Clinical characteristics and outcomes

	Total (n=29)	Survivors (n=23)	Deceased (n=6)

Intensive Care Medicine Experimental 2025,* 13(1)*:001088

Introduction: Septic shock is associated with a very high mortality. Recent expert recommendations have emphazised on the need of a personalized approach for early resuscitation to avoid the risk of overesuscitation and its related-morbidity(1,2). Among strategies to achieve this goal, the recent ANDROMEDA–SHOCK trial demonstrated that targeting capillary refill time (CRT) as compared to lactate was associated with better outcomes and less treatment intensity (3). To further advance in this direction we designed the ANDROMEDA–SHOCK 2 (A2) trial, a major RCT, where we tested if a personalized septic shock resuscitation based on simple physiological principles was associated with better outcomes when compared with usual care (ClinicalTrials.gov NCT05057611).
Methods: A two-tier algorithm was designed as shown in Fig. 1. This strategy included CRT targeting but with an algorithm where initial decision making was based on the bedside hemodynamic phenotyping considering variables such as pulse pressure (PP), diastolic arterial pressure (DAP), fluid responsiveness status, and echocardiography in a key position (4). A fundamental part was to position 4 hemodynamic challenges to test CRT response in 30–60 min according to the signals provided by the algorithm as a way to personalize further interventions (fluid, DAP, MAP and inodilator challenges).
After ethical approval, consent signature, and intensive training early septic shock patients (< 4 h after diagnosis) where centrally randomized to intervention or usual care groups for a 6 h study period. The usual care group was resuscitated according to attendings preferences.
The main outcome was a composite one of 28-day mortality, time to organ support cessation and hospital length of stay as analyzed with the win-ratio method. The sample size was estimated in 1500 pts.
Results: The study started on March 2022 and up-to-date (April 10,2025) has recruited 1470/1500 pts in 80 centers of 17 countries in 3 continents. Importantly, very heterogeneous centers have participated including selected University Hospitals in Western Europe together with big public hospitals in Latin America and other regions, a fact that may allow to analyze results under high versus LMIC countries perspective.
Central Coordination and Data Quality Monitoring were performed at 3 institutions (PUC Chile, Fundación Valle del Lili Colombia, and HCOr Brazil). Data were uploaded to a Castor EDC database and stored at Erasmus MC, NL.
An independent DSMB performed interim analyses at 25% and 75% of the sample size allowing to continue recruiting because of no harm signals.
Compliance with the Intervention so far was considered as satisfactory with only a 4.8% of mayor deviations and 14% of minor ones.
Recruitment will be completed by early May 2025 and the database lock expected by mid-June for starting the statistical analysis at HCOr.
Conclusions: The ANDROMEDA–SHOCK-2 trial, a complex multinational study, is about to be completed. In the meantime, it appears that implementation of this kind of personalization efforts to improve early septic shock resuscitation is feasible among different contexts. If positive, A2 will open new avenues for further optimizing resuscitation strategies but with simple physiologically-based interventions based on the bedside universally available signals.

Intervention algorithm applied in the A2 trial.

Impact of anaesthetics on the renoprotective effect of remote ischemic preconditioning: the HypnoRenalRIP randomized clinical trial

A. Zarbock[1], R. Weiss[1], J. Gerss[2], J. Kellum[3], L. Schöne[1], C. Strauß[1], M. Sadjadi[1], H. Booke[1]

Intensive Care Medicine Experimental 2025,* 13(1)*:001090

Introduction: Remote ischemic preconditioning (RIPC) has been shown to reduce acute kidney injury (AKI) in high-risk patients after cardiac surgery. The protective effects are restricted to patients with early and transient increases of the two cell cycle arrest markers, tissue inhibitor of metalloproteinases-2 (TIMP-2) and insulin-like growth factor-binding protein 7 (IGFBP7) in the urine. The studies suggest that propofol may attenuate the preconditioning effect on the myocardium.

Objectives: The purpose of this study was to investigate whether propofol also diminishes the preconditioning effect on the kidneys by measuring [TIMP-2]*[IGFBP7].
Methods: This is a single-center, randomized clinical trial among high-risk patients undergoing cardiac surgery with cardiopulmonary bypass. Patients were randomized to receive either propofol+ sham− RIPC, propofol+ RIPC, sevoflurane+ sham− RIPC or sevoflurane+ RIPC. The primary endpoint was the change in urinary [TIMP2]*[IGFBP7] between post- and preintervention. Secondary outcomes included the incidence of AKI within 72 h after cardiac surgery.
Results: The results are presented in Table 1. 160 patients were included in the trial (propofol + sham-RIPC: $n = 20$, propofol + RIPC: $n = 60$, sevoflurane + sham-RIPC: $n = 20$, sevoflurane + RIPC: $n = 60$). Median change in [TIMP2]*[IGFBP7] before and after RIPC was significantly greater in patients receiving sevoflurane (0.070; IQR −0.120, 0.418) compared with those receiving propofol (−0.015; IQR −0.138, 0.068; $p = 0.029$). Four hours after CPB, [TIMP2]*[IGFBP7] did not increase with sevoflurane + RIPC group whereas it did in the other groups ($p = 0.001$). There were no statistically significant differences in patient-centred outcomes, including AKI, between the groups.
Conclusions: RIPC-induced transient changes of [TIMP2]*[IGFBP7], which are associated with renoprotective effects, were only seen with sevoflurane anesthesia, but not when propofol was used. These results may explain the lack of renoprotection in propofol-anesthetized patients receiving RIPC.

Table 1 (abstract 001090) [TIMP-1]*[IGFBP7] values at different time points. Abbreveations: CBP, cardiopulmonary bypass; RIPC, remote ischemic preconditioning

Intensive Care Medicine Experimental 2025,* 13(1)*:001091

Introduction: Microcirculatory dysfunction is associated with organ failure and poor prognosis in critically ill patients (1). Numerous tools allow bedside microcirculation assessment, making their relevance probably context dependent.
Objectives: To determine the extent to which the most commonly used devices in the intensive care unit (ICU) can detect initial microcirculatory alterations and whether they provide distinct or complementary prognostic information in different subpopulations of critically ill patients.
Methods: This prospective, monocentric cohort study was conducted in a 34-bed ICU in Belgium. Adult patients with an expected ICU stay of at least 3 days were included. Microcirculatory parameters were simultaneously recorded on day 1 (within 24 h of ICU admission), including peripheral perfusion index (PPI), Mottling score (MS), capillary refill time (CRT), core-to-skin temperature gradient (ΔT), skin blood flow at basal temperature (SBF BT) and regional tissue oxygenation (rSO_2). The primary outcome was to assess correlations between various microcirculatory parameters on day 1.
Results: Fifty-five patients were included (median age 64 years, 65.5% male). Circulatory failure (36.4%) was the most common reason for ICU admission, followed by acute brain injury (ABI) (29.1%) and acute respiratory failure (25.4%). PPI and CRT showed strong correlations with SBF BT and ΔT, while rSO_2 had no significant associations with other tools (Fig. 1). Correlations were stronger in circulatory failure group, but weaker in ABI group. CRT had the highest predictive value for ICU mortality (AUC = 0.75, $p = 0.007$), followed by MS (AUC = 0.72, $p = 0.021$), SBF BT and PPI (Fig. 2). ΔT had lower predictive performance and rSO_2 was the weakest predictor. In the circulatory failure group, none of the parameters showed significant discriminatory ability (AUCs 0.52–0.62, all $p > 0.05$). In contrast, in ABI CRT had the highest predictive value (AUC = 0.92, $p = 0.03$), and MS showed good but nonsignificant predictive ability (AUC = 0.81, $p = 0.112$). Other parameters had lower, nonsignificant predictive performance (AUCs 0.55–0.75).
Conclusions: Microcirculatory parameters correlated differently depending on the underlying condition, with stronger associations in circulatory failure. CRT was the best predictor of ICU mortality, particularly in ABI while other parameters showed limited or no prognostic value.

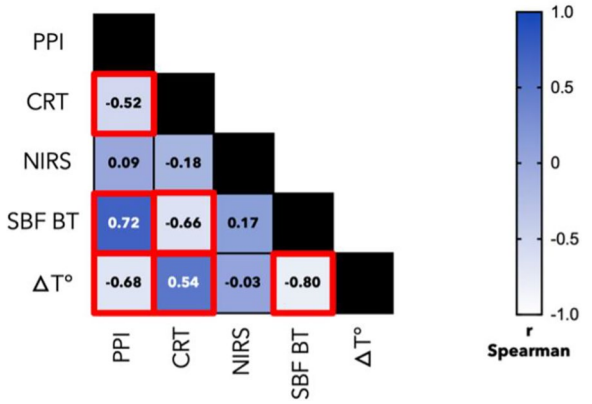

Fig. 1 (abstract 001091) Correlation matrix of the studied parameters in the overall population at day 1. This matrix displays the Spearman's correlation coefficients (ρ) between PPI, CRT, NIRS, SBF BT, and Gradient T ($\triangle T$). Significant correlations ($p < 0.005$) are encircled in red

Intensive Care Medicine Experimental 2025,* 13(1)*:001093

Introduction: In our unit, transcranial Doppler (TCD) is part of the basic daily neuromonitoring protocol in patients with aneurysmal subarachnoid hemorrhage (aSAH), used for screening vasospasm (VSP), flow alterations, and intracranial hypertension.
Objectives: To describe the characteristics of patients with aSAH and to determine the predictive capacity of TCD as a screening tool of VSP in our sample.
Methods: Retrospective study of patients admitted with aSAH to critical care areas in a tertiary hospital from March 2018 to December 2024. Demographic, clinical, and mortality variables were analyzed. Vasospasm (VSP) was defined as present when confirmed by angiography. TCD was considered positive for VSP if mean velocity in the middle cerebral artery was ≥ 120 cm/s or in the anterior cerebral artery ≥ 130 cm/s and TCD was considered negative if the velocities were under these values. In our sample, delayed cerebral ischemia (DCI) was defined as the appearance of new focal deficits or a decrease of at least two points on the Glasgow Coma Scale for more than 1 h attributed to no other cause than VSP. Sensitivity (Se), specificity (Sp), and predictive values (PV) of TCD for the diagnosis of VSP were calculated. The data are presented as numbers and percentages or median and standard deviation. Mann–Whitney and Chi-square tests were used as appropriate.
Results: Data were collected from 128 patients, with a median age of 61.7 years [IQR 51–70.1]; 71.1% were female. Among these, 91.4% were classified as Fisher IV, 64.8% as Hunt & Hess grades 4–5, and 67.1% as WFNS grades 4–5. Median ICU stay was 11 days [IQR 3–18.8], and median hospital stay was 22.9 days [IQR 11–36]. Of the 128 patients, 57 were diagnosed with VSP by angiography and were classified into two groups based on TCD findings: Group 1 ($n = 31$) included patients with a positive TCD prior to angiography, and Group 2 ($n = 26$) included

patients with a negative TCD. Table 1. No significant differences were found between the groups in terms of DCI, length of stay, functional outcome, or mortality. Group-specific results are shown in Table 2.
In our sample, TCD had a sensitivity of 54.4%, specificity of 86%, positive predictive value of 76%, and negative predictive value of 70%. These results are shown in Table 2.
Conclusions: In our sample, 54.4% of patients with confirmed vasospasm showed suggestive findings on TCD. The sensitivity and specificity of TCD are consistent with the recent literature[1]. However, a larger sample size is needed to better estimate the diagnostic value of TCD for VSP.

Evaluating the efficacy of tea trolley training to teach bis monitoring in ITU

E. Granger[1], E. Hall[2]
[1]Anaesthetics, Gateshead Health NHS Foundation Trust, Windy Nook, Gateshead, UK, Newcastle upon Tyne, United Kingdom; [2]Critical Care and Anaesthetics, Northumbria NHS Foundation Trust, Silver Fox Way, Newcastle Upon Tyne, UK, Newcastle Upon Tyne UK, United Kingdom
Correspondence: E. Granger
Intensive Care Medicine Experimental 2025,* 13(1)*:001095

Introduction: Over or undersedation of patients in intensive care units (ITU), particularly those receiving neuromuscular blocking drugs (NMBD), has been associated with delayed extubation, increased rates of delirium, prolonged ITU stay and higher rates of PTSD[1, 2]. Bispectral Index (BIS) monitoring has been used in some ITUs to titrate sedation more closely to patients' EEG activity and traditional sedation scoring systems like the Richmond Agitation Sedation Scale (RASS), to reduce the incidence of these adverse effects [3]. We planned to introduce BIS monitoring for proned patients, any receiving NMBD or Level 3 NELA patients in our ITU in a District General Hospital and used the tea trolley training [4] method to train ITU staff on its use.
Objectives: To evaluate whether tea trolley training can be effectively utilised to deliver teaching on the use and interpretation of BIS in an ITU.
Methods: The members of ITU staff, including nurses, Advanced Critical Care Practitioners and doctors, were asked to complete a Likert questionnaire before the teaching assessing their understanding of how to use BIS monitoring. Responses ranged from "very well/confident" to "not at all confident". We delivered tea trolley training on the unit to 31 staff members over a 3-month period demonstrating the use and interpretation of a BIS monitor, in line with our unit guideline which outlines how to utilise BIS monitoring alongside the RASS and clinical assessment. They were asked to complete the questionnaire again immediately after the teaching to assess whether their understanding had improved.
Results: The preteaching survey was completed by 24 people and the post teaching survey by 20 people. The average percentage of all responses indicating low confidence and understanding dropped from 69 to 0.6% after teaching. An average of 75% of answers after teaching were "very confident" or "confident", as opposed to 9% before teaching. The mean proportion of responses indicating "slightly confident" remained the same at 21%.
Conclusions: The results suggest that tea trolley training is effective at delivering BIS training and can continue to be used for this on our unit. The project is ongoing with further teaching planned. We felt the consistency in the average responses of "slightly confident" reflected the difficulty in conveying certain concepts in a short time, such as suppression ratios and the EEG. Burst suppression, what the BIS number means and how to respond to it using the guideline were concepts that were more easily understood. There were some limitations we found that could be addressed to improve the teaching, including more explanation of the suppression ratios and waveform, re-assessing understanding at an interim period to gauge knowledge retention and using a more efficient way to assess understanding than the questionnaire, as this required an email login to access which affected compliance.

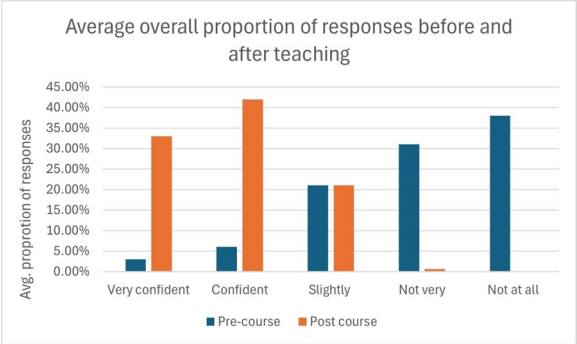

Table showing the average overall proportion of responses before and after teaching.

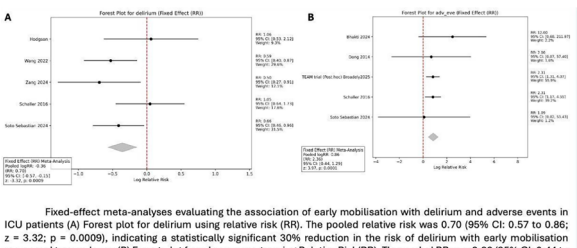
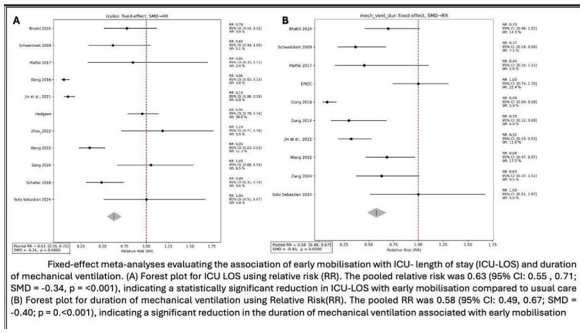
Intensive Care Medicine Experimental 2025,* 13(1)*:001099

Introduction: Early mobilization (EM) during critical illness has been focused upon since many years to improve the outcomes of patients in an intensive care unit (ICU), especially ICU acquired weakness (ICU-AW) and it forms an important component of many guidelines. Mechanical ventilation is considered as a barrier to early mobilization. The effects of early mobilization on short term and long term outcomes in mechanically ventilated patients is not clear.
Objectives: We aimed to conduct a systematic review and meta-analysis to assess the effects of early mobilization when compared with standard or usual care in mechanically ventilated patients in an intensive care unit (ICU).
Methods: We conducted a comprehensive search on PubMed, EMBASE and Cochrane databases from inception to 31 January 2025. Randomized controlled trials published in English language, which assessed the effects of early mobilization when compared with usual or standard care in mechanically ventilated patients were included.
Our search strategy was ("mobilization" OR "exercise" OR "physical therapy" OR " rehabilitation") AND ("critical care" OR "intensive care" OR "critically ill" OR "critical illness" OR "mechanical ventilation") AND (RCT OR "Randomized controlled trial" OR "Randomized trial"). Statistical analysis was done using python programming on jupyter notebook and R studio 4.3.2. Custom scripts were developed and executed to perform data pre-processing, effect size calculations and meta-analysis on python. On R studio, relative risk ratio (RR) and Odds ratio (OR) with 95% confidence interval were pooled with fixed effects model. Heterogeneity was assesses using I^2 statistics. Quality assessment and risk of bias were performed according to the Cochrane recommendations.
We included patients with age > 18 years, mechanically ventilated for atleast 24 h, mobilized within 72 h- sitting out of bed, standing or walking compared with usual care (care that was normally provided in each ICU). The primary outcomes were ICU length of stay, ICU-AW, delirium and coginitive function. We also measured adverse events, ICU mortality, duration of mechanical ventilation and mortality at 180 days.
We excluded patients who were dependent, had cognitive impairment, proven or suspected acute brain lesion and/or spinal cord injury other neuromuscular disease, chronic underlying medical condition, death deemed inevitable and had rest-in-bed orders.
Results: We screened a total of 4738 studies. After removing the duplicates, reading the title and abstract and screenig the full text, 14 studies comprising of 2401 patients were included. Of these, 1204 (50.14%) patients received early mobilization. In the pooled data, there is statistical significant reduction in ICU length of stay (RR:0.63; 95% CI 0.55,0.71; $p = 0.00$, $I^2 = 0\%$), ICU-AW (RR:0.74; 95% CI −0.47, −0.13; $p = 0.0004$; $I^2 = 0\%$), incidence of delirium (RR:0.70; 95% CI −0.57, −0.15; $p = 0.0009$; $I^2 = 0\%$) and the duration of mechanical ventilation (RR:0.58; 95% CI 0.49,0.67; $p = 0.00$; $I^2 = 0\%$) in early mobilization group compared with standard or usual care in mechanically ventilated patients.
There was significant increase in the incidence of adverse events associated with early mobilization group compared with standard care. (RR:2.36; 95% CI 0.44,1.29; $p = 0.0001$; $I^2 = 0\%$).
There was no difference in ICU mortality (RR:1.24; 95% CI −0.29,0.73; $p = 0.403$, $I^2 = 0\%$), mortaliity at 180 days (RR:1.05; 95% CI −0.48,0.56; $p = 0.86$; $I^2 = 0\%$) and ventilator free days (SMD = 0.14; 95% CI −0.04,0.31; $p = 0.12$; $I^2 = 0\%$) between the two groups.
There was no statistical difference in the long term cognitive impairment (upto 1 year) (SMD;1.20; 95% CI −1.58,3.98; $p = 0.40$; $I^2 = 94.6\%$) and in the subggroup analysis based on health-related quality of life (QoL) measurement tools (EQ-5D-5L, SF-36, SGRQ) (SMD:0.61; 95% CI−0.23,1.46; $p = 0.15$; $I^2 = 97\%$) between the two groups. Among the three tools, SGRQ showed the larger effect size favouring early mobilization.
Conclusions: Our meta-analysis showed that when early mobilization was compared with usual or standard care in mechanically ventilated patients, there was improvement in ICU-AW, duration of mechanical ventilation, dellirium and ICU length of stay. There was no difference in mortality at 180 days, cognitive impairment and health-related QoL(upto 1 year).





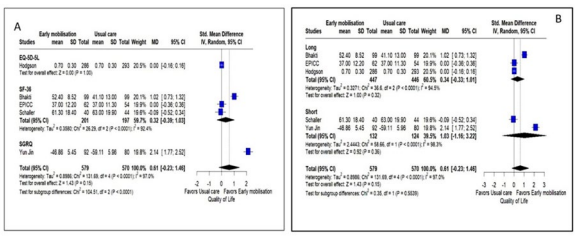


Fig. 1 (abstract 001099) Forest plots of delirium and adverse events when early mobilization is compared with usual care in mechanically ventilated patients

Fixed-effect meta-analyses evaluating the association of early mobilisation with ICU- length of stay (ICU-LOS) and duration of mechanical ventilation. (A) Forest plot for ICU LOS using relative risk (RR). The pooled relative risk was 0.63 (95% CI: 0.55 , 0.71; SMD = -0.34, p = <0.001), indicating a statistically significant reduction in ICU-LOS with early mobilisation compared to usual care (B) Forest plot for duration of mechanical ventilation using Relative Risk(RR). The pooled RR was 0.58 (95% CI: 0.49, 0.67; SMD = -0.40; p = 0.<0.001), indicating a significant reduction in the duration of mechanical ventilation associated with early mobilisation

Fig. 2 (abstract 001099) Forest plot of ICU length of stay and the duration of mechanical ventilation when early mobilization is compared with usual care in mechanically ventilated patients

Subgroup Analyses of Early Mobilisation Versus Usual Care on Quality of Life in ICU Patients

A: Subgroup analysis based on Quality of Life measurement tools (EQ-5D-5L, SF-36, SGRQ). Among the three tools, the SGRQ (Yun Jin study) showed the largest effect size (SMD 2.14), favoring early mobilisation.

B: Subgroup analysis based on follow-up duration. Short-term studies (≤3 months) showed a non-significant trend favoring early mobilisation. No statistically significant subgroup differences were observed.

Fig. 3 (abstract 001099) Forest plot of health-related quality of life (QoL) (upto 1 year) when early mobilization is compared with usual care in mechanically ventilated patients

Intensive Care Medicine Experimental 2025,* 13(1)*:001104

Introduction: Neurologic outcome after eCPR depends on multiple factors mainly due to quality of conventional prolonged resuscitation and an increased risk of neurologic complications associated with ECLS. The range varies from severe impairment to normal neurologic condition. Currently, only limited data are available on long-term neurological and neuropsychiatric outcomes after eCPR in OHCA.

Methods: Retrospective observational cross-sectional study at the University Regensburg ECMO-Center. All patients after eCPR for OHCA between 03/2011 and 11/2023 were included. Behavioral and cognitive dysfunction was obtained by frontal behavioral inventory (FBI) raised by a relative, Montreal cognitive assessment (MoCA) test and instrumental activities of daily living (IADL) test. FBI assesses behavioral changes caused by frontal lobe abnormalities. For 18/30/32 patients a follow-up visit with assessment of FBI/MoCA/IADL was available.

Results: 223 patients had eCPR for OHCA, Age was (median, IQR 25th-75th) 56.2 (49.4–65.3) years. A follow up exceeding 12 months was available for 34 patients. 3 of these had suffered intracranial hemorrhage or ischemia, 2 depended on care. FBI (normal: 0, max. per category 3, max. total 72 points) showed a total of 8.0 (4.0–17.0) points. A noticeable deviation was shown in the categories emotional flatness (1.0, 0–2.0), inflexibility (1.0, 0–2.0) and disorganization (1.0, 0–2.0). Regarding cognitive impairment assessed by the MoCA test (normal > 26, max. 30), the included patients showed a score of 26 (24–28). The IADL (max. 8) showed a median 8 (8 – 8).

Conclusions: To our knowledge, this is the largest cohort of patients after eCPR reporting on long-term neurological outcome. Besides the high risk of neurologic impairment associated with OHCA we showed a good neurological and neuropsychiatric long-term outcome of survivors more than 12 months after eCPR. Regarding the FBI, MoCA and IADL test most of long-term survivors did not develop severe neurological sequelae.

Intensive Care Medicine Experimental 2025,* 13(1)*:001105

Introduction: The arterial oxygen partial pressure to inspired oxygen fraction ratio (PaO2/FiO2) is a critical metric for evaluating the prognosis of patients with acute respiratory distress syndrome (ARDS). This ratio offers valuable insights for making informed treatment decisions, particularly in assessing mortality risk. Despite its widespread use, the reliability of the PaO2/FiO2 ratio in accurately gauging ARDS severity and predicting mortality remains a topic of debate.
Objectives: This study aimed to evaluate the accuracy of the PaO2/FiO2 ratio in predicting hospital mortality among ARDS patients in Vietnam.
Methods: We conducted a retrospective observational study that included all adult patients with ARDS admitted to a central hospital in Vietnam from August 2015 to August 2023. The diagnosis of ARDS was based on the Berlin definition. To categorize the severity of ARDS, we applied this definition and converted its categories into a numerical grading system known as the Berlin score. This score ranges from 1 (PaO2/FiO2 > 300 mmHg) to 4 (PaO2/FiO2 $\leq$ 100 mmHg). To evaluate the predictive accuracy of the PaO2/FiO2 ratio, the Berlin score, the Sequential Organ Failure Assessment (SOFA) score, the Acute Physiology and Chronic Health Evaluation II (APACHE II) score, and the CURB-65 score for hospital mortality, we calculated the areas under the receiver operating characteristic curve (AUROC). Lastly, we performed multivariable analysis for each variable of interest (i.e., PaO2/FiO2 ratio, Berlin score, SOFA score, APACHE II score, and CURB-65 score), controlling for the same set of confounders to identify the association of these variables with hospital mortality.
Results: Of the 345 patients, 67.5% were male, and the median age was 55.0 years (IQR: 39.0–66.0). Among these patients, 61.2% (211/345) died in the hospital. On the first day of admission, the PaO2/FiO2 (AUROC: 0.585 [95% CI 0.522–0.649]) had a poor predictive ability for hospital mortality. Incorporating the PaO2/FiO2 into the Berlin score did not improve its predictive accuracy (AUROC: 0.578 [95% CI 0.516–0.641]) for hospital mortality. Both the PaO2/FiO2 ratio and the Berlin score demonstrated lower accuracy in predicting hospital mortality compared to the SOFA (AUROC: 0.650 [95% CI 0.590–0.711]), APACHE II (AUROC: 0.685 [95% CI 0.628–0.742]), and CURB-65 scores (AUROC: 0.689 [95% CI 0.617–0.762]). Higher values of PaO2/FiO2 (adjusted OR [AOR]: 0.988 [95% CI 0.979–0.996]) were independently associated with a lower mortality risk. Higher scores on the Berlin (AOR: 2.477 [95% CI 1.190–5.156]), SOFA (AOR: 1.278 [95% CI 1.102–1.482]), APACHE II (AOR: 1.236 [95% CI 1.108–1.379]), and CURB-65 (AOR: 7.142 [95% CI 2.581–19.763]) were independently associated with an increased mortality risk.
Conclusions: This study investigated a selected cohort of ARDS patients with high mortality rates at a central hospital in Vietnam. The findings revealed that the PaO2/FiO2 ratio poorly predicted hospital mortality. Incorporating the PaO2/FiO2 ratio into the Berlin score did not improve its predictive accuracy. Furthermore, the PaO2/FiO2 ratio and Berlin score demonstrated lower predictive accuracy for hospital mortality than the SOFA, APACHE II, and CURB-65 scores. Nevertheless, lower PaO2/FiO2 ratio and higher scores on the Berlin, SOFA, APACHE II, and CURB-65 scores remained independent predictors of hospital mortality. These findings highlight the need for further studies to develop more accurate scoring systems for predicting outcomes in ARDS patients.

Intensive Care Medicine Experimental 2025,* 13(1)*:001107

Introduction: The intensive care unit (ICU) is a high-stress environment where critically ill patients require intensive monitoring and treatment. This setting can be overwhelming for both patients and their families, often leading to emotional distress and challenging interactions with healthcare providers. Traditionally, ICU care has been highly clinician-driven, with limited family involvement. However, recent shifts in healthcare practices emphasize the importance of family-centered care. Research suggests that family participation can improve patient outcomes by enhancing communication, providing emotional support, and helping to monitor and advocate for patient safety.
ICUs are complex environments, and despite best efforts, they remain prone to patient safety incidents such as medication errors, infections, and falls. Incident reporting systems (IRS) are crucial tools for identifying and addressing these errors. This study seeks to explore whether involving family members in patient care in the ICU can influence the frequency and nature of these safety incidents. Specifically, it aims to investigate the association between family presence during ICU care and the number of safety-related events reported in the IRS across multiple hospitals in Saudi Arabia.
Objectives: To evaluate the impact of family involvement on patient safety incidents in ICUs, including medication errors, falls, and communication issues.To compare common patient safety incidents in ICUs with and without family participation.
Methods: This is a multicenter, retrospective cohort study conducted across five private-sector hospitals in Saudi Arabia, all accredited by the Saudi Central Board for Accreditation of Healthcare Institutions

(CBAHI). The study included records of adult patients (aged ≥ 18 years) who were admitted to the intensive care units (ICUs) between 2022 and 2024.
Patients were categorized into two groups based on the level of family involvement in their care during ICU admission. This information was extracted from patient records; in cases where data was missing, family members were contacted by phone to verify their involvement. The primary outcome measured was the number of patient safety incidents, as reported in each hospital's Incident Reporting System (IRS).
A total of 3,274 patients were included in the study (1,637 in each group). Data were analyzed using descriptive statistics and inferential tests. Independent t tests or Mann–Whitney U tests were used for continuous variables, while chi-square tests were used for categorical variables. A $p < 0.05$ was considered statistically significant.
Results: A total of 3,274 ICU patients were included in the analysis, divided equally into two groups: those with family involvement in care ($n = 1,637$) and those without ($n = 1,637$). The overall number of reported patient safety incidents was significantly lower in the group with family involvement compared to the group without (incidents per 1,000 patient-days: 3.2 vs. 5.7; $p < 0.01$).
Further analysis revealed that the most common types of incidents were medication errors, falls, and documentation-related issues. In all categories, the frequency of incidents was consistently lower among patients whose families were actively involved in their care.
There were no significant differences in baseline demographics (age, sex, primary diagnosis) between the two groups, supporting the validity of the comparison. Statistical tests confirmed a significant association between family involvement and a reduction in patient safety incidents, suggesting a protective effect of family presence in the ICU.
Conclusion: This multicenter retrospective cohort study demonstrates a significant association between family involvement in ICU patient care and improved patient safety outcomes. Patients whose families were actively involved experienced fewer reported incidents, particularly in areas such as medication errors and documentation issues. These findings support the integration of family-centered care models in intensive care settings as a strategy to enhance safety, promote transparency, and foster a culture of shared responsibility. Hospitals and policymakers should consider expanding policies that encourage and facilitate meaningful family participation in ICU care.

Intensive Care Medicine Experimental 2025,* 13(1)*:001108

Introduction: Neutrophil gelatinase-associated lipocalin (NGAL), a well-established biomarker for acute kidney injury1, has also been reported to be increased in patients with acute brain injuries (ABI)2,3 4; however, its prognostic roles in severe ABI patients remain poorly understood.
Objectives: In this study, we investigated the association between serum NGAL levels measured within 24 h and neurologic outcomes, aiming to evaluate its potential role as a biomarker in severe acute brain injury patients requiring ICU care.
Methods: The data were obtained from candidates admitted in Seoul National University Bundang Hospital from 23/01/01 to 24/12/31 enrolled in NCART-KR registry, a retrospective multicenter cohort of neurocritical units from 6 tertiary centers in South Korea. Patients with ABI (including TBI, SAH, ICH and Ischemic stroke) admitted within 72-h from onset without significantly elevated admission serum creatinine levels (> 4.0 mg/dL) or a history of renal replacement therapy (RRT) were included. Serum NGAL levels were measured within 24 h of ICU admission. The association between NGAL levels and ICU mortality was evaluated using the Cox proportional hazards model. Additionally, the relationship between admission Glasgow Coma Scale (GCS), NGAL levels, and ICU mortality was assessed using causal mediation analysis.
Results: Of the 275 ABI patients (mean age 66.3; male 51%; median GCS 12; ICH/IVH 36.0%, SAH 16.7%, TBI 25.5%, Ischemic stroke 21.8%), NGAL quartiles were evaluated as Q1: 62.9, Q2: 85.9, Q3: 122.8, and Q4: 3000. NGAL levels varies significantly by admission GCS: median NGAL was 76.0 for GCS 13–15, 80.7 for GCS 9–12, and 111.8 for GCS 3–8. Over a mean ICU stay of 9.9 days (SD 12.1), mortality occurred in 15% of patients. Risk of ICU death increased according to NGAL quartiles, with highest quartiles of NGAL significantly associated with ICU mortality (HR 5.57 [1.62–19.19], $p \leq 0.01$). On causal mediation analysis, NGAL quartiles were an independent predictor of ICU mortality (indirect effect $\beta = 0.013$, $p = 0.03$), mediating 7.1% of the total effect.
Conclusions: Elevated early serum NGAL levels are related with admission GCS and ICU mortality in severe acute brain injury patients, indicating its potential as a prognostic biomarker. Further research is needed to explore the pathophysiological mechanisms of NGAL in severe ABI.

Association between intensive care units design and patient safety in Saudi Arabia: a multicenter cross-sectional study

A. Abdelmaguid[1], A. Heikel[2], A. El Haddad[3], S. Basma[4]
[1]Critical care, Dr. Hamid S. Al-Ahmadi Hospital-ITC, Madinah, Saudi Arabia; [2]Critical care, Royal commission hos, yanbu, Saudi Arabia; [3]Critical care, Royal commission hosp, jubail, Saudi Arabia; [4]Research, Kasr al -Aini, cairo, Egypt

Correspondence: A. Abdelmaguid
Intensive Care Medicine Experimental 2025,* 13(1)*:001109

Introduction: The design of Intensive Care Units (ICUs) is a crucial yet often overlooked factor in enhancing patient safety and clinical outcomes. Environmental variables such as light intensity, noise levels, and room layout can significantly influence both patient recovery and the efficiency of healthcare providers. The research suggests that suboptimal ICU environments—characterized by poor lighting, high noise levels, and overcrowded or open-ward layouts—may contribute to higher rates of medical errors, staff fatigue, and compromised patient safety. For instance, inadequate lighting can hinder critical care tasks, while excessive noise may disrupt patient rest and elevate stress levels. Similarly, the configuration of ICU rooms (e.g., single-patient rooms versus open-ward setups) affects both patient comfort and staff workflow, which in turn can impact the quality of care delivered.
Although several studies have explored the impact of ICU design on staff well-being and patient satisfaction, a gap remains in the literature regarding the direct correlation between ICU design characteristics and patient safety outcomes—particularly in Saudi Arabia. This study aims to address that gap by investigating how specific ICU design features influence the frequency and nature of incidents reported to the Incident Reporting System (IRS). By identifying environmental factors that directly contribute to improved patient safety, this research seeks to provide valuable insights to inform the redesign of ICUs across Saudi hospitals, ultimately enhancing both patient care and operational efficiency.
Objectives: This study aims to evaluate the association between Intensive Care Unit (ICU) design features—specifically light intensity, noise levels, and room layout—and patient safety, measured by the frequency of incidents reported to the Incident Reporting System (IRS) in CBAHI-accredited hospitals across Saudi Arabia.
Methods: A multicenter cross-sectional study was conducted from October 2024 to February 2025 in five CBAHI-accredited private hospitals in Saudi Arabia. ICU design characteristics—including light intensity (measured in Lux using Extech SDL400 light meters), noise levels (measured in decibels using a microphone array), and room layout (open ward vs. single-patient rooms)—were assessed through standardized surveys and environmental measurements. Incident data were extracted from each hospital's Incident Reporting System (IRS), including the number and type of incidents, along with basic patient demographics. A total of 674 patient reports were analyzed. Statistical analysis included descriptive statistics, t tests, ANOVA, chi-square tests, correlation analysis, and multivariable linear regression to evaluate the association between ICU design features and incident frequency.
Results: A total of 674 ICU patient reports were analyzed across five hospitals. ICUs with higher light intensity (> 300 Lux) reported significantly fewer incidents (mean = 4.3/month) compared to those with lower lighting (< 150 Lux; mean = 7.8/month, $p = 0.003$). Similarly, ICUs with lower average noise levels (< 55 dB) experienced fewer incidents (mean = 3.9/month) than those with higher noise levels (> 65 dB; mean = 8.1/month, $p < 0.001$). Single-patient room ICUs showed a 35% lower incident rate (mean = 4.5/month) compared to open-ward ICUs (mean = 6.9/month, $p = 0.01$). Regression analysis confirmed that increased light intensity ($\beta = -0.42$, $p = 0.006$), reduced noise ($\beta = 0.61$, $p < 0.001$), and single-patient room layout ($\beta = -0.33$, $p = 0.02$) were significant independent predictors of lower incident rates.
Conclusions: ICU design characteristics—specifically higher light intensity, lower noise levels, and single-patient room layouts—are significantly associated with reduced incident rates, indicating improved patient safety. These findings underscore the importance of integrating evidence-based environmental design principles into ICU planning and renovation strategies. Optimizing ICU environments have the potential to enhance the safety outcomes for patients, families, and healthcare professionals in critical care settings.

Intensive Care Medicine Experimental 2025,* 13(1)*:001110

Introduction: Global population aging is a reality that impacts our daily clinical practice. Treatments must be adapted to these specific patient's characteristics, including any invasive therapy they received.
Objectives: To describe invasive treatment applied to elderly population in our intensive care unit (ICU), analyzing vasoactive support (VAS), invasive mechanical ventilation (IMV) and continuous renal replacement therapy (CRRT), as well as mortality rates. We define the elderly population as those patients aged 75 years and older, according to the World Health Organization's definition.
Methods: Retrospective observational study of elderly patients admitted in our ICU between January 1st, 2022 and December 31st, 2023. It is a multipurpose ICU with 12 beds. Demographic characteristics, reasons for ICU admission, severity (APACHE II), application of invasive

therapies (VAS, IMV, CRRT), as well as overall mortality and mortality within each group receiving invasive therapy are analyzed.
Results: During the study period, 979 patients were admitted to our ICU. 166 (16.95%) were over 75 years old (y.o). 94 were males (56.62%). The mean age was 80.31 y.o (95% CI 79.63–80.98), with a median of 79 and a mode of 78. The most common medical histories were hypertension in 126 patients (75.90%), dyslipidemia in 102 (61.44%), diabetes mellitus in 59 (35.54%) and obesity in 33 (19.88%. The most frequent reasons for ICU admission were postoperative control (POP) in 43 patients (25.90%), atrioventricular block (AVB) in 32 (19.27%), septic shock in 25 (15.06%), and acute coronary syndrome (ACS) in 15 (9.03%). The mean APACHE II score was 18.63 (95% CI 17.46–19.81); the average length of stay was 5.59 days (95% CI 4.18–7.02).
The overall survival rate was 59 patients (35,54%). 142 (85.55%) survived in the ICU, 126 (75.90%) one month postdischarge, and 123 (74.10%) one year later. 69 patients (41.57%) received VAS. Survival in this group was 45 patients (65,22%) in the ICU, 38 (55,07%) at one month postdischarge and 32 (46,38%) at one year. 59 patients (35.54%) recieved IMV, with 37 (62,71%) patients surviving in ICU, 28 (47,45%) in one month postdicharge and 27 (45,76%) in one year. 19 patients (11.44%) received CRRT, with 8 (42,10%) patients surviving in ICU, and 5 (26,32%) survivors at first month postdischage and at one year.
Conclusions: Older patients represented 16.95% of admissions to our ICU. The survival rates was 85.55% in the ICU, 75.90% one month postdischarge, and 74.10% one year later. The survival rate for patients who received invasive therapy was 65.22% in the ICU, 55.07% one month postdischarge, and 46.38% one year later.
Therefore, while age should be a characteristic to consider, it should not be a limiting factor when applying invasive measures; however, these measures should be tailored to the individual characteristics of each patient.

Empowering infectious disease-led Stewardship in ICU: reducing MDROs through targeted intervention in a tertiary-level eastern European center

F. Berisha[1], B. Zogu[2], N. Hasani[1], B. Zenelaj[1], J. Krasniqi[1]

Intensive Care Medicine Experimental 2025,* 13(1)*:001111

Introduction: ICUs are epicenters for multidrug-resistant organisms (MDROs), where antimicrobial overuse intersects with immunocompromised hosts. While antibiotic stewardship programs (ASPs) are well-established in high-resource ICUs, their implementation in resource-limited, infectious disease-led units remains underreported. Our ICU, led by infectious disease specialists, implemented a focused ASP to address high MDRO burden and optimize antimicrobial use.
Objectives: To assess the clinical and operational impact of a structured ASP and infection control protocol, led by infectious disease physicians, on antibiotic use, MDRO incidence, and patient outcomes in an Eastern European tertiary infectious disease ICU.
Methods: We conducted a prospective, quality improvement initiative from Jan 2023 to Mar 2025. Core interventions included:
1) Daily real-time antibiotic prescription auditing and feedback;
2) Multidisciplinary ICU rounds with infectious disease specialists, pharmacists, and microbiologists;
3) Reinforcement of infection control protocols (hand hygiene, contact isolation, staff re-education).

Primary outcomes: inappropriate antibiotic use, MDRO infection rate, ICU length of stay, mortality.
Results: Among 214 patients admitted during the study period, inappropriate antibiotic use decreased from 47 to21% ($p < 0.001$), and MDRO infections dropped by 30%. ICU length of stay decreased by 1.8 days. Qualitative feedback from staff highlighted increased awareness and adherence to stewardship guidelines. The model proved sustainable with minimal external support.
Conclusions: Infectious disease-led stewardship programs can yield significant reductions in antimicrobial misuse and resistance, even in resource-constrained ICUs. Our experience highlights the power of multidisciplinary collaboration, real-time feedback, and targeted interventions. This model may serve as a blueprint for similar units in Eastern Europe and beyond.

Intensive Care Medicine Experimental 2025,* 13(1)*:001112

Introduction: Patients with acute severe respiratory failure receiving veno-venous extracorporeal membrane oxygenation (VV-ECMO) have high mortality risk. Management of the process of VV-ECMO withdrawal is challenging, especially in awake patients. Yet there is no guidance to guide clinicians to manage these morally distressing and ethically ambiguous decisions.
Objectives: To establish consensus recommendations for management of the process of VV-ECMO withdrawal to reduce practice variability and improve care quality.
Methods: Our process for generating recommendation statements for consideration at our consensus meeting included semi-structured interviews and a scoping review. We recruited healthcare professionals with experience in VV-ECMO withdrawal to participate in interviews and a consensus meeting led by an independent facilitator. Using modified nominal group technique, participants discussed and voted on statements, categorising them as essential, desirable, or not required. A subsequent voting round identified key priorities for future research.
Results: During our item generation process we interviewed 12 healthcare professionals with VV-ECMO expertise and identified 41 publications (21 empiric studies and 20 opinion pieces) focused on ECMO withdrawal. We developed 16 recommendation statements from these data, of which 17 participants representing 7 UK ECMO centres considered 8 as essential, 6 desirable, 1 not required; 1 was without consensus. The three priority areas for future research were developing a standardised framework for managing disagreements; creating tools to enhance communication and documentation of information provided; and designing quality improvement strategies to ensure consistency in the clinical and technical aspects of VV-ECMO withdrawal.
Conclusions: Using rigorous methods, we have established consensus on eight essential and six desirable recommendations for management of VV-ECMO withdrawal and three future research priorities.

These recommendations should be considered the foundations of a framework to facilitate a standardised approach to support patients, family members and clinicians through this challenging clinical situation.

Intensive Care Medicine Experimental 2025,* 13(1)*:001113

Introduction: The early identification of sepsis-related mortality risk is critical, particularly in resource-limited settings. The quick Sequential Organ Failure Assessment (qSOFA) score, combining respiratory rate, mental state, and systolic blood pressure, is a simple clinical tool validated in various environments, including emergency departments and intensive care units (ICUs). However, its low sensitivity has raised concerns. Lactate, a byproduct of anaerobic metabolism, is associated with sepsis severity and has shown promise as a diagnostic and prognostic marker. Elevated lactate levels significantly increase mortality risk in septic patients. Combining lactate measurements with qSOFA score into a Lactate-enhanced qSOFA (LqSOFA) score may enhance sepsis recognition and mortality risk assessment, offering a more effective strategy for bedside evaluations than using qSOFA alone.
Objectives: This study aimed to compare the accuracy of the LqSOFA score with the qSOFA score in predicting mortality among ICU patients with sepsis in a lower-middle-income country.
Methods: We conducted a multicentre cross-sectional study of septic patients (≥ 18 years old) presenting to 15 adult ICUs across Vietnam on four specific dates—January 9th, April 3rd, July 3rd, and October 9th—representing different seasons in 2019. We calculated the areas under the receiver operator characteristic (ROC) curve (AUROC) to evaluate the predictive capacity of the LqSOFA and qSOFA scores for hospital mortality at the time of ICU admission. We utilized ROC curve analysis to determine the optimal cutoff values for each score, and Z statistics were employed to assess differences in AUROC for predicting hospital mortality. Finally, logistic regression analyses identified the association of the LqSOFA and qSOFA scores with hospital mortality.
Results: Of the 200 patients, 62.0% were men, the median age was 65 years (Q1–Q3: 53.25–77.75), and 39.0% died in the hospital. The LqSOFA score demonstrated poor discriminatory ability for hospital mortality (AUROC: 0.653 [95% confidence interval, CI 0.576–0.730]; cut-off value: ≥ 2.5; sensitivity: 75.6%; specificity: 47.5%; PAUROC < 0.001). Similarly, the discriminatory ability of the qSOFA score exhibited poor discriminatory ability for hospital mortality (AUROC: 0.613 [95% CI 0.533–0.694]; cut-off value: ≥ 2.5; sensitivity: 33.3%; specificity: 84.4%; PAUROC = 0.007). The AUROC curves of the LqSOFA and qSOFA scores showed a significant difference in predicting hospital mortality (AUROC difference: 0.040; 95% CI 0.007–0.073; Z-statistic: 2.38; $p = 0.017$). The multivariable analyses, with the same set of confounding factors, revealed that a LqSOFA score ≥ 2.5 (adjusted odds ratio [AOR]: 2.697; 95% CI 1.359–5.354; $p = 0.005$) and a qSOFA score ≥ 2.5 (AOR: 3.145; 95% CI 1.442–6.858; $p = 0.004$) were independently associated with an increased risk of hospital mortality.
Conclusions: This study examined a selected cohort of septic patients with a high mortality rate admitted to ICUs across Vietnam. Both the LqSOFA and qSOFA scores were valuable for predicting mortality; however, the LqSOFA score demonstrated significantly better accuracy and higher sensitivity than the qSOFA score. Despite this, both scores showed poor discriminatory ability in predicting mortality outcomes. These findings underscore the need for further research to develop new scoring systems that can enhance the accuracy of predicting outcomes for septic patients.

Increasing the reflection efficiency of the Sedaconda ACD-S by thermocycling using sevoflurane in a bench study

D. Kellner, I. Camyurdu, K. Scheffler, T. Volk, A. Meiser, F. Albrecht
Department of Anesthesiology, Intensive Care and Pain Therapy, Saarland University Medical Center and Saarland University Faculty of Medicine, Homburg, Germany
Correspondence: D. Kellner
Intensive Care Medicine Experimental 2025,* 13(1)*:001114

Introduction: Inhaled sedation of intensive care patients using Sedaconda ACD-S is widely used. Volatile anaesthetics like sevoflurane are potent greenhouse gases, making it more environmentally sustainable to minimize their consumption and contribute to green anaesthesia [1].
Objectives: This study aims to identify the optimal temperature difference between clinical conditions and thermocycling (periodic cooling and heating of the reflector) to enhance reflection efficiency [2] in 5 °C steps.
Methods: Sevoflurane was administered to the ACD-S via a syringe pump at infusion rates of 0.5, 1, 2, 5 and 10 ml/h.
A test lung, maintained under BTPS and normocapnic conditions, was ventilated (IPPV, tidal volume = 500 ml, respiratory rate = 12/min, FiO2 = 0.21). BTPS conditions were achieved by filling the test lung with 100 ml of distilled water and heating it in a water bath. The ventilation circuit between the test lung and the ACD-S was split into an inspiratory limb, heated to 37 °C using a humidifier, and an expiratory limb, where the gas was channelled through a copper tube in a freezer. The expiratory gas temperature was adjusted across six levels (26 °C to 1 °C in 5 °C steps) by controlling the freezer's cooling level, varying the copper tube's exposure, and insulating the tube (Fig. 1). Temperature at the expiratory limb before the ACD-S, as well as temperature, humidity, sevoflurane, and CO_2 concentrations inside the test lung were continuously monitored. Sevoflurane concentration was measured three times on different days for each temperature and infusion rate combination over a 5-min steady-state period. Reflection efficiency was calculated. In addition, a clinical baseline was measured with a shorter tube system.
Results: Intensified thermocycling led to increased sevoflurane concentration in the test lung at a constant infusion rate. An interpolation of the data shows, that in order to achieve a sevoflurane concentration of 1 Vol%, the infusion rate could be reduced from 5.75 ml/h under clinical conditions to 1.6 ml/h at the most intensified thermocycling, ID EST by 72% (Fig. 2). Reflection efficiency improved in a nonlinear fashion across all concentrations tested (Fig. 3).
Conclusions: Reflection efficiency increases with cooling intensity. The increase in efficiency follows a first order with the highest increase within the first few degrees and levels off at approximately 16 °C. Notably, even moderate thermocycling (5 °C steps) significantly impacts reflection efficiency, potentially simplifying cooling techniques and offering a more climate-friendly approach.

Patient-ventilator dyssynchrony induced by diaphragmatic paralysis: similarity to reverse triggering

G. Guidetti[1], M. Valdivia Marchal[2], N. Merino Pizarro[2], M. C. Bermúdez Ruiz[2], J. F. Martínez Carmona[1], J. M. Serrano Simón[2]
[1]Intensive Care Unit, Hospital Regional Universitario de Málaga, Malaga, Spain; [2]Intensive Care Unit, Hospital Universitario Reina Sofia, Córdoba, Spain

Intensive Care Medicine Experimental 2025,* 13(1)*:001115

Introduction: Reverse triggering (RT) is respiratory entrainment triggered by the ventilator usually in heavily sedated and attributed to reflexes phenomenon. RT is a cause of 'double breaths'; it is likely to be injurious for lung. We have observed a similar dyssynchrony during spontaneous ventilation modes in patients with diaphragmatic paralysis (DP). We hypothesized this could be generated due to a misbalance of transdiaphragmatic pressure.
Objectives: Our objective was to review tracings during PSV, obtained in patients with diaphragmatic paralysis, with consecutive efforts after initiating a ventilator breath, patient triggered, to describe this asynchrony and its characteristics.
Methods: Design. A prospective observational study at HU. R. Sofia, Córdoba; period September 2023–December 2024. Protocol was approved by the local ethics committee (Musc-Txp-23). We studied a group of patients mechanically ventilated (MV) during PSV, in whom we observed clinical signs thus as paradoxical (negative) swing abdominal wall, elevated hemidiaphragm on chest X-rays, and they did not wean after 7 days of controlled mechanical ventilation.
Data acquisition. Transdiaphragmatic pressure (Pdi) and its components, gastric pressure (Pga) and esophageal pressure (Pes) were registered, as well as airway and tracheal pressures (Paw, Ptra) and flow. Sampling 1126 Hz. Ten respiratory cycles were averaged for calculations.
Measurements: Respiratory mechanics (Elastance and resistances of respiratory system, Ers and Rrs), DPgas/Pes. Assesment of the dyssynchronie: Angle phase (Ø)of coupling between ventilator breath – patient triggered- and consecutive effort, coefficient of variation (CV), and frequency of appearance of asynchrony.
Data were analyzed by descriptive statistical methods and are expressed as mean ± SD, medians, and the IQR, frequency and percentages.
Results: Patients: N 12. Unilateral paralysis 10, 83.3%. Male: 9 (75%). Age 62 (55.75–65) years. Diagnosis: Trauma 2 (16.6%), lung transplant 10 (83.3%). MV at inclusion 15.5 (7–27.5) days. Respiratory components: Ers 20.9 (18.3–25.7) cmH2O/L; Rrs 12 (9.8–14.1) cmH2O/L/s. DPdi 7.3 (4–9) cmH2O. D Pgas/Pes 0.6 (−0.2 to −0.7) cmH2O. Inspiratory pressure 13.5 (10–15), PEEP 6 (5–7.3) cmH2O. Coupling dyssynchrony: Ø = 67.5 ± 28.4°. CV = 33.7 ± 16.8%. Ratio 1/1 (51.7%) in high support; coexisting 2/1, 3/1 (74.5%) and variable in medium and low support. Double cycling 33%. A representative case is shown in the figure.
Conclusions: Dyssynchronies can occur during spontaneous ventilation modes in patients with DP, particularly unilaterally. This asynchrony resembles RT; however, occurs after patient-initiated effort with wide coupling variability, which could be attributed to paradoxical diaphragmatic movement. We could adopt the term pseudo reverse-triggering to describe this phenomenon.

Representative case of apparent reverse triggering ratio 1/1 at two levels of pressure support ventilation. Traumatic right diaphragm paralysis in a male 65-year. Tracing of airway pressure (Paw), esophageal (Pes), gastric (Pgas), and transdiaphragmatic (Pdi) pressure; flow and volume. Note the depression of Pgas during inspiration, active expiration, and low amplitude transdiaphragmatic pressure. Two ventilatory impulses are appreciated during inspiration; the first can be induced by active expiratory release, the second by changes in transdiaphragmatic pressure (imbalance between the paretic and patent diaphragm). The angular phase of the asynchrony and its coefficient of variation are shown.

Representative case.

The role of the intensivist in the emergency room: a single-center experience from a peripheral hospital

M. B. Dias Vieira, M. Almeida, B. Cunha, E. Ribeiro, M. Melo, A. Oliveira
Intensive Care Unit, Unidade Local de Saúde da Região de Aveiro, Aveiro, Portugal
Correspondence: M.B. Dias Vieira
Intensive Care Medicine Experimental 2025,* 13(1)*:001118

Introduction: Intensivists are trained to manage the full spectrum of critical illness, both within and beyond the boundaries of the Intensive Care Unit (ICU). The concept of an "ICU without walls" reflects this comprehensive approach, emphasizing a care model that prioritizes the clinical needs of the patient over their physical location within the hospital. Nevertheless, the role of intensivists in the Emergency Department (ED) is often limited, with early decision making frequently led by other specialties. Some authors advocate for the early involvement of intensivists in the care of acutely ill patients in the Emergency Room (ER), suggesting that this may help prevent clinical deterioration and reduce the need for ICU admission. At our hospital, the Intensive Care Department has been responsible for the management of the ER since 2021. Owing to constraints in human resources within the ICU medical team, full-time intensivist coverage in the ER has so far only been feasible during daytime hours (8am to 8 pm). During the night shift, emergency care is provided by teams from Internal Medicine and General Surgery, with intensivists available for consultation and patient assessment upon request. The stroke fast track protocol, available 24 h a day in our ER, is managed by neurologists and Internal Medicine physicians.
Objectives: The aim of this study is to characterize the activity of the ICU medical team as first-line responders in the initial assessment and management of patients admitted to the ER and subsequently to the ICU.
Methods: A retrospective study was conducted using the data from electronic medical records of adult patients admitted to the ER of the ED and subsequently to the ICU in a peripheral hospital, between January and June 2024.
Results: During the first semester of 2024, a total of 1086 patients were admitted to the ER, 783 during daytime hours and 300 during the nighttime. A total of 818 patients (75%) were referred directly from the triage area, where the Manchester Triage System is applied, while the remaining 268 were referred from other areas of the ED or the hospital. Among the triage group, 129 patients (15.7%) were classified as red priority, 400 (48.9%) as orange, and 289 (35.3%) were admitted via

the stroke fast track pathway. Of the 1086 patients, 625 (57.6%) were assessed by intensivists at the time of admission. During this period, a total of 223 ICU admissions were registered, with 198 patients (89%) being directly referred from the ER following initial assessment by the intensivist. Among these ER-to-ICU admissions, 140 patients (71%) were medical, 45 (23%) surgical, and 13 (6%) trauma-related. Most of these ICU admissions occurred within 2–4 h of ER arrival, with patients already receiving targeted and/or invasive therapies upon transfer. The most common primary diagnoses were septic shock (32%), altered mental status or coma due to acute neurological injury (15%), trauma-related sequelae (7%), postcardiac arrest neuroprotection (6%), intoxications (3%), diabetic ketoacidosis (2%), and hemorrhagic shock (2%). The average ICU length of stay was 6.3 days for patients admitted from the ER, compared with 11.3 days for those admitted from other departments. A total of 49 deaths occurred in the ICU during this period, 41 of which (84%) involved patients admitted directly from the ER, corresponding to a mortality rate of 20% in this subgroup (41/198). Among patients admitted to the ICU from other departments, 8 deaths were reported, representing a higher mortality rate of 32% (8/25).

Conclusions: This study highlights the importance of the physical presence of intensivists in the ER, aiming to ensure the early initiation of therapeutic interventions—particularly invasive procedures—in critically ill patients, especially in resource-limited hospitals. This approach facilitates continuity of care for those requiring subsequent admission to the ICU. Overall, our team's experience suggests that this strategy contributes to resource optimization, reduced waiting times, prompt evaluation of ICU admission criteria, and the multidisciplinary establishment of treatment ceilings. Looking ahead, we aim to secure the necessary human resources to provide full coverage of the ER during night shifts.

Intensive Care Medicine Experimental 2025,* 13(1)*:001121

Introduction: Neurological sequelae following cardiac arrest (CA) have a significant impact on patients' quality of life, especially in those who survive but remain comatose. Early identification of patients with poor neurological prognosis is crucial to guide therapeutic decisions, enabling a more personalized and effective approach to their management.

Objectives: This study focuses on evaluating neurological prognostic factors in comatose patients after resuscitated CA, using diagnostic tools such as electroencephalogram (EEG), somatosensory-evoked potentials (SSEPs), cranial computed tomography (CT), transcranial Doppler ultrasound, and biomarkers like neuron-specific enolase (NSE).

Methods: This retrospective study included adult comatose patients following resuscitated CA, admitted to a 16-bed ICU between 2014 and 2024. Patients who died within the first 24 h or regained consciousness within the first 72 h were excluded. Collected data included clinical, biochemical, and neurodiagnostic variables. Neurological outcomes were assessed at 6 months using the Cerebral Performance Category (CPC) scale.

Descriptive statistics were used for quantitative variables (mean ± SD or median [IQR]) and qualitative variables (frequencies and percentages). Associations between prognostic variables and neurological outcomes were evaluated using the Chi-square test for qualitative variables and Student's t test for quantitative ones. A p value < 0.05 was considered statistically significant.

Results: During the study period, 50 patients were included, median age of 64 years (48–76); 62% were male. CA was respiratory in 40%, cardiac in 34%, and 64% were out-of-hospital arrests, with the most frequent initial rhythm being asystole/PEA (78%). The CA was witnessed in 94% of cases, and the mean time to return of spontaneous circulation (ROSC) was 20 ± 15 min.

The key clinical and biochemical parameters included: admission troponin level of 0.29 ng/ml (0.06–0.66), peaking at 1.12 ng/ml (0.59–14.38); admission pH of 7.14 ± 0.13; and lactate 7.79 ± 6.16 mmol/L. NSE at 24 h was 43 ng/ml (21–73), increasing to 91 ng/ml (63–212) at 72 h.

Common complications included early pneumonia (36%), cardiogenic shock (26%), and need for high-dose vasopressors (> 0.5 mcg/kg/min of norepinephrine) in 32%.

Neurodiagnostic findings indicating poor prognosis included: severe diffuse cerebral edema on CT at 48 h in 35% of cases; brain herniation in 2%. EEG at 72 h revealed nonconvulsive status epilepticus in 19%, nonspecific diffuse slowing in 51%, and severe generalized encephalopathy in 24%. Bilateral absence of N20 response in SSEPs was observed in 50%. Transcranial Doppler showed reverberating flow in 30% and systolic spikes in 60%. In addition, 20% exhibited myoclonus after 48 h; 56% had absent or extensor motor response at 72 h; 34% lacked pupillary reflexes at 72 h.

In-hospital mortality was 78%, with an ICU mortality rate of 58%. Post-anoxic encephalopathy was present in 84%, and 20% progressed to brain death. At 6 months, functional outcomes were: CPC 1–2 (good recovery/moderate disability) in 8%, CPC 3 (severe disability) in 8%, and CPC 4–5 (persistent coma/death) in 84%.

Significant correlations between CPC and prognostic variables included: ROSC duration (r = 0.36, p = 0.01), Lactate > 4 mmol/L (r = 0.36, p = 0.01), absent/extensor motor response (r = 0.37, p = 0.01), EEG findings (r = 0.8, p = 0.01), combination of multimodal tests (EEG, SSEPs, CT, Doppler) (r = 0.63, p = 0.01).

Conclusions: The results of this study highlight the importance of early neurological assessment in postcardiac arrest patients to guide therapeutic decisions. Despite the high in-hospital mortality observed, the survivors who achieved favorable functional recovery were exceptional. Multimodal diagnostic tools, such as EEG, SSEPs, and CT, proved to be the key in differentiating patients with a favorable neurological prognosis from those with irreversible damage. These findings suggest that integrating these tests within the first 72 h could not only improve the accuracy of prognosis prediction but also allow for greater personalization in patient management, optimizing resources and supporting more informed decision-making.

Intensive Care Medicine Experimental 2025,* 13(1)*:001122

Introduction: Critically ill patients are highly susceptible to difficult-to-treat (DTR) infections caused by Gram-negative bacteria (GNB). In recent years, four novel β-lactam/β-lactamase inhibitor (BLBLI) combinations—ceftolozane–tazobactam (C/T), ceftazidime–avibactam (CAZ-AVI), imipenem–relebactam (IMI/REL), and meropenem–vaborbactam (MER/VAB)—have been developed and approved for the treatment of selected DTR-GNB infections.
Objectives: To evaluate the clinical cure rates and 28-day mortality following treatment with the newly approved BLBLIs in critically ill patients with GNB infections, as well as to assess associated adverse events.
Methods: A retrospective analysis was conducted on 118 cases of GNB infections in patients admitted to the intensive care unit (ICU) between January 2024 and January 2025 who received at least one of the novel BLBLIs. Patient demographics, comorbidities, type of infection and causative pathogens, presence of sepsis or septic shock, and disease severity scores (APACHE II, SOFA, and Charlson Comorbidity Index [CCI]) were recorded.
Results: Of the 118 infections reviewed, 76 cases were included in the final analysis; 42 were excluded due to pathogen susceptibility falling outside the BLBLI activity spectrum. Among the 76 patients analyzed, 50 (65.8%) were male, with a mean age of 59.3 ± 16.7 years. The mean APACHE II, SOFA, and CCI scores were 20.3 ± 8.1, 6.9 ± 3.36, and 3.63 ± 2.38, respectively. Sepsis was present in 81.6% of patients, and 54% met criteria for septic shock. The most common infections were ventilator-associated pneumonia (VAP) and hospital-acquired pneumonia (HAP) (57.9%), followed by primary bacteremia (11.84%), complicated intra-abdominal infections (10.53%), secondary bacteremia (7.9%), and complicated urinary tract infections (3.95%). *Pseudomonas aeruginosa* (56.6%) and *Klebsiella pneumoniae* (35.2%) were the predominant pathogens. CAZ-AVI was the most frequently prescribed BLBLI (51.3%), followed by C/T (19.7%), IMI/REL (17.1%), and MER/VAB (11.8%).
The overall clinical cure rate was 73.68%, and the 28-day mortality rate was 18.42% (Fig. 1). Subgroup analysis revealed clinical cure rates of 73.68%, 93.35%, 61.54%, and 88.9% for CAZ-AVI, C/T, IMI/REL MER/VAB group, respectively. Corresponding 28-day mortality rates were 20.51%, 6.7%, 30.8%, and 11.11%, for each group, respectively (Fig. 1). The most commonly reported adverse events were acute kidney injury (7.63%), acute liver failure (0.85%), and *Clostridium difficile* enterocolitis (3.39%).
Conclusions: Novel BLBLIs demonstrate high clinical efficacy in the treatment of severe infections in critically ill patients. Mortality rates observed in this cohort are consistent with the existing literature. Further prospective studies are warranted to confirm these findings and to optimize the use of these agents in critically ill populations.

28-day mortality and clinical success rates in whole study group and BLBLIs groups separately.

Machine learning-derived temperature trajectories identify coagulation phenotypes in sepsis: a multicenter analysis

R. Zhang, L. Lei
Department of Critical Care Medicine, Ruijin Hospital, Shanghai Jiao Tong University School of Medicine, Shanghai, China
Correspondence: R. Zhang
Intensive Care Medicine Experimental 2025,* 13(1)*:001125

Introduction: Sepsis-induced coagulopathy ranges from mild coagulation activation to disseminated intravascular coagulation (DIC), significantly impacting outcomes. The current diagnostic approaches lack precision in predicting individual patient trajectories. This study explores temperature trajectories as digital biomarkers to identify distinct coagulation phenotypes in sepsis patients across multiple cohorts (MIMIC-IV, eICU, and local validation). We investigate phenotype-specific coagulation profiles, predictors of phenotype membership, and differential responses to anticoagulation therapy, aiming to enable more personalized management approaches. The research represents the first large-scale validation of temperature trajectory-based coagulation phenotypes in sepsis.
Objectives: Sepsis-induced coagulopathy exhibits significant heterogeneity, challenging precise risk stratification and targeted treatment. We hypothesized that machine learning-derived temperature trajectories could identify distinct coagulation phenotypes with prognostic and therapeutic implications.
Methods: In this multicenter retrospective study, we analyzed 1,542 sepsis patients from three cohorts: MIMIC-IV (n = 533), eICU (n = 238), and a local validation cohort (n = 771). Using dynamic time warping and unsupervised clustering of temperature measurements during the first 48 h of ICU admission, we identified temperature trajectory phenotypes and evaluated their association with coagulation parameters, clinical outcomes, and response to anticoagulation therapy.
Results: Four distinct temperature trajectory phenotypes were identified: normothermic (42.3%), hypothermic (16.8%), hyperthermic (23.7%), and fluctuating (17.2%). The hypothermic phenotype demonstrated the most severe coagulation abnormalities with rapid platelet

decline (−5.63 × 10^9/L/h), elevated INR (median 1.8, IQR 1.4–2.3), and highest 28-day mortality (38.9%). Age was the dominant predictor of phenotype development (SHAP feature importance 0.718). External validation confirmed the reproducibility of these phenotypes with consistent coagulation profiles across all cohorts (calibration slope 0.94, 95% CI 0.88–1.01). Treatment-response analysis revealed that therapeutic anticoagulation was associated with reduced mortality in the hypothermic phenotype (adjusted OR 0.68, 95% CI 0.52–0.89) but not in the normothermic phenotype (adjusted OR 0.94, 95% CI 0.76–1.18; interaction $p = 0.03$).

Conclusions: Temperature trajectories identify distinct coagulation phenotypes in sepsis with differential response to anticoagulation therapy. These digital biomarkers may enable precision approaches to coagulation management in sepsis.

Mechanical power as a predictive tool for clinical outcome in ventilated patients: a prospective observational study in an onco-critical care unit (MePoVent study)

S. Mukherjee, M. Paul, P. S. Ghosh, A. Yadav
Critical care medicine, tata medical center, Kolkata, India
Correspondence: S. Mukherjee
Intensive Care Medicine Experimental 2025,* 13(1)*:001126

Introduction: Prevention of ventilator induced lung injury is the key goal in intensive care unit (ICU). Low tidal volume ventilation is the standard intervention in lung protective strategy. However, mechanical power as a predictor of lung injury and clinical outcome has evolved recently with heterogenous results.

Objectives: The aim of the study is to evaluate the impact of mechanical power on the clinical outcome in mechanically ventilated patients who has undergone Open lung ventilatory (OLV) strategy. Primary objective is difference in mechanical power between 28 days survivors and non-survivors. The secondary objectives are difference in 28-day ventilator-free days, 28-day ICU-free days, need for rescue (prone) ventilation and incidence of other organ failure.

Methods: This is a prospective observational study done in the medical ICU of Tata Medical Center Kolkata. After obtaining IRB clearance, patients requiring mechanical ventilation more than 24 h have been included in the study. Mechanical ventilation has been continued as per standard OLV strategy. All the necessary data were collected from the patients' files and electronic medical records (EMR). Patients' clinical outcome was evaluated from the medical records in terms of mortality, ventilator days and ICU stay. Mean value of mechanical power was compared between survivor and nonsurvivors as primary objective. Similarly, patients' baseline clinical data, organ failure and other clinical outcomes were compared between the two groups.

Results: Over a period of 3 months, 54 patients have been recruited in the study period (male = 33, female = 21) (Table 1). Eleven patients in this cohort have lung cancer and rest 43 patients have other malignancy as their primary disease. 14 patients (2.6%) have chronic lung pathology on admission. Mean age of the population is 59.5 years. On ICU admission, mean APACHE 4 score was 86.2 and mean respiratory SOFA score was 2. Six patients are lost to follow up and we have outcome data for 48 patients. Twenty-seven patient (56%) have died during their ICU stay. The on-admission APACHE 4 score, chronic lung pathology, respiratory SOFA score and mean PaO2 / FiO2 ratio are comparable between the survivor and the non-survivor groups (Table 2). The mean value of mechanical power among the non-survivor group (32.29 J /min) was significantly higher compared to the survivor group (23.86 J/ min) ($p = 0.034$). This difference remains statistically significant even after weighted for APACHE 4 score on admission. There is no statistically significant difference in need for rescue ventilation, ventilator and ICU free days between survivor and non survivors (Table 3).

Conclusions: Mechanical power can be an important predictor of clinical outcome for mechanically ventilated patients, including mortality. We need randomized control trial on large patient population to validate our observation.

Table 1 (abstract 001126) Demographic profile of the patients

	Value	Percentage (%)
Total no of patients	54	
Mean age (Years)	59.5	
Male	33	61%
Female	21	39%
Lung cancer	11	20%
Non- lung cancer	43	80%
Chronic lung disease	14	26%
No lung pathology	40	74%
Mean APACHE 4 score	86.2	
Mean respiratory SOFA score	2	

Table 2 (abstract 001126) Severity of clinical condition on admission ($n = 48$)

	Survivors (n =21)	Non-survivors (n= 27)
APACHE 4 score*	86.17	86.3
Respiratory SOFA*	2	2
PaO2/ FiO2 ratio*	254.25	253.85

*Statistically non-significant

Table 3 (abstract 001126) Clinical outcome between survivors and nonsurvivors ($n = 48$)

	Survivors (n =21)	Non-survivors (n= 27)
Mechanical power (J / min)#	23.86	32.29
Ventilator free days*	11.01	10.43
ICU free days*	8.0	7.52

*Statistically non-significant

Deep learning-enhanced electrical impedance tomography for mechanical ventilation weaning prediction: a phenotype–trajectory integrated approach

R. Zhang[1], L. Yun[2], H. Huaiwu[3], Q. Hongping[1]
[1]Department of Critical Care Medicine, Ruijin Hospital, Shanghai Jiao Tong University School of Medicine, Shanghai, China; [2]Department of Critical Care Medicine, Peking Union Medical College Hospital, Beijing, China; [3]Department of Intensive Care Unit, Peking Union Medical College Hospital, Beijing, China
Correspondence: R. Zhang
Intensive Care Medicine Experimental 2025,* 13(1):*001127

Introduction: Predicting successful liberation from mechanical ventilation remains challenging despite advances in respiratory care. This study introduces a novel approach integrating dynamic phenotyping with temporal trajectory analysis using electrical impedance tomography (EIT) during 2-h spontaneous breathing trials (SBTs).
Methods: In this multicenter study (NCT06756204), we enrolled 278 mechanically ventilated patients from three tertiary hospitals. Our framework combines: (1) Pendelluft-driven phenotyping defining three clinical phenotypes (stable compensatory/occult decompensation/rapid failure); (2) Spatiotemporal trajectory modeling using attention-enhanced LSTM networks; and (3) Real-time risk stratification based on phenotype–trajectory coupling. EIT measurements (32 × 32 pixels, 50 Hz sampling) were continuously recorded during SBTs with synchronized respiratory mechanics monitoring.
Results: The machine learning model demonstrated superior predictive performance with an AUC of 0.85, significantly outperforming traditional clinical metrics which ranged from 0.65 to 0.71. Our analysis identified three distinct clinical phenotypes with markedly different outcomes. Although the stable compensation group represented 42.3% of cases with a relatively low failure rate of 12.8%, the rapid deterioration phenotype, although the smallest at 20.2%, showed the highest failure rate of 58.5%. The latent decompensation group accounted for 37.5% of cases with intermediate outcomes (34.6% failure rate). Feature importance analysis revealed ventilation heterogeneity as the most significant predictor (28.3%), followed by pendelluft phenomenon (21.7%) and regional compliance (18.4%). Notably, dorsal region activation scores showed dramatic differences between success and failure cases (0.31 vs 0.78, $p < 0.001$), providing physiological validation of the model's predictions. The model provided median early warning of 5.2 h (IQR: 4.1–6.3) before clinical deterioration. Implementation reduced ICU length of stay by 1.8 days ($p = 0.007$) and reintubation rates by 47% in the high-risk group.
Conclusions: Our dynamic phenotyping and trajectory analysis framework transforms mechanical ventilation weaning from a static decision point to a continuous risk-monitored process. By revealing the heterogeneous mechanisms of weaning failure and compensatory dynamics, this approach enables precision critical care medicine.

(abstract 001127) Performance comparison of different models description:this bar chart compares the AUC values of six different predictive models, including three machine learning methods (Deep Learning, Random Forest, XGBoost) and three traditional clinical metrics (RSBI, *P/F* ratio, CROP Index). The deep learning model achieved the highest AUC of 0.85, followed by XGBoost (0.78) and Random Forest (0.76). Traditional metrics showed lower performance, with RSBI scoring 0.68, *P/F* ratio 0.71, and CROP Index 0.65.

Comparative analysis of 2 community-based CPR/AED training programmes

M. Chia

Emergency Department, Tan Tock Seng Hospital, Singapore, Singapore

Correspondence: M. Chia

Intensive Care Medicine Experimental 2025,* 13(1):*001128

Introduction: Cardiopulmonary resuscitation (CPR) and automated external defibrillator (AED) can help save an out-of-hospital cardiac arrest (OHCA) victim if carried out and applied promptly and properly. The public must be taught to perform CPR effectively and to apply AED properly.

Poor learning and skill decay can lead to decline in CPR performance and improper or delayed application of an AED, that in turn, can affect the probability of victim survival.

Objectives: This study aims to explore whether the enhanced version of a dispatcher-assisted first responder (DARE) programme leads to improved learning and retention as compared to the current DARE programme (enhanced DARE programme utilises digital application called the "DARE Instructor App" to conduct the training, with enhanced components such as gamified testing of the cognitive learning via game-based learning platform such as Kahoot! and incorporation of a game at the end of the training session via QCPR race competition to allow learner to experience performing CPR in high-tension situations in an informal and fun way vs. current DARE programme which utilises the conventional way of teaching via classroom style lecture, using PowerPoint slides and training videos, followed by hands-on practice and a practical assessment at the end).

Methods: 21 participants with no CPR/AED training before or no training within the last 3 years were randomly assigned to the current DARE programme or the enhanced DARE programme.

Their CPR/AED knowledge was assessed via a post-training survey and an online knowledge retention assessment 42 days after the training.

Results: Mean score (total score out of 5) for the pre-training survey was 2.9 for the current DARE group and 3.7 for the enhanced DARE group. After training, mean score for the post-training survey was 4.3 for the current DARE group and full score of 5.0 for the enhanced DARE group. During knowledge retention assessment, mean score for the knowledge retention survey was 4.4 for the current DARE group and 4.6 for the enhanced DARE group.

Overall compression performance from QCPR Training Application was 89% for the current DARE group and 97% for the enhanced DARE group.

Participants in both programmes showed increased confidence and likelihood of performing CPR and using AED in real emergencies.

Participants in the enhanced DARE group achieved a higher mean score during the post-training and online knowledge retention assessment.

CPR compression performance data indicated that the participants in the enhanced DARE group achieved an overall higher compression performance.

Conclusions: The study showed that participants exposed to the enhanced DARE programme resulted in better knowledge, greater improvement in confidence and attitudes towards possible CPR/AED use in real emergencies, and better quality of CPR chest compression after training. However, both programmes did not result in better knowledge retention 42 days after.

Intensive Care Medicine Experimental 2025,* 13(1):*001131

Introduction: Intrahospital cardiopulmonary arrest (IHCA) is a critical event with high morbidity and mortality in resource-limited settings.

Objectives: This study determines causes, outcome of cardiopulmonary resuscitation (CPR) of IHCA and their associated factors in Democratic Republic of Congo (DRC).

Methods: This is an 18 months prospective cohort study conducted in North-Kivu Province at HEAL Africa and Kyondo hospitals. 84 adult patients who sustained IHCA were included in the study. We analyzed data by SPSS version 26 using the Pearson Chi-square test or Fisher's exact test and multinomial regression. The $p < 0.05$ was considered statistically significant.

Results: IHCA was common in men (58.3%), the mean age of patients was 57.7 years (± 17.1). IHCA was triggered by a combination of several reversible causes (39.3%) and isolated hypoxia (33.3%). Most patients had various diagnosis (45.2%) and cardiovascular diseases (28.6%). Emergency Point of Care was performed in 42.9%. Metabolic acidosis was observed in 50%. Hyponatremia and hyperkalemia were the most common electrolyte disturbances encountered in IHCA. The National Emergency Warning Score 2 (NEWS2) was assessed in 52.4%. 51.2% had a NEWS2 score ≥ 5. In 41.6% the alert was launched after CA. 47.6% of CPR was initiated between 1 and 4 min. Half of life-threatening distressed patients were monitored by a multiparameter monitor. Asystoly was noted in 83.3%. Advanced CPR with intubation was performed in 45.2%. The rate of return of spontaneous cardiac activity (ROSC) after IHCA was 42.9%. The determinants of ROSC were marital status and weekend resuscitation. The survival rate on the thirtieth day was 6%. Three over 5 patients had a complete recovery on the thirtieth day.

Conclusions: IHCA in North-Kivu is triggered by reversible causes and often occurs in patients with multiple combined and cardiovascular diseases. Early detection and prevention measures of IHCA are still limited. The high ROSC rate has paradoxically a very low survival rate at day 30 after IHCA. Advanced Cardiac Life Support training and

implementation of a Rapid Response Team are essential to improve prevention and management of IHCA in the DRC.

Comparative performance of pediatric risk of mortality IV and pediatric index of mortality 3 in critically ill children with cancer: a prospective observational study

S. Bhosale, K. Kushal, K. Atul
Critical Care Medicine, TATA MEMORIAL Centre, Homi Bhabha Block, Mumbai, India
Correspondence: S. BHOSALE
Intensive Care Medicine Experimental 2025,* 13(1)*:001132

Introduction: In pediatric critical care, Pediatric Risk of Mortality (PRISM) and Pediatric Index of Mortality (PIM) scoring systems are the most widely used severity of illness scoring systems. The current versions of these scoring systems (PRISM IV and PIM 3) have not been validated in critically ill oncology population.
Objectives: The aim of this study was to evaluate the comparative performance of Pediatric Risk of Mortality IV and Paediatric Index of Mortality 3 in Critically Ill Children with cancer.
Methods: 415 critically ill pediatric patients were recruited at a single-center, mixed medical-surgical ICU in a prospective observational study. Patients with an expected ICU stay of greater than 24 h were included. Demographic, physiological and laboratory parameters required to calculate the PRISM IV and PIM 3 scores were collected; laboratory data from 2 h prior till 4 h after admission, and physiological data within 4 h of admission. The worst value was considered for calculating the scores. Both scores and their predicted mortality risk were calculated using online calculators.
Results: The mortality at ICU discharge and at hospital discharge was 32.7% and 36.1% respectively. For the prediction of hospital mortality, the AUROC for PRISM IV score was 0.71and PIM 3 estimated mortality (%) was 0.78 respectively. There was a statistically significant positive correlation between PRISM IV scoreand PIM 3 estimated mortality (%) with the hospital mortality. The logistic model for PRISM IV score also passed the goodness-of-fit test indicating a good model fit. The goodness-of-fit test for the PIM 3 model suggests that the model may not fit the data well and may require further investigation or improvement.
Conclusions: Both PRISM-IV and PIM-3 scores showed acceptable discriminative ability between survivors and nonsurvivors in critically ill pediatric oncology population. However, only the PRISM-IV score showed good calibration in the prediction of survival.

Intensive Care Medicine Experimental 2025,* 13(1)*:001133

Introduction: Acute brain injury is a major cause of mortality and neurological disability. A state of cerebral glucose hypo-metabolism, impaired glycolytic pathways and reduced glucose availability are typically presents in the postinjury period. Supplemental ketone bodies (KB) exert various neuroprotective properties in experimental settings of traumatic brain injury (TBI); however, only few clinical data are available in TBI and subarachnoid hemorrhage (SAH) patients.
Objectives: The aim of this study was to assess whether the administration of KB might reduce the energetic dysfunction following TBI and SAH, which is associated with poor long-term outcomes.

Methods: This is a prospective ongoing single-arm interventional pilot study including adult (> 18 years of age) and severe (Glasgow Coma Scale, GCS on admission < 9) consecutive TBI and SAH patients admitted to the intensive care unit (ICU), undergoing multimodal neuromonitoring, including cerebral microdialysis (CMD) as part of standard care. Energetic dysfunction was defined as a lactate to pyruvate ratio (LPR) > 25 for at least 3 consecutive hours within the first 5 days after injury. Ketone ester (KE) therapy was administered via nasogastric tube for 6 h (e.g. bolus of 500 mg/kg followed by 125 mg/kg/h for 6 h), aiming to maintain blood beta-hydroxybutyrate (BHB) around 3 mmol/L. Primary outcome was changes in LPR, glucose and glutamate measured by CMD from baseline to the end of KE administration.
Results: Among 46 screened patients, 14 (8 TBI and 6 SAH) were enrolled. Eleven patients were male (78.6%). The median age was 46 (IQR 31–61) years-old and the admission GCS was 5 (3–9). Three patients died in the ICU (21.4%) and 11 (78.6%) had an unfavorable outcome at 3 months, defined as a Glasgow Outcome Scale of 1 to 3. A significant increase in arterial blood BHB levels over time [from 0 (0–0.2) at baseline to 3.5 (3.5–3.2) mmol/L at the end of KE administration ($p = 0.001$)] was detected. There was a slight, yet not statistically significant, decrease in cerebral LPR over time during KE administration [from 37.5 (29.0–39.9) at baseline to 33.2 (29.9–38.4) after 6 h, $p = 0.17$]. Cerebral glucose did not change over time [from 1.35 (1.02–1.86) at baseline to 1.16 (1.04–1.87) after 6 h, $p = 0.89$]. Glutamate decreased over time during KE administration [from 4.04 (1.33–10.45) at baseline to 3.5 (0.94–12.88) after 6 h; $p = 0.06$].
Conclusions: These preliminary findings shown that administration of KE successfully increased serum levels of BHB and was associated with nonsignificant changes in interstitial metabolites.

Mechanical power vs driving pressure as a prognostic marker in severe ARDS due to Influenza A

Y. Bailach Cabrerizo[1], L. Sanchez Martín[1], J. D. Martínez Carmona[2], M. Mora Moreno[1], C. Garcia Lozano[1]
[1]Intensive Care Unit, Hospital Regional Universitario de Málaga, Malaga, Spain; [2]Cardiology Unit, Hospital Universitario Virgen de la Victoria, Málaga, Spain
Correspondence: J.F. Martínez Carmona
Intensive Care Medicine Experimental 2025,* 13(1)*:001134

Introduction: In patients with severe ARDS requiring invasive mechanical ventilation, the intensity of ventilation as reflected by driving pressure (DP) or mechanical power (MP) analysis has been shown to have a significant relationship with patient prognosis. PD values > 15 cmsH2O or MP > 17 J/min are associated with increased 28-day mortality as well as increased hospital stay.
Objectives: The aim of the study is to evaluate the relationship between DP and MP with prognosis in patients with severe Influenza A ARDS.
Methods: Retrospective study of patients admitted to the ICU between 2022 and 2025 for severe ARDS secondary to Influenza A with need for invasive mechanical ventilation. The Gattinoni formula was used to calculate MP in patients on volume controlled ventilation with constant flow and the Becher formula for patients on pressure-controlled ventilation. Variables collected: age, sex, comorbidity, APACHE II, SOFA on admission, duration of MV, ICU and hospital stay and mortality. Respiratory mechanics: DP (by pause method), MP, elastance of the respiratory system, PaO_2, PaO_2/FiO_2.
Results: A total of 18 patients was admitted for acute respiratory failure due to Influenza A, only 10 patients required invasive mechanical ventilation. 60% women, median age 52 years; 50% smokers; 30% immunocompromised and 30% with morbid obesity. Median MV duration 16 days; median ICU stay 26 days; mortality 10%. Respiratory mechanics during the first 7 days of invasive MV: mean MP 24.67 J/min; mean DP 12.17 $cmsH_2O$; mean elastance SR 27.75 cmsH2O/L. A multivariate analysis was performed, evaluating PM and PD separately, and no statistically significant relationship was observed between mortality, duration of MV or ICU/hospital stay. A linear relationship between PM and PD was observed in both models (p 0.005) con R20.7026 (p 0.034) and R2 0.7833 (p 0.016), respectively.
Conclusions: The analysis of respiratory mechanics is key in patients with severe ARDS.
We observed a significant correlation between DP and MP, however, we did not observe a significant relationship with mortality, MV duration or length of stay.

Short- and long-term outcomes in intensive care unit patients with acute kidney injury treated with renal replacement therapy: a retrospective cohort study

L. Plant, B. O'brien
Intensive Care Medicine, Cork University Hospital, Cork, Ireland
Correspondence: L. Plant
Intensive Care Medicine Experimental 2025,* 13(1)*:001136

Introduction: Acute kidney injury treated with renal replacement therapy (AKI-RRT) in intensive care units (ICU) is known to be associated with poor outcomes. Although data on ICU outcomes are readily available, in the Irish context published data on longer term outcomes of these patients is limited. This study aims to determine both the short- and long-term outcomes of AKI-RRT patients in a tertiary university hospital critical care units and to examine the factors associated with same.
Objectives: The objectives of this study were to determine the incidence of AKI-RRT in ICU patients, describe their demographics and characteristics, determine their outcomes in terms of mortality, dialysis dependence, renal recovery and Major Adverse Kidney Events (MAKE) at ICU discharge, hospital discharge, 90 days and 1 year, and to examine the factors that influence these outcomes in these patients.
Methods: A single center retrospective review was conducted in a 20 bed ICU in Cork University Hospital (CUH). Data were collected through the critical care electronic patient record in CUH. All ICU admissions between January 2019 and December 2023 were screened for inclusion. Ultimately, 458 patients were included in the analysis.
Results: The study cohort consisted of 388 patients with AKI-RRT, which was 16% of all patients admitted to ICU during the study period. Survival was 56% at ICU discharge, decreasing to 45% by hospital discharge and 37% at 1 year. At hospital discharge, 7.6% were on dialysis increasing to 13% by 1 year. At hospital discharge, 47% of patients had incomplete renal recovery decreasing to 40% at 1 year. MAKE was present in 54% at hospital discharge and 63% at 1 year. Of the hospital survivors 36.4% had follow-up with nephrology after discharge.

Nonsurvivors were older, had higher illness severity, and more hemodynamic instability. Logistic regression found that medical admission, male sex, late RRT initiation and increased illness severity were associated with decreased survival. Incomplete renal recovery was associated with medical admission, late RRT initiation and higher creatinine at RRT initiation.
Conclusions: The patient cohort had high rates of mortality and incomplete renal recovery, primarily linked to illness severity. This study's findings provide insights into AKI-RRT outcomes in an Irish ICU and emphasize areas for further research, specifically focusing on long-term recovery and quality of life.

Predictive value of procalcitonin, NT-proBNP, and troponin for septic cardiomyopathy: biomarker performance in sepsis

A. R. Figueiredo[1], S. Esteves[1], I. Araújo[1], C. Gregório[1], M. Azaredo Raposo[1], A. Abrantes[1], J. M. Ribeiro[2], D. Silva[2]
[1]Cardiology, Hospital de Santa Maria, Lisboa, Portugal; [2]Serviço de Medicina Intensiva, Hospital de Santa Maria, Lisboa, Portugal
Correspondence: A.R. Figueiredo
Intensive Care Medicine Experimental 2025,* 13(1)*:001137

Introduction: Sepsis-induced myocardial dysfunction is a major cause of morbidity and mortality in critically ill patients and earlyidentification of patients at risk can significantly impact prognosis. Various biomarkers have been investigated as potential predictors of this condition but none is well defined.
Objectives: To assess the ability of procalcitonin, NT-proBNP, troponin, and their peak values to predict the occurrence of septic cardiomyopathy in septic patients.
Methods: Retrospective, observational study of consecutive patients with sepsis diagnosis, admitted in a Polivalent Intensive Care Unit. The area under the curve (AUC), sensitivity, specificity, and diagnostic accuracy were calculated to assess the predictive value of the 3 biomarkers.
Results: A total of 306 patients were included, of which 19% had septic cardiomyopathy (SC) and 81% did not. The prevalence of cardiovascular comorbidities and prior structural heart disease was comparable between the two groups (SC: 20.4% vs. no SC: 22.2%). Procalcitonin, NT-proBNP and troponin T levels were investigated as potential predictors of SC. At admission, procalcitonin exhibited an area under the curve (AUC) of 0.608, with an optimal cutoff value of 38.55, yielding a sensitivity of 48.3%, specificity of 74.2%, and diagnostic accuracy of 1.225. These results suggest that procalcitonin has limited diagnostic utility for septic cardiomyopathy, with relatively low sensitivity. NT-proBNP at admission demonstrated a slightly higher AUC of 0.653, with a cutoff of 11072, resulting in a sensitivity of 58.5%, specificity of 75.2%, and diagnostic accuracy of 1.337. While NT-proBNP showed better performance than procalcitonin, its diagnostic accuracy remains moderate. Troponin T at peak levels showed the highest AUC (0.684), with a cutoff value of 238, sensitivity of 46.6%, specificity of 85.3%, and diagnostic accuracy of 1.319. Despite its lower sensitivity, peak troponin T exhibited excellent specificity, indicating its potential role in ruling out septic cardiomyopathy. Peak procalcitonin demonstrated an AUC of 0.630, with a sensitivity of 63.8% and specificity of 63.3%, yielding a diagnostic accuracy of 1.271. This suggests a moderate performance but does not outperform the other markers. Finally, peak NT-proBNP showed an AUC of 0.663, with a cutoff value of 11180.5, sensitivity of 60%, specificity of 72.8%, and diagnostic accuracy of 1.328, making it the most promising marker in this study for predicting septic cardiomyopathy.
Conclusions: Although none of the biomarkers demonstrated high diagnostic accuracy, peak NT-proBNP and peak troponin T showed the best diagnostic performance. These findings suggest that a strategy of biomarkers combination, especially of their peak values, may enhance the diagnosis of septic cardiomyopathy in septic patients.

Impact of beta-blockers on mortality and hemodynamics in septic shock: a systematic review and meta-analysis

J. Trentin[1], A. De Souza Bertoli[2], G. Landal De Almeida Lobo[3], V. B. D. O. Chaiben[2]
[1]Intensive Care Medicine, Hospital Universitário Cajuru, Curitiba, Brazil; [2]Intensive Care Medicine, Hospital São Marcelino Champagnat, Curitiba, Brazil; [3]Department of Emergency Medicine, University of Iowa Healthcare, Iowa City, IA, USA, United States of America
Correspondence: J. Trentin
Intensive Care Medicine Experimental 2025,* 13(1)*:001138

Introduction: Septic shock is a critical condition marked by severe circulatory and inflammatory disturbances, with high associated mortality. The recent interest has emerged around the use of beta-blockers to control heart rate and improve hemodynamic stability in this setting, with evidence indicating potential benefit.
Objectives: To evaluate the impact of beta-blocker therapy on mortality, ICU length of stay, lactate levels, and vasopressor requirements in patients with septic shock.
Methods: A systematic review and meta-analysis were conducted. A total of 247 studies were initially identified through database searches and screened by two independent reviewers. Six studies met the inclusion criteria and were included in the final analysis.
Results: Beta-blocker use was associated with lower mortality (odds ratio 0.71; 95% CI 0.51–0.98) and improved lactate clearance (mean difference −0.19 mmol/L; 95% CI −0.41 to −0.03). No significant differences were found in ICU length of stay or vasopressor requirements between groups.
Conclusions: The use of beta-blockers in patients with septic shock may offer mortality and metabolic benefits; however, clinical significance remains to be fully established. Although initial findings are promising, further large-scale randomized controlled trials are needed to establish definitive clinical recommendations.

Flow index derived from electrical impedance tomography predicts high-flow nasal cannula failure in acute respiratory failure: a prospective observational study

R. Zhang, L. Jialin, Q. Hongping
Department of Critical Care Medicine, Ruijin Hospital, Shanghai Jiao Tong University School of Medicine, Shanghai, China
Correspondence: R. Zhang
Intensive Care Medicine Experimental 2025,* 13(1)*:001139

Introduction: High-flow nasal cannula (HFNC) oxygen therapy has emerged as a widelyadopted noninvasive respiratory support strategy for patients with acuterespiratory failure. HFNCprovides high-flow, heated, and humidified oxygen, which can improveoxygenation, reduce work of breathing, and enhance patient comfort. However, a significant proportion of patients may experience HFNC failure, requiring escalation to invasive mechanical ventilation, which is associated with increased morbidity and mortality. Early identification of patients at high risk of HFNC failure is crucial for optimizing clinical management and improving patient outcomes. Traditional assessment methods, such as the Rapid Shallow Breathing Index (RSBI) and esophageal pressure-derived metrics, have been used to evaluate respiratorydrive and predict HFNC failure. However, these techniques have limitations, such as invasiveness and the requirement forspecialized equipment. Electrical impedance tomography (EIT) is a noninvasive imaging technique that can provide real-time, quantitative assessments of regional lung function. EIT-derived parameters, such as the Flow Index, have shown promise in evaluating respiratory mechanics and couldpotentially serve as novel predictors of HFNC failure.The aim of this study was to investigate the utility of the EIT-derived FlowIndex in assessing respiratory drive and predicting HFNC failure in patientswith acute respiratory failure.
Objectives: High-flow nasal cannula (HFNC) therapy has become increasingly important inmanaging acute respiratory failure. However, predicting HFNC failure remainschallenging. This study investigates the predictive value of Flow Index, derived from Electrical Impedance Tomography (EIT), for HFNC failure.
Methods: In this prospective observational study, we enrolled adult patients with acuterespiratory failure requiring HFNC therapy. EIT measurements were performedat baseline and at predetermined intervals. Flow Index was calculated using anovel algorithm based on EIT data. The primary outcome was HFNC failure, defined as the need for intubation or noninvasive ventilation within 48 h.
Results: We enrolled 120 patients (mean age 64 $\pm$ 15 years, 55% male). HFNC failureoccurred in 35 patients (29.2%). Flow Index was significantly higher in thefailure group compared to the success group (2.8 $\pm$ 0.6 vs. 1.9 $\pm$ 0.4, $p < 0.001$).ROC analysis showed Flow Index had excellent predictive value (AUC 0.85,95% CI 0.78–0.92). A Flow Index threshold of 2.4 showed sensitivity of 82%and specificity of 78% for predicting HFNC failure.
Conclusions: Flow Index derived from EIT is a promising tool for predicting HFNC failure inacute respiratory failure patients. This noninvasive method could help optimize timing of respiratory support escalation.

Comparative outcomes analysis: baseline characteristics, significant flow index differences and ROC curve of Flow Index.

Effect of artificial intelligence in extracorporeal membrane oxygenation: a systematic review and meta-analysis

S. Chen[1], L. Songqiao[2]
[1]Department of Critical Care Medicine, Southeast University, Nanjing, China; [2]Department of Critical Care Medicine, Zhongda, Nanjing, China

Intensive Care Medicine Experimental 2025,* 13(1)*:001142

Introduction: Extracorporeal Membrane Oxygenation (ECMO) is a life-saving support for patients with severe cardiopulmonary failure, but its high complexity and resource demands necessitate innovative solutions. Artificial Intelligence (AI) offers potential in optimizing ECMO management by enhancing clinical decision making, predicting outcomes, and guiding initiation timing. However, challenges such as data heterogeneity and model generalizability limit its widespread adoption. Our research aimed to evaluate the effectiveness of AI in ECMO, addressing the need for innovative strategies to improve patient outcomes and resource allocation.
Methods: A systematic review and meta-analysis were conducted following PRISMA guidelines. The literature searches were performed in PubMed, Embase, and Cochrane Library for studies published between January 1980 and June 2024. Studies were screened based on inclusion criteria focusing on AI applications in ECMO, clinical outcomes, and research designs. Data extraction included AI methodologies, performance metrics, and key findings. Meta-analysis was performed using a random-effects model, with pooled AUCs calculated for ECMO initiation and prognosis prediction.
Results: Of 212 inital records, 36 studies met criteria for inclusion. Studies with AI models demonstrating high accuracy for both ECMO initiation and prognosis prediction were included. For initiation decision-making, the pooled AUC was 0.838 (95% CI 0.8042–0.8727), and for prognosis prediction, the pooled AUC was 0.7760 (95% CI 0.7546–0.7974). Ensemble learning models outperformed non-ensemble methods in both tasks. Subgroup analysis revealed that single-center studies exhibited higher AUCs for both tasks compared to multi-center studies. Key applications included patient identification, mortality prediction, and real-time monitoring, with notable improvements in resource allocation and clinical decision making. However, heterogeneity across studies, data variability, and limited external validation were significant limitations.
Conclusions: AI has shown promise in improving ECMO management by providing predictions for initiation timing and patient outcomes. Future research should focus on multi-center validation, data standardization, and real-time clinical integration.

Bridging disciplines: development of an interprofessional neurocritical care simulation course

M. Tanaka[1], H. Ford[1], A. Kailaya-Vasan[2], S. Muldoon[1], L. Colorado[3], N. Kalyal[2], M. Bianchin[1], S. Canestrini[1], A. Wong[4]

Intensive Care Medicine Experimental 2025,* 13(1)*:001143

Introduction: King's College Hospital is a major regional neurosurgical and neurovascular centre serving a population of 4.5 million across Southeast England. As a major trauma centre with a 90-bed Critical Care Unit (CCU), it manages a high volume of complex neurocritical care patients. To promote patient safety through enhancement of clinical knowledge, optimised communication and interdisciplinary teamworking, we developed a high-fidelity simulation course tailored to the neurocritical care environment, involving neurosurgeons, intensivists, CCU nurses, and advanced critical care practitioners (ACCPs).
Objectives: To design, implement, and evaluate an interprofessional neurocritical care simulation course, aimed at optimising collaborative decision-making, interdisciplinary communication, and improving clinical knowledge, ensuring alignment of curriculum competencies across specialties.
Methods: The NeuroICU Simulation NeuroSIM course was co-designed by a multidisciplinary team, including neurosurgeons, intensivists, simulation experts, and a practice development nurse. Each scenario was collaboratively developed and curriculum-mapped to interdisciplinary frameworks for: the National Standards for Adult Critical Care Nurse Education (CC3N), the Intercollegiate Surgical Curriculum Programme for Neurosurgery, the Faculty of Intensive Care Medicine, and CoBaTrICE Neurocritical Care Competencies. Iterative scenario refinement was informed by focus groups and participant feedback. Critical care leads, neurosurgical consultants, and nurse practitioner leads were invited to observe and contribute to formative evaluation. Feedback was gathered from both participants and observers for ongoing development.
Results: Twenty-five participants (6 neurosurgeons, 11 CCU nurses, 7 CCU doctors and an ACCP) attended two simulation courses, with experience ranging from under 3 years to over 8 years. Core scenarios included traumatic brain injury, subarachnoid haemorrhage, and refractory status epilepticus. Based on the feedback, the course evolved to include brainstem death testing, and faculty was expanded by an ACCP. Notably, 68.2% had not previously had simulation training for neurosurgical patients. Participants rated the training highly for

clinical relevance, structure, and facilitation. Feedback from 2024 highlighted team integration; 2025 emphasized communication, reflection, and the need for expanded content, duration, and variety. Participants were overall comfortable will intradisciplinary communication. (Charts 1–2). Discrepancies in baseline knowledge—particularly around ventilation and delayed cerebral ischemia—highlighted the need for harmonized Objectives:

Conclusions: The NeuroSIM course sought to improve interdisciplinary communication and collaboration in high-acuity neurocritical care. Aligned curricula and shared clinical scenarios fostered mutual understanding. Ongoing development will focus on differentiated content and structured prelearning to support individual needs and optimise outcomes.

The high-drive ARDS phenotype: characterization of ventilatory heterogeneity, metabolic dysregulation and clinical consequences

R. Zhang, L. Jialin, Q. Hongping
[1]Department of Critical Care Medicine, Ruijin Hospital, Shanghai Jiao Tong University School of Medicine, Shanghai, China

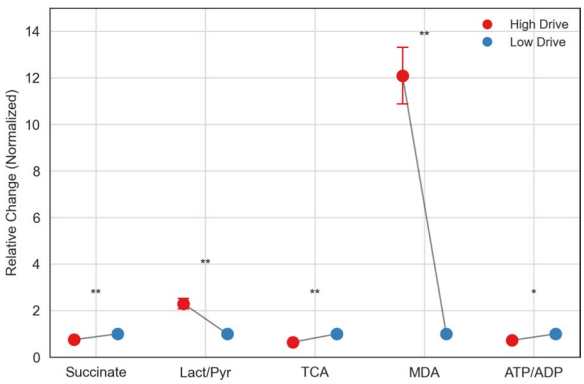
Intensive Care Medicine Experimental 2025,* 13(1)*:001144



Introduction: Acute respiratory distress syndrome (ARDS) remains a significant cause of mortality in intensive care units, with respiratory drive emerging as a critical but understudied determinant of clinical outcomes. Although excessive respiratory effort is increasingly recognized as a contributor to patient self-inflicted lung injury (P-SILI), the pathophysiological mechanisms linking high respiratory drive to adverse outcomes remain poorly understood. The current ventilator strategies focus primarily on mitigating ventilator-induced lung injury, yet growing evidence suggests that patient-ventilator asynchrony and excessive respiratory effort may be equally detrimental. The recent studies have identified respiratory drive, as measured by P0.1, as an independent predictor of weaning failure and mortality. However, these investigations have largely focused on clinical outcomes without exploring the underlying biological mechanisms. Furthermore, the potential metabolic consequences of sustained high respiratory effort—particularly regarding energy metabolism and oxidative stress—have not been systematically evaluated in ARDS patients.

This study sought to comprehensively characterize the high respiratory drive phenotype in ARDS through three complementary approaches: (1) detailed analysis of clinical outcomes, (2) electrical impedance tomography (EIT)-based assessment of ventilation heterogeneity, and (3) targeted metabolomic profiling. We hypothesized that high respiratory drive would be associated with distinct metabolic derangements and that these changes would correlate with both physiological measures of lung injury and clinical outcomes. Our findings provide new INSIGHTS into the biological consequences of excessive respiratory effort and support the development of personalized ventilation strategies based on the respiratory drive assessment.

Methods: This retrospective cohort study analyzed 242 adult ARDS patients admitted to ICUs across three tertiary care hospitals between January 2020 and December 2022. Patients were stratified into high-drive (P0.1 $\geq$ 3.5 cmH_2O) and low-drive groups based on initial respiratory drive measurements obtained within 24 h of mechanical ventilation initiation. Blood samples collected at enrollment underwent targeted metabolomic analysis via LC–MS to quantify TCA cycle intermediates (succinate, citrate), oxidative stress markers (malondialdehyde, MDA), and energy metabolites (ATP/ADP ratio). Clinical outcomes included 28-day ventilator liberation success (primary outcome), ICU mortality, and ventilator-induced lung injury (VILI) incidence, diagnosed by predefined radiological and physiological criteria. Multivariable logistic regression adjusted for age, ARDS severity, and comorbidities. The predictive performance of a novel multimodal model (incorporating drive parameters, metabolic markers, and EIT data) was compared against SOFA and APACHE II scores using ROC analysis.

Results: High respiratory drive (P0.1 $\geq$ 3.5 cmH_2O) in ARDS patients (n = 153 vs. low-drive n = 89) was associated with significantly worse outcomes, including lower 28-day weaning success (41.2% vs. 68.5%, $p = 0.002$), higher mortality (34.6% vs. 18.3%, $p = 0.012$), and increased VILI incidence (29.8% vs. 11.4%, $p = 0.004$). These patients exhibited greater ventilation heterogeneity (right/left lung ratio 1.8 $\pm$ 0.6 vs. 1.2 $\pm$ 0.3, $p < 0.001$) and metabolic derangements, including 35.7% reduced TCA intermediates ($p = 0.003$) and 12.1-fold elevated oxidative stress ($p < 0.001$). A multimodal model integrating these features achieved superior weaning prediction (AUC = 0.89) versus conventional scores (SOFA = 0.71, APACHE II = 0.65).

Conclusions: This study identifies high respiratory drive as a key predictor of poor outcomes in ARDS, associated with nearly doubled mortality (34.6% vs 18.3%) and significant metabolic dysfunction. These findings support routine respiratory drive assessment in ARDS management and highlight potential therapeutic targets in metabolic pathways.

Differential metabolic profiles in ARDS patients stratified by respiratory drive.

Introduction: Isoflurane is gaining attention in the ICU as an inhaled sedative due to its advantages overother widely used sedatives. We conducted a descriptive study of its use in the two ICU withinour province during 2024.
Objectives: To describe the use of isoflurane in the Territorial Intensive Care Medicine Department in Lleida (Spain) during 2024.
Methods: It is a retrospective bicenter study of a sequential cohort of patients withisoflurane-inhaled sedation in two hospitals in Lleida (Spain) during 2024 (Hospital UniversitariArnau de Vilanova -HUAV- and Hospital Universitari Santa Maria -HUSM-).Indication, duration, side effects, withdrawal, and awakening quality were analised. Data-analysis was performed using SPSS (Mann–Whitney and Chi-square).
Results: A total of 133 patients were analysed (98 men, 73.7%; 35 women, 26.3%), 113 patients were admitted in HUAV (85%) and 20 patients were admitted in HUSM (15%). 88 patientssuffered from medical pathologies (66.2%), 32 had surgical pathologies (24.1%) and 13 werepolytraumatic (9.8%). Indications for isoflurane sedation to be initiated was moderate to deep sedation (RASS-3/-5) of any cause except neurocritical patients. Severe respiratory failure was the main cause (72%).The isoflurane vaporizer was mostly located in proximal (Y-piece) arrangement (121; 91%). During the first semester, there were 52 patients with isoflurane (39.1%) and 81 wereunder isoflurane sedation during the second semester (60.9%).
Causes of completion: fast (<6 h) weaning (47; 35.3%), slow (>6 h) weaning (38;28.6%), death/LLST (21; 15.8%), suspected adverse effects (11; 8.3%), interhospital transfer(8; 6%), EEG (2; 1.5%) or others (6; 4.5%). Quality of awakening: good (extubation according to expectation; 40; 30.1%),regular (hyperactive delirium and use of dexmedetomidine: 33; 24.8%), or bad(reintroduction of isoflurane/other hypnotic; 14; 10.6%), not registered/death (46;34.5%). Mean duration of use was 5.15 days (1–30 days).
Conclusions: Isoflurane is used as a first-line sedative mainly used in respiratory failure and in the second semester in our units.

Intensive Care Medicine Experimental 2025,* 13(1)*:001146

Introduction: Sleep is essential for physiological and emotional well-being. Sleep deprivation in the critically ill has been shown to impact patient cognition, increase intensive care unit (ICU) and hospital length of stay. To date, there is limited data on this harmful yet frequently overlooked condition among our local ICU population.
Objectives: The main objectives of our study are to.
1. Detect the frequency of poor sleep among the surgical ICU population
2. Evaluate the impact of a pilot bundle of interventions, aimed at improving sleep hygiene, on the subjective and objective sleep quality in critically ill surgical patients

Methods: We conducted a quasi experimental before-after study in our surgical ICU at a tertiary hospital in Singapore. Adult patients aged 21 years or older who stayed in the ICU for one night or more, and no pre-existing sleep disorder, cognitive impairment or delirium were eligible for enrolment. The study was conducted in two phases, before (Phase 1) and after (Phase 2) implementation of the 'Good Sleep Bundle'. The bundle includes light and noise management, and rationalization of ICU nocturnal patient care activities. Phase 1 and Phase 2 consisted of separate groups of patients. Subjective sleep quality was assessed using the Richards–Campbell Sleep Questionnaire (RCSQ); while objective sleep quality was monitored with WatchPAT-300, a wearable arterial tonography home sleep apnea testing device. Enrolled patients were monitored for two nights, unless discharged from ICU prior to completion of two nights upon enrolment.
Data were analysed for the prevalence of poor sleep, defined as RCSQ $\leq$ 50, sleep efficiency less than 80%, sleep duration less than 7 h, sleep latency more than 20 min, rapid eye movement (REM) sleep less than 10%, or wake episodes more than 20. The effect of the 'Good Sleep Bundle' on measured and subjective sleep quality were evaluated.
Results: Each phase consisted of 22 patients, with generally similar demographic and clinical characteristics across the phases. A total of 69 sleep studies were completed. 61.9% reported poor sleep in Phase 1, compared to 57.1% in Phase 2 ($p = 0.753$). 23.8% reported very poor sleep (RCSQ $\leq$ 25) in Phase 1, which decreased to 4.8% in Phase 2; while the proportion of patients reporting very good sleep increased from 4.8% in Phase 1 to 23.8% in Phase 2. However, Fisher's exact test ($p = 0.092$) indicated that these differences were not statistically significant (Fig. 1).
RCSQ scores reflected slightly higher sleep quality across all dimensions in Phase 2, albeit none of these differences reached statistical significance. The mean RCSQ total score was 42.3 ($\pm$ 23.4) in Phase 1 and 53.4 ($\pm$ 27.8) in Phase 2 ($p = 0.169$). Sleep depth, sleep latency, awakenings, ability to return to sleep, and overall sleep quality followed a similar trend, with Phase 2 showing numerically higher scores ($p = 0.113$–0.794).
There were no statistically significant differences in objective sleep measures between the two phases (Fig. 2), and similar finding from the multiple linear regression analysis adjusted for age, gender, BMI and maximum noise level.
Our findings of a paradox where participants who subjectively reported poor sleep demonstrated better objective sleep parameters may suggest that measurements from WatchPAT do not consistently align with RCSQ scores. This is consistent with results reported by Lochova et al. and Zhang et al. reflecting a lack of robust correlational evidence supporting the relationship between RCSQ and actigraphy.
While general noise exposure remained stable across both phases, Phase 2 observed significantly lower maximum noise level. Nocturnal care activities and light reduction remained consistent across phases.
Conclusions: Our study demonstrates a high prevalence of poor sleep in our critically ill surgical patients. While our findings did not provide evidence for an effect of the Good Sleep Bundle on objective sleep parameters, the wide confidence intervals indicate uncertainty about the true effect, and larger studies would be needed to draw definitive conclusions about the intervention's impact.

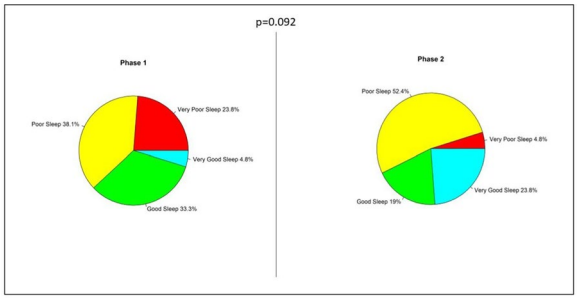

Fig. 1 (abstract 001146) Categorization of RCSQ total score and comparison of their distributions between phases 1 and 2. Very poor sleep (0–25), Poor sleep (26–50), Good sleep (51–75), Very good sleep (76–100)

Intensive Care Medicine Experimental 2025,* 13(1)*:001147

Introduction: The gastrointestinal failure (GIF) is a common entity at critical ill patients, associated with worst outcomes and a higher short- and long-term mortality. It is defined as the interruption of enteral nutrition secondary to high reisdual gastric volume, abdominal disconfort, distension, emesis and diarrhea, which happens on 30.5% of the patients with invasive mechanical ventilation for at least 72 h on the intensive care unit (ICU).
Objectives: Verify the prevalence of the gastrointestinal failure at patients under invasive mechanical ventilation (IMV), evaluate the degree of failure and aim the association with vasopressors, opioids, hypoperfusion markers, obesity, PEEP and the driving pressure.
Methods: A prospective, obervational, descriptive study performed at the intensive unit care for a 6-month period including all inpatients with invasive mechanical ventilation with integrity of the gastrointestinal tract.
Results: A total of 77 inpatients to the ICU were included. Gastrointestinal Failure was presented on 22 patients with a prevalence of the 28.5% which 59.1% of them were males, with an average age of 47 ± 15.4 years. The main reason for admition was acute respiratory distress syndrome (ARDS) on 27.2% ($n = 6$) and septic shock was present at 50% ($n = 11$). (Table 1). The frecuency of the degree of GIF was: degree 2 with 63.6% ($n = 14$), degree 3 with 22.7% ($n = 5$) and degree 4 with 13.6% ($n = 3$), respectively. Starting at 6.5 ± 6.3 days of admission to the ICU. The most prolonged GIF was observed in degree 4 patients with a total of 8.67 ± 4.5 days ($p = 0.021$). BMI was associated with the degree of gastrointestinal failure ($p = 0.022$), being the most at degree 3 (41.46 ± 12.7). Vasopressors were present on 95.5% ($n = 21$) with a prevalent use of norepinephrine and vasopressin ($n = 11$), but not significally association was found; neither with the use of opioids or the lactate level. A significant association was found with the levels of PEEP (8.68 ± 3.45 cmH_2O; $p = 0.028$). The length of stay in intensive care unit were 15 ± 8.8 days (range 4–39) without statistically significant difference with the degree of disease, however the patients with GIF degree 4 had the long stay (23.3 ± 9 days). (Table 2).
Conclusions: Prevalence of gastrointestinal failure was similar to the reported on the literature. A significant relationship of GIF with BMI and PEEP leves was found; without signfically association with use of vasopressors or opioids and hypoperfusion markers. The length of disease was longer in GIF degree 4.

Intensive Care Medicine Experimental 2025,* 13(1)*:001148

Introduction: Acute Kidney Injury (AKI) is a common and potentially serious complication in critically ill patients, occurring in up to 50% of ICU admissions. While standardized classification using the Kidney Disease: Improving Global Outcomes (KDIGO) criteria is essential for consistent research and clinical evaluation, applying these definitions to large datasets remains challenging due to the absence of accessible and reliable tools. To address this gap, we present pyAKI, an open-source solution that automates AKI classification by implementing the KDIGO 2012 criteria in time series data. By enabling reproducible and standardized AKI classification at scale, pyAKI supports improved data quality and research in critical care nephrology.
Objectives: The objective of this study was to develop and validate pyAKI, an open-source tool that automates the classification of acute kidney injury (AKI) in large clinical datasets using the KDIGO 2012 criteria. The study aimed to address the lack of accessible and standardized solutions for AKI detection by creating a reliable, scalable pipeline that improves accuracy, efficiency, and reproducibility in AKI research.
Methods: pyAKI was developed and validated using the Medical Information Mart for Intensive Care (MIMIC-IV) database. The pipeline implements the KDIGO 2012 guidelines for AKI classification, utilizing both serum creatinine (SCr) and urine output (UO) data. To enable consistent processing, a standardized data model was created, and interpolation techniques were applied to address data sparsity. Validation of the tool was performed by comparing pyAKI's output with expert annotations generated by a panel of junior and senior physicians.
Results: Validation results showed that pyAKI achieved an accuracy of 1.0 across all KDIGO stages, outperforming human annotations, which had a sensitivity of 0.96 and a specificity of 0.99. The pipeline also demonstrated high efficiency, completing dataset labeling in just 0.27 s, compared to 970 min required by physicians. With its consistent accuracy and speed, pyAKI provides a valuable solution for AKI classification in large-scale datasets, reducing variability from human annotation and supporting more reproducible research.
Conclusions: pyAKI provides a reliable, open-source solution for AKI classification based on the KDIGO 2012 criteria. It surpasses human-level accuracy and improves the consistency and scalability of AKI research. By automating a time-consuming task, pyAKI supports clinical research and decision making in critical care, offering a powerful tool that saves time and enhances reproducibility in large-scale research projects.

Intensive Care Medicine Experimental 2025,* 13(1)*:001150

Introduction: Critical care survivors are often left with physical and non-physical morbidity, commonly termed post intensive care syndrome. As a result, significant rehabilitation needs persist after leaving hospital with recovery taking many months and less than half of survivors returning to work at 12 months following hospital discharge [1]. A lack of specialist follow-up services means that patients only source of support may be their primary care physicians, although previous work has suggested they may lack the experience and expertise to effectively support ICU survivors [2].
Objectives: To evaluate primary care clinicians' awareness and involvement in the care of survivors of critical illness.
Methods: As part of a National Confidential Enquiry into Patient Outcomes and Death (NCEPOD), case reviews were completed to evaluate the care provided to survivors of critical illness. Inclusion criteria were adults, admitted to ICU for > 4 days between 1st October 2022 and

31st December 2022, and surviving to hospital discharge. As part of this review, primary care physician records were accessed to evaluate contact and support provided.

Results: A total of 248 primary care case records were reviewed during the study period. Of these, around a third (31%) of clinicians reported they were not aware the patients had been in the ICU and only 34% reported to having a standardised approach to identify if patients had been in hospital. Where an ICU stay was identified, 31% of practices reported this would trigger them to contact the patient automatically for review and 6% would place a flag on the patient's medical record.

The majority of patients (86%) had attended for at least one appointment with the primary care physician over the first year following hospital discharge, with around half of these (49%) being directly related to the ICU admission. Just under half (47%) required an assessment of rehabilitation need and 29% required onward referrals for rehabilitation.

Primary care physicians highlighted a need for more education around likely post ICU rehabilitation needs and how they could support recovery. They also highlighted a lack of awareness of what rehabilitation pathways were available, with one stating:

"There is no information available in primary care as to what help is available for rehabilitation. The wait list for any community services in our area is so long that any input is irrelevant by the time it is received."

Conclusions: Critical care survivors regularly access their primary care clinician for support following hospital discharge. This study highlights the need to improve discharge planning and communication between hospitals and primary care. Increasing awareness of the challenges faced by survivors of critical illness and education of primary care physicians around the availability of rehabilitation services is urgently required.

Intensive Care Medicine Experimental 2025, **13(1)**:*001151*

Introduction: Fluid responsiveness is important in optimizing fluid therapy and improving outcomes in critically ill patients. Hence, accurate assessment of fluid responsiveness is essential to avoid both inadequate and excessive fluid administration, as these can have detrimental effects on organ function and patient morbidity.

Objectives: Precisely determining fluid responsiveness in spontaneously breathing critically ill patient population remains challenging, and consensus regarding most reliable and accurate method is yet to be established. Consequently, our study aimed to evaluate and compare diagnostic accuracy and feasibility of three distinct methods; left ventricle outflow tract-velocity time integral (LVOT-VTI) variability, inferior vena cava (IVC) collapsibility index, and change in carotid artery parameters—for predicting fluid responsiveness in spontaneously breathing intensive care unit(ICU) patients.

Methods: This prospective observational study was carried out at a tertiary care center over 15 months (Sept 2021–Jan 2023) after ethical approval. Participants included patients aged above 18 years who were spontaneously breathing and admitted to ICU. Patients with pregnancy, pulmonary hypertension, severe tricuspid regurgitation, atrial fibrillation, intraabdominal hypertension, liver disease, carotid disease, COPD, known severe cardiovascular or renal impairment, poor echo image quality, abdominal surgery, patients without spontaneous breathing effort, patients with neck surgery, trauma, radiotherapy, or those with obesity (BMI > 35 kg/m2) were excluded from study.

Measurements were taken before and after administering 250 ml of crystalloids over 10 min.

Transthoracic echocardiography was performed to measure stroke volume, LVOT-VTImax, and LVOT-VTImin during four breathing cycles. IVCmax and IVCmin diameters were also measured during breathing cycles. The variability of LVOT VTI was calculated using the formula: {(VTImax—VTImin) / [(VTImax—VTImin) / 2] × 100%}.

For IVC measurements, inferior vena cava was visualized using B-mode from a longitudinal paramedian subxyphoid view. IVC measurements were taken in M-mode 2 cm below confluence of the hepatic veins. Maximal expiratory diameter of vein was recorded (dIVC expiration), and the collapsibility index (IVCCI) was calculated using the formula: IVCCI = (dIVC expiration—dIVC inspiration)/dIVC expiration × 100.

Stroke volume (SV) was calculated using LVOT VTI and LVOT diameter, defined as SV = cross-sectional area × VTI. Carotid Doppler parameters, including systolic VTI, systolic time (Ts), diastolic time (Td), and cycle time (Tc), were measured. Doppler was performed in common carotid artery (CCA) 1–1.5 cm proximal to bifurcation of left carotid artery.

Positive fluid responsiveness was defined as an increase in SV of at least 15% after fluid challenge. The study group was divided into fluid responders and nonresponders, and changes in above parameters before and after fluid administration were collected for analysis.

Results: Of the 100 patients included in study, 49 were fluid responders and 51 nonresponders. Significant differences were observed between responders and nonresponders in IVC collapsibility index, LVOT VTI variability, and carotid artery parameters (FTc, ΔVpeak).

The receiver-operating characteristic (ROC) curve analysis was performed to determine diagnostic accuracy of methods. IVC collapsibility index exhibited the highest diagnostic accuracy among studied methods, with an area under curve (AUC) of 0.741 ($p < 0.001$). LVOT VTI variability had AUC of 0.665, while change in corrected carotid flow time and change in carotid VTI had AUCs of 0.241 and 0.314, respectively. These findings suggest that IVC collapsibility index has moderate diagnostic accuracy for predicting fluid responsiveness in spontaneously breathing ICU patients.

Conclusions: IVC collapsibility index has the highest diagnostic accuracy and hence, can aid clinicians in optimizing fluid therapy decisions in spontaneously breathing ICU patients.

Introduction: Pulmonary fibrosis following acute respiratory distress syndrome (ARDS-PF) is a critical complication affecting long-term patient prognosis. Its development is closely associated with dynamic changes in myeloid immune cells. However, the phenotypic characteristics and mechanisms of key subpopulations remain unclear.
Methods: In this study, three patients with severe ARDS were included. The early (non-fibrotic stage, NPF stage) and late (fibrotic stage, PF stage) phases were defined based on the evidence of pulmonary fibrosis on lung CT. Single-cell RNA sequencing was performed on bronchoalveolar lavage fluid (BALF) samples from these patients, and a multi-stage comparative analysis was conducted in conjunction with three healthy control samples from a public database, involving a total of 68,027 cells.
Results: Our study found that a significant increase in CCL3hi neutrophils during early fibrosis. As disease progressed, pro-inflammatory S100A8/A9hi neutrophils and IL1Bhi monocytes accumulated progressively, while immunosuppressive HLA-DRlowS100Ahi monocytes markedly decreased after fibrosis formation. Alveolar macrophage populations also showed significant depletion. Compared with healthy controls, neutrophils and monocytes in PF stage exhibited enriched chemokine signaling and multiple inflammatory pathways. Cell communication analysis further confirmed that intensified neutrophil–monocyte interactions through CCL3-CCR1 and CCL3L1-CCR1 chemokine axes during PF stage, driving escalating inflammatory responses.
Conclusions: These findings collectively suggest that the temporal activation of pro-inflammatory neutrophils and monocytes through inflammatory microenvironment remodeling may constitute a key driver of ARDS-PF progression. This study identifies an intervention window for targeting myeloid cell hyperinflammation and provides theoretical foundation for developing stage-specific anti-fibrotic strategies.

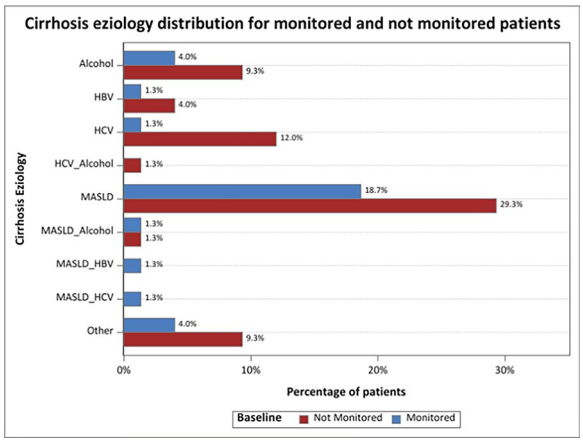
Intensive Care Medicine Experimental 2025,* 13(1)*:001154



Introduction: Chronic liver diseases (CLD) require continuous, proactive monitoring to prevent decompensation and to reduce hospital admissions. Traditional outpatient follow-up is often inadequate for timely intervention. This study introduces a new multidisciplinary care model integrating hepatologists, physiotherapists, a project coordination team, IT engineers, and data scientists to improve early detection of clinical deterioration in patients awaiting liver transplantation. The system combines wearable devices, functional and cognitive assessments, and AI-powered predictive analytics to enhance remote patient management and enable earlier, personalized interventions.
Objectives: Assess the feasibility of an AI-assisted telemonitoring system in CLD patients on the liver transplant waiting list, and describe the baseline characteristics of the enrolled population. The project aims to redefine the standard of care shifting from reactive to proactive management, improving functional surveillance, reducing preventable complications, and optimizing clinical resource allocation.
Methods: A single-center, assessor-blind, randomized controlled trial (1:2 allocation) was launched at IRCCS ISMETT UPMC involving 75 CLD patients. Patients were randomized in a telemonitoring group ($n = 25$) and a control group ($n = 50$). The intervention included daily home monitoring of vital and functional parameters via wearable sensors and tablets, supported by a scalable AI platform for real-time data analysis and clinical alerts. Baseline, 4-, 8-, and 12-month assessments included Liver Frailty Index (LFI), PROMs, MOCA, and activity trackers. Hepatologists guided clinical care, physiotherapists conducted remote assessments, and data scientists developed predictive models based on acquired data.
Results: Enrollment was completed in January 2025, with baseline evaluation performed on all patients. Median age was 62 years, 77% were male, and the most frequent etiology was MASLD (48%), HCC 45%, Child Pugh B 61.3%, history of ascites 57.3%, EPS 24% (Table 1). At baseline, median Liver Frailty Index was 3.4 [IQR 3.0–3.8], with 61.6% of patients classified as pre-frail. SARC-F score median was 3.0, MOCA score median was 23 (Table 2). Initial descriptive analysis highlights differences in baseline functional profiles between groups. The AI model development was initiated using these early data, with the goal of identifying risk trends to guide timely intervention.
Conclusions: This project was a structured, multidisciplinary effort to innovate care pathways in advanced CLD. The integration of clinical expertise, physiotherapy, technological infrastructure, and data science enables to create a scalable model of care capable of anticipating clinical deterioration and enhancing patient outcomes Future developments will focus on refining predictive algorithms, increasing patient engagement, and evaluating long-term impact on quality of life, healthcare sustainability and tele-rehab.

AI-based serum creatinine to cystatin C ratio estimation from chest X-ray in children

H. Ota, Y. Asami, Y. Nakano, A. Kunikata, T. Fujimura, H. Nozawa, H. Ebishima
Department of Pediatrics, The University of Tokyo, Tokyo, Japan
Correspondence: H. Ota
Intensive Care Medicine Experimental 2025,* 13(1):*001156

Introduction: Although sarcopenia is a significant problem in children, there is a paucity of modalities for skeletal muscle quantification in this age group, particularly in the critically ill children. Serum creatinine to cystatin C ratio (SCCR) is a potent surrogate marker for skeletal muscle mass in adults and in children, however, it is not widely accepted because serum cystatin C is not routinely measured. Modalities with wider availability are required.
Objectives: To build an estimation model for SCCR from a chest X-ray image (CXR).

Methods: A single-centre retrospective study was conducted. The derivation cohort consisted of patients aged under 15 years who visited or were admitted to The University of Tokyo Hospital between April 2012 and May 2022 with serum creatinine, serum cystatin C, and CXR within a month. Subjects with impaired renal function (eGFR < 50 ml/minute/1.73m2) or who intubated in the pediatric intensive care unit (PICU) were excluded. The validation cohort included patients aged under 15 years who were admitted to the PICU at the same hospital in 2023 and 2024 with the same measurements as in the derivation cohort within three days of admission. Subjects with impaired renal function (eGFR < 50 ml/minute/1.73m2) or who were already included in the derivation cohort, were excluded from the validation cohort. The SCCR was estimated using a transfer learning approach on an image-recognition model (ConvNeXt V2), which was pretrained to estimate the age from CXR using an open dataset (VinDR-PCXR). The performance of the trained model was evaluated using Pearson's correlation coefficient, and the attention of the model was evaluated by GradCAM.
Results: A total of 160 and 71 patients were included in the derivation and the validation cohort, respectively. The participants' age, serum creatinine, and serum cystatin C for the derivation and the validation cohort were 6.2 (2.5–10.3) and 1.85 (0.3–4.3), 0.32 (0.23–0.45) and 0.23 (0.19–0.27), and 0.80 (0.67–0.96) and 0.74 (0.60–0.97), respectively (median (IQR)). Pearson's correlation coefficient between SCCR and estimated SCCR was 0.77 (95% CI 0.66–0.85, $p < 0.001$). The GradCAM suggested the commitment of the sucapulohumeral region to the estimation.
Conclusions: A Chest X-ray image may provide a significant information about the skeletal muscle mass in children.

Estimated serum creatinine to cystatin C ratio (SCCR) versus true SCCR. Pearson's $r = 0.77$ (95% CI 0.66–0.85, $p < 0.001$).

Intensive Care Medicine Experimental 2025,* 13(1)*:001157

Introduction: The aim of this study is to assess the postoperative outcomes of patients undergoing resection of an intracranial tumor via craniotomy and to compare supratentorial cases with infratentorial cases.
Methods: This descriptive study was carried out in the Intensive Care Department of a University Hospital. It included all patients admitted in 2024 who underwent surgical intervention for brain neoplasia. A general analysis was performed, and the patients were divided into two groups based on the surgical approach: supratentorial versus infratentorial. Statistics: Qualitative variables are expressed as percentages and compared using the χ^2 test. Quantitative variables are expressed as means and standard deviations ($\pm$ S.D.). The significance level was set at $p < 0.05$. Statistical analysis was conducted using specific software (IBM SPSS Statistics for Windows, Version 19.0. Armonk, NY: IBM Corp).
Results: A total of 79 patients were included, 47% of whom were women, with a mean age of 60.4 years (SD 13.5). Elective interventions accounted for 75% (60) of the cases, and 88% (70) involved a supratentorial approach. Table 1 presents the main differences based on the type of surgical approach, but no statistically significant differences were found. The image shows the Glasgow Outcome Scale Extended (GOSE) at hospital discharge according to the type of surgical approach performed.
Conclusions: In our sample, no statistically significant differences were found between the two types of surgical approaches (supratentorial versus infratentorial). However, as reported in the literature, patient prognosis tends to be worse for those undergoing the infratentorial approach, even though pre-surgical clinical symptoms are more frequent in supratentorial cases. The supratentorial approach is also associated with a higher frequency of non-elective surgeries, longer procedure durations, and more postoperative complications. Given the sample size, the higher proportion of female patients in the infratentorial group, and the lack of long-term prognostic follow-up, we consider it necessary to expand the sample size and extend the follow-up period, as well as to incorporate a gender perspective.

The image shows the GOSE at hospital discharge according to the type of surgical approach performed.

Table 1	Supratentorial	Infratentorial
Female sex	44,3%	66,7%
Glioblastoma multiforme	34%	0
Meningioma	24%	43%
Metastasis	17%	11%
Pre-surgical motor focality	33%	22%
Pre-surgical language alteration	29%	11%
Pre-surgical cranial nerve involvement	16%	22%
Pre-surgical seizures	23%	0
Non-elective surgery	23%	0
Surgery duration > 4 hours	47%	22%
Post-surgical cranial nerve involvement	9%	55%
Post-surgical surgical complications	24%	1,2%
Post-surgical medical complications	14 %	13%
Reoperation during admission	3 %	0

Outcome results.

Review of practice and recommendation for exclusion of routine chest X-ray confirmation following CVC insertion post-HPB surgery in a tertiary ICU

A. Bhattacharya[1], S. Hanna-Jumma[2], A. Holley.[2]
[1]AICU, Glenfield Hospital Leicester, Leicester, United Kingdom; [2]AICU, Glenfield Hospital, Leicester, United Kingdom
Correspondence: A. Bhattacharya
Intensive Care Medicine Experimental 2025,* 13(1)*:001158

Introduction: Background: Pneumothorax remains a well-documented complication of central venous catheter (CVC) insertion, prompting routine use of chest X-rays (CXR) for confirmation as per national guidelines, including the ICS LocSSIP checklist. However, the actual utility of this practice in ICU settings with real-time waveform transduction remains under scrutiny.
Objectives: To evaluate the diagnostic and therapeutic value of routine post-insertion CXR in patients undergoing hepatopancreatobiliary (HPB) surgery and subsequently admitted to ICU with CVCs placed under standardised conditions.
Methods: We conducted a retrospective audit of all post-HPB surgery ICU admissions at Glenfield Hospital from May 2022 to March 2025. Data were collected on CVC insertion site, confirmation methods, complications (especially pneumothorax and malposition), and whether CXR findings led to any change in clinical management.
Results: Out of 864 patients, 621 (72%) had CVCs inserted in the internal jugular vein, predominantly in the right IJV. All CVCs were transduced with appropriate venous waveforms. Routine CXR was performed in all cases.
Only 4 cases (0.6%) of pneumothorax were detected, none requiring intervention beyond observation, with one attributable to intraoperative events. Malposition was identified in 9 cases (4 in subclavian vein, 5 at cavo-atrial junction/right atrium), none of which necessitated repositioning. All lines were safely used under continuous waveform monitoring. No CXR led to a change in clinical management.
Conclusions: Routine CXR following CVC insertion in post-HPB surgery patients admitted to ICU did not influence patient outcomes or guide intervention. With real-time waveform confirmation and standardised insertion techniques, CXR can be omitted unless clinically indicated (e.g., difficult insertion, respiratory deterioration). This approach aligns with safe, cost-effective, and patient-centered care.
Recommendations: Revise local protocols to exclude routine CXR post-CVC insertion in ICU when venous waveform is confirmed and no clinical concern exists. Reserve imaging for targeted indications.

Intensive Care Medicine Experimental 2025,* 13(1)*:001160

Introduction: Critically ill patients with cirrhosis and ascites are at high risk of developing intraabdominal hypertension (IAH), which is associated with increased mortality. Clinical guidelines recommend maintaining intra-abdominal pressure (IAP) below 16 mmHg. However, over 75% of these patients develop IAH within the first week of ICU admission. Large-volume paracentesis (LVP) is the standard treatment to relieve abdominal wall tension in these patients, resulting in intermittent reduction of IAP associated with transient improvements in renal and pulmonary function. Continuous passive paracentesis (CPP) offers a strategy to treat and prevent IAH, potentially improving clinical outcomes. However, no studies have compared paracentesis strategies for IAH management.
Objectives: This study aims to compare clinical outcomes of patients with cirrhosis and ascites treated with CPP versus LVP in intensive care.
Methods: A randomized clinical trial in a tertiary hospital center, open to collaboration with other centers, with an estimated duration of 36 months. A total of 72 patients with liver cirrhosis and grade 2 ascites will be enrolled and randomly allocated (1:1) to either the LVP (control) or CPP (intervention) groups. Randomization within the initial 24 h of admission will be stratified based on the maximum values of serum creatinine concentration (sCr) and IAP. LVP will be performed intermittently according to clinical guidelines, while CPP will drain ascitic fluid for up to 7 days. The primary outcome is sCr measured up to day 7, with secondary outcomes including 28-day mortality.
Results: Between September 2022 and November 2024, 89 patients were screened, and 26 (29%) were included in the study and in this preliminary analysis (LVP n = 10 vs. CPP $n = 16$, henceforth). The most frequent exclusion criterium was minimal ascites ($n = 21$). The median patient age was 58 (50–62) years-old and male gender represented 73%. Clinical severity at admission showed SAPS II 44 (30–76), MELD-Na 31 (25–38), ACLF 3 (1–3) and CLIF-SOFA 13 (9–17) and CLIF-C 56 (37–63) median score values. The baseline sCr was similar between groups (2.0 vs 1.9 mg/dL, $p = 0.9$). The results for sCr from days 1 to 4 post-randomization are presented. No significant differences between groups were observed (general linear model repeated measures, $p = 0.06$). The overall 28-day mortality rate was 42%, with no significant group difference (50% vs. 38%, $p = 0.7$), as depicted by Kaplan–Meier analysis.
Conclusions: This preliminary analysis of the COPPTRIAHL clinical trial revealed a slow patient recruitment rate. There was no significant difference in sCr or 28-day mortality between critically ill patients with cirrhosis and ascites submitted to LVP or CPP. The study remains open for collaboration with other centers.

TGF-β3 inhibits SKP1-mediated ubiquitination degradation of AMPKα and enhances its phosphorylation to promote mitochondrial biogenesis and autophagy in cardiomyocytes to attenuate septic cardiomyopathy

X. Shang, H. Zhang, L. Chen, J. Gao, B. Xu, X. Wang, L. Wang
Department of Critical Care Medicine, Fuzhou University Affiliated Provincial Hospital, Fuzhou, China
Correspondence: X. Shang
Intensive Care Medicine Experimental 2025,* 13(1)*:001161

Introduction: The development of septic cardiomyopathy (SCM), a prevalent condition that increases patient mortality, is closely associated with mitochondrial dysfunction in cardiomyocytes.
Objectives: To elucidate the mechanism by which TGF-β3 attenuates SCM by promoting mitochondrial biogenesis and autophagy in

cardiomyocytes, demonstrating that it can be an effective target for intervention in SCM.
Methods: Peripheral blood and clinical information of patients were collected. SCM rat model was established by cecum puncture ligation method, and TGF-β3 was interfered or overexpressed by adenoviral vector myocardial in situ injection; LPS-induced SCM cell model was constructed and overexpressed by plasmid transfection of TGF-β3. Group comparisons were meticulously designed according to the experimental purpose, followed by the qualitative or quantitative detection and analysis of myocardial tissues, cardiomyocytes and mitochondria using molecular biology techniques such as transmission electron microscopy, fluorescence staining, RT-PCR, ELISA, WB, IP-MS, flow cytometry, and so on.
Results: There is a partial correlation between TGF-β3 levels and the condition of SCM patients. The down-regulation of TGF-β3 expression in cardiomyocytes in SCM and the concomitant mitochondrial damage in cardiomyocytes were verified in cellular models. Overexpression of TGF-β3 in constructed SCM cells and animal models confirmed that it promotes mitochondrial biogenesis and autophagy and reduces myocardial pathological damage and inflammatory factors. TGF-β3 was also found to act on SKP1, an assembly factor of the E3 ubiquitination ligase SCF complex, in cardiomyocytes, and TGF-β3 inhibited SKP1-mediated degradation of AMPKα ubiquitination and enhanced the level of AMPKα phosphorylation, which promoted mitochondrial biogenesis and autophagy in cardiomyocytes. Finally, molecular docking was utilized to screen the TGF-β3 high-affinity drug thiamine pyrophosphate (TPP) and confirm its SCM therapeutic effects.
Conclusions: TGF-β3, a protective factor in the myocardium, exerted a role in attenuating SCM by inhibiting SKP1-mediated degradation of AMPKα ubiquitination and enhancing AMPKα phosphorylation promoting mitochondrial biogenesis and autophagy in cardiomyocytes.

Intensive Care Medicine Experimental 2025,* 13(1)*:001163

Introduction: To explore the causal association between sepsis and sarcopenia-related traits through a prospective observational study combined with Mendelian randomization analysis.
Methods: A prospective observational study was conducted in our intensive care unit (ICU) from June to September, 2024. Adult patients expected to stay in ICU over three days were included, and received skeletal muscle ultrasound examination on days 1, 3 and 7 after admission. Ultrasound characteristics including thickness of rectus femoris, vastus intermedius and quadriceps femoris, cross-sectional area of rectus femoris (RF-CSA) and pennation angle of tibialis anterior (TA-PA) were recorded, clinical diagnosis and laboratory examinations were also collected. Patients were classified to three groups: sepsis at admission, sepsis after admission and non-sepsis according to the time of sepsis diagnosis to compare the differences of skeletal muscle ultrasound characteristics. Binary logistic regression was used to investigate the relationship between ultrasound characteristics and occurrence of sepsis after admission. Besides, bidirectional two-sample Mendelian randomization analysis was adopted to assess the causal relationship between sepsis and sarcopenia-related traits using the Genome-wide Association Study (GWAS) database of European populations and the UK Biobank (UKB) database, alternating usual walking pace and sepsis as exposure and outcome variables. Sensitivity analysis was conducted using MR–Egger approach and Mendelian Randomization Pleiotropy Residual Sum and Outlier (MR–PRESSO) test.
Results: 94 patients in the cohort were analyzed in which 30 were sepsis at admission, 18 were sepsis after admission and 46 were nonsepsis. Skeletal muscle ultrasound characteristics of ICU patients on day 3 and day 7 were all lower than baseline ($P < 0.01$). Sepsis at admission group had significantly lower muscle thickness, cross-sectional area and pennation angle ($P < 0.05$) and higher rate of RF-CSA loss (21.65% vs. 9.40%, $P = 0.023$) on day 7 after admission compare to non-sepsis group. Sepsis after admission group had significantly lower baseline TA–PA than nonsepsis group (7.20 ± 1.20° vs. 8.31 ± 1.69°, $P = 0.014$), while other muscle ultrasound characteristics did not show statistical difference. Logistic regression indicated that TA–PA on day 1 was an independent predictive factor of sepsis after admission (adjusted OR = 0.604, 95% CI 0.392–0.930, $P = 0.022$). Mendelian randomization analysis showed that sepsis could decrease usual walking pace (inverse variance weighted: $\beta = -0.019$, SE = 0.009, $P = 0.030$).
Conclusions: The skeletal muscle mass of patients with sepsis was more significantly reduced during ICU stay than those without sepsis, and traits related to muscle function had bidirectional causality with sepsis. Pennation angle of tibialis anterior measured by bedside ultrasound might be a potential indicator for occurrence of sepsis.

Intensive Care Medicine Experimental 2025,* 13(1)*:001168

Introduction: Elevated cardiac troponin (cTn) levels are common among patients with sepsis. However, whether cTn increases are due to myocardial injury or infarction remains unclear. The primary objective of this study is to evaluate the incidence of acute myocardial injury (AMInj) and acute myocardial infarction (AMI) in patients with septic shock in the ICU. Secondary objectives are to assess the independent association of AMInj and AMI with organ support-free days at 30 days and mortality up to 365 days after ICU admission.
Methods: This multicenter study included 276 ICU patients with septic shock, identified according to the Sepsis-III criteria. The data were collected during ICU admission, at 30 days, and at 365 days following ICU admission. Blood samples were collected daily during ICU stay (max 7 days), and ECGs were performed on days 1, 3, and 7. AMInj and AMI were defined according to the 4th Universal Definition of Myocardial Infarction (UDMI). Organ support-free days (OSFD) were defined as days without invasive mechanical ventilation, vasopressors, inotropes, or renal replacement therapy within 30 days of ICU admission. Multivariable logistic regression analysis was performed to assess the relationship between AMInj/AMI and the outcomes, adjusted for age, BMI, SOFA score, presence of cardiovascular risk factors, and history of coronary artery disease.
Results: A majority of patients (85.9%) fulfilled the UDMI definition of AMInj and 22.3% had AMI. Mortality rates were 14.1% in the ICU, 18.6% at 30 days, and 31.8% at 365 days after ICU admission. Neither AMInj nor AMI was independently associated with mortality at in ICU (AMInj: aOR 1.06, CI 0.21–5.49; AMI: aOR 1.42, CI 0.52–3.92), at 30 days (AMInj: aOR 1.76, CI 0.35–8.89; AMI: aOR 1.07, CI 0.43–2.69), or at 365 days (AMInj: aOR 0.69, 95% CI 0.19–2.50; AMI: 1.50, 95% CI 0.64–3.51) after ICU admission.
There was a significant difference in OSFD in patients with and without AMInj (24 vs 27, $p = 0.018$), but not between those with and without

AMI (23 vs 25, $p = 0.416$). AMInj was not independently associated with OSFD (beta −4.64, 95% CI −9.79 to 5.11) or AMI (beta −0.84, 95% CI −4.52 to 2.83).
Conclusions: Cardiac troponin increases fulfilling consensus definitions for acute myocardial injury and myocardial infarction are common in septic shock patients in the ICU. However, neither AMInj nor AMI were independently associated with mortality in the ICU, at 30 days, or at 1 year in this cohort. AMInj was not associated with organ support-free days, suggesting that while myocardial injury is prevalent in septic shock, it does not affect short-term organ outcomes.

Neutrophil–lymphocyte ratio in traumatic brain injury, what value can it bring in the first 48 h?

A. Marcos-Morales[1], E. Aguirre-González[1], JA. Barea-Mendoza[1], C. Mudarra-Reche, F. Delgado Moya, J. Gutiérrez, A. A. Caballo Manuel, A. Castaño-Leon[2], M. Chico Fernández, A. Lagares Gomez-Abascal[2]
[1]Intensive Care, Hospital 12 de Octubre, Madrid, Spain; [2]Neurosurgery, Hospital 12 de Octubre, Madrid, Spain
Correspondence: A. Marcos-Morales
Intensive Care Medicine Experimental 2025,* 13(1)*:001169

Introduction: The neurophil-to-lymphocyte ratio (NLR) has been associated with global critical illness(1), greater levels indicating hemodynamic shock or major neurological injury, among others. Its use in traumatic brain injury (TBI) patients is currently being studied(2).
Objectives: To determine if a greater NLR during the first 48 h after TBI is related to patient prognosis and to need of invasive procedures.
Methods: Retrospective study in a trauma intensive care unit. Patients with trauma admitted from 2022 to 2024 were included, those with an Abbreviated Injury Scale of 0 in the head were excluded. They were grouped by Glasgow coma scale (GCS) and AIS head. The maximal NLR obtained during the first 48 h of admission was registered. A multivariate analysis was performed, entering as predictor variables GCS, NLR, age and hemodynamic status, studying the association with the need of urgent neurosurgery (< 24 h), tracheostomy, intracranial pressure (ICP) invasive monitoring, as well as with ICU mortality. Statistical analysis was performed with R studio.
Results: Final inclusion gathered 312 patients, 79% male with a median age of 47 years (standard deviation of 19). Severe TBI patients (GCS 3–8) represented 26% of patients, 100% of them had an Abbreviated Injury Scale (AIS) of the head area ≥ 3. Moderate TBI (GCS 9–13) were 29%, with 71% of them having AIS head ≥ 3, and finally mild TBI patients (GCS 14–15) were 45%, with 46% of them having AIS head ≥ 3. Median Injury Severity Score was 22 (interquartile range 13 to 29). Thirty one patients (10%) presented with hemodynamic instability on admission, two thirds of them in the 3–8 GCS group.
In multivariate analysis, a greater NLR was related with a greater need of urgent neurosurgery, invasive ICP monitoring also tracheostomy, but was not related to ICU mortality. After cutoff study with Youden index calculation, we found that having a NLR > 14 during the first 48 h multiplied by 4 the need of invasive ICP monitoring and the need of tracheostomy, and by 5 the probability of urgent neurosurgery.
Conclusions: The NLR may carry important prognostic value since the first hours of TBI. Greater NLR levels during the first 48 h of TBI were associated with need for invasive ICP, urgent neurosurgery and ulterior tracheostomy.

$ECCO_2R$ in severe ARDS: efficacy in acidosis control and protective ventilation, associated complications and mortality

O. A. González Fernández, R. Marín Ráez, M. M. Panduro Meza, C. Martinez Martinez, G. Collado Bello, R. De Pablo Sanchez
[1]Intensive care medicine, Hospital Universitario Ramón y Cajal, Madrid, Spain
Correspondence: O.A. González Fernández
Intensive Care Medicine Experimental 2025,* 13(1)*:001170

Introduction: Extracorporeal carbon dioxide removal ($ECCO_2R$) is a useful tool in the ICU for patients with severe ARDS who have refractory hypercapnia and acidosis despite optimized mechanical ventilation. By facilitating CO_2 clearance at lower ventilatory pressures, $ECCO_2R$ allows for ultraprotective ventilation, potentially reducing ventilator-induced lung injury and improving outcomes in cases where conventional therapies are insufficient.
Objectives: To assess the efficacy, clinical course, and complications associated with $ECCO_2R$ therapy in patients with severe ARDS.
Methods: Prospective observational study analyzing patients admitted to the ICU for severe ARDS between 2019 and 2023. Inclusion criteria: pH ≤ 7.25 with pCO_2 > 60 mmHg and/or driving pressure (Dp) > 15 cmH_2O despite optimized mechanical ventilation (MV) and adjunctive therapies. Patients meeting ECMO criteria were excluded.
Collected data included clinical and demographic variables, Dp, PaO_2/FiO_2 ratio, pH, pCO_2, adjunctive therapies, and $ECCO_2R$-related complications.
Hospital mortality and its association with target achievement were analyzed. The results are expressed as percentages and mean ± standard deviation.
Results: 43 patients were included, 83.7% male, mean age 62 ± 8 years. Etiology of ARDS: 28% bacterial pneumonia, 9% septic shock, 5% alveolar hemorrhage, 56% COVID-19, 2% autoimmune hepatitis.
$ECCO_2R$ was initiated due to respiratory acidosis in 32.5%, Dp > 15 in 18.6%, and both in 48.9% of cases.
Acidosis was corrected ($p < 0.05$) starting at 2 h after $ECCO_2R$ initiation. Protective MV was achieved by 24 h and maintained at 48 and 72 h ($p < 0.05$).
$ECCO_2R$ was considered successful if acidosis was corrected and Dp < 15 cmH_2O was achieved. This was attained in 62.7% at 24 h, 65.3% at 48 h, and 50% at 72 h.

Complications occurred in 79% of patients, all mild to moderate: 65% thrombosis related to the $ECCO_2R$ circuit, 35% non-severe bleeding. No catheter-associated infections were observed.
Overall hospital mortality was 46.5%. Among patients who did not achieve Dp < 15 at 48 h, mortality was 88.8% ($p < 0.05$).
Conclusions: $ECCO_2R$ in patients with severe ARDS proved effective in correcting respiratory acidosis and facilitating protective mechanical ventilation. The therapy was associated with a high rate of mild to moderate complications, without severe clinical impact. Overall the mortality was high and significantly greater in patients who did not achieve Dp < 15 within 48 h.

Intensive Care Medicine Experimental 2025,* 13(1)*:001172

Introduction: Sleep disorders in the intensive care unit (ICU) are associated with an increased incidence of delirium, alterations in the immune system, and neuroendocrine function, with their abnormalities linked to cardiovascular changes, neuropsychiatric diseases, and mortality. Poor sleep quality in critically ill patients may be related to factors associated with critical illness or healthcare-related factors. Unicentric studies have demonstrated that it is possible to improve care-related factors, impacting the subjective assessment of sleep.
Objectives: The aim is to demonstrate an improvement in sleep quality in critically ill patients through a reduction in the Richards–Campbell Sleep Questionnaire (RCSQ) score after implementing a structured package of evidence-based measures to enhance sleep in critically ill patients.
Methods: This is a multicenter clinical trial with a quasi-experimental design. The first stage involved assessing the quality of sleep in patients admitted to the ICU by applying the RCSQ over three consecutive days and the ICU Sleep Questionnaire (SICUQ) on the day of ICU discharge. The second stage involved training for the implementation of a Multidisciplinary Sleep Improvement Protocol for Critically Ill Patients. Subsequently, data collection was repeated, and the questionnaires were applied to a new group of patients. Approval from the local ethics committee was obtained under opinion number 5.882.443. Comparisons between quantitative variables were performed using the *t* test or Wilcoxon test. For categorical variables, the Chi-square test was used. The statistical significance level was set at 5% for all analyses; thus, *p* values less than 5% ($p < 0.05$) were considered statistically significant.
Results: The data were collected between March 2023 and March 2024. During the baseline and intervention phases, respectively, 61 and 51 patients were included in the final analysis. There were no significant differences in patient characteristics. According to the RCSQ, there was a significant difference in the reduction of noise in the assessed units before and after the first night. There was also an improvement in the sleep quality item and time to resume sleep on the second night, as well as a perceived reduction in noise. Regarding the SICUQ, the analysis demonstrated an improvement in sleep quality during the final period of hospitalization in the ICU, a reduction in daytime sleepiness in the middle and end of the ICU stay, and a decrease in sleep interruptions due to pain, noise, light, examinations, laboratory tests, and nighttime medication administration.
Conclusions: The implementation of a multidisciplinary care protocol to improve the sleep quality of patients hospitalized in the intensive care environment reduces environmental and cultural barriers in patient care, contributing to an enhancement in patients' sleep quality.

Overall RCSQ score, by phase of the study and on the three days of assessment.

Necrotising fasciitis: reviewing the cases of the past to prepare for the cases of the future

A. C. Cunha[1], A. Albuquerque[2], V. F. Vieira[2], S. Mexia[2], S. Costa[2], O. Gomes[2]
[1]Serviço de Medicina Intensiva, ULS Região de Leiria, Leiria, Portugal; [2]Intensive Care Unit, Unidade Local de Saúde da Região de Leiria, Leiria, Portugal.

Intensive Care Medicine Experimental 2025,* 13(1)*:001173

Introduction: Necrotizing fasciitis (NF) is a severe and rapidly progressing soft tissue infection characterized by the destruction of muscle fascia and subcutaneous tissues. It can lead to rapid systemic deterioration, making prompt identification and treatment crucial.
In approximately 80% of cases, it results from bacterial invasion through a breach in the skin, which allows the pathogen access to deeper tissues. The infection is usually polymicrobial in nature, with the involved organisms often producing gas. Gram-positive cocci, particularly strains of *Staphylococcus aureus* and *Streptococcus* species, are the most common causative agents in these infections.
Overall, the aggressive nature of necrotizing fasciitis demands immediate medical attention, as delays in diagnosis or intervention can lead to significant morbidity and mortality. The best chance for survival lies in prompt and radical debridement, intravenous hydration, and the administration of broad-spectrum antibiotics. The outcome predictor scores have been proposed, such as LRINEC and the lactate/albumin ratio to attempt at an earlier recognition or prognostication of the condition, but the fact remains that clinical suspicion upon patient's assessment is key. Hence, the relevance of clinical audit remains significant and provides a learning opportunity for the multidisciplinary team to optimize strategies of care.
Methods: A single centre retrospective analysis where all the patients admitted to the ICU in context of soft tissue infections in the past five years (2019–2024) was performed, and the cases with clinical suspicion and imagiological confirmation of necrotising fasciitis were selected.
A complete analysis included demographics, risk factors and comorbid conditions, surgical protocol, support treatment, infection control measures, severity scores and literature suggested biomarkers, made with the intention of audit of practice, including diagnosis and treatment optimisation within the institution.
Results: There was an incidence of 15 cases in the span of 5 years: 6 were Fournier's gangrene, one abdominal fasciitis, one fasciitis of the upper limb and seven cases of lower limb fasciitis. All the patients were admitted to the ICU via the emergency department, after inicial resuscitation and surgical care. Most of the patients presented with septic shock upon admission to the unit (80%). Overall outcomes included 6,7% mortality and 6,7% of patients with amputation of limb. One patient underwent hyperbaric oxygen treatment with a positive outcome.
Blood and surgical samples were sent for microbiological cultures and its results directed antibiotherapy in 73% of cases.
Conclusions: With multidisciplinary management, the challenge of necrotising fasciitis can be overcome with a much lower risk of mortality and morbidity. Early recognition of the condition and assertive surgical approach along with adequate supportive care can result in significant outcome improvements even in severe infections caused by multirresistant bacteria.

Non-invasive measurement of myocardial work by transthoracic cardiac ultrasound in intensive care patients: the MYOLOAD study

T. Citti[1], C. Nafati[2], D. Aurenche-Mateu[1], L. Morand[1], J. Dellamonica[1], M. Jozwiak[1]
[1]Intensive care unit, CHU de Nice, Nice, France; [2]13000, CHU Marseille, Marseille, France

Intensive Care Medicine Experimental 2025,* 13(1)*:001174

Introduction: Myocardial work (MW) is an emerging parameter in echocardiography, used as a surrogate for cardiac energetics. Its measurement is based on myocardial deformation (global longitudinal strain) and left ventricular afterload (systolic blood pressure) assessment. To date, no study has assessed the feasability of myocardial work by echocardiography in ICU patients.
Objectives: The objectives of this study were to assess the feasibility of non-invasive measurement of myocardial work by transthoracic echocardiography (TTE) in ICU and to evaluate the effects of fluid administration on the different components of myocardial work (MW).
Methods: This was a prospective, longitudinal, multicenter study conducted in three ICUs of French teaching hospitals (Archet and Pasteur in Nice and Timone in Marseille) from June to August 2024. A TTE examination was performed before and after fluid administration in patients already equipped with an arterial catheter. The MW components were calculated using the EchoPAC software (Global work index (GWI), Global constructive work (GCW), Global wasted work (GWW) and Global work efficiency (GWE)). Patients with an increase in VTI > 15% after fluid administration were considered responders. An operator with a university degree in TTE and practical experience of > 2 years was considered an expert.
Results: The measurement of MW was obtained in 59% of patients and was more frequently obtained when TTE was performed by an expert (75% vs. 36%, $p = 0.03$). GWE significantly increased after fluid administration in responders only. The fluid-induced increase in GWI (56% vs. 10%, $p = 0.01$) and GCW (30% vs. 8%, $p = 0.01$) was higher in responders than in non-responders.
Fluid-induced changes (%) in VTI were correlated with fluid-induced changes in GWI ($r = 0{,}60$; $p < 0.001$) and GCW ($r = 0.62$; $p < 0.001$), but not with fluid-induced changes in GWW and GWE.
Conclusions: The MW is a new and promising parameter that requires a high level of TTE expertise to be obtained. These preliminary results suggest that response to fluid administration should also be assessed in terms of cardiac energetics rather than just cardiac output. Indeed, some patients could benefit from fluid administration in terms of cardiac energetics (by improving their GWE), without necessarily showing an increase in cardiac output (VTI > 15%) by established norms.

Intensive Care Medicine Experimental 2025,* 13(1)*:001175

Introduction: Sedation is fundamental for critically ill patients undergoing mechanical ventilation. Light sedation is recommended in international guidelines [1], but may be difficult to achieve, leading to a "mismatch" between the desired sedation level and the level observed. Implications of this mismatch are poorly understood [2].
Objectives: To test the hypothesis that a higher proportion of sedation mismatch is associated with fewer ventilator-free days at day 28 in adults receiving invasive mechanical ventilation (MV).
Methods: Retrospective study including adult patients who received ≥ 48 h of invasive MV between 2011 and 2024 at a single center. The exposure was the proportion of ventilated days with at least two consecutive mismatches between target and observed Richmond Agitation–Sedation Scale (RASS) scores (assessed every four hours) over 28 days. The primary outcome was ventilator-free days through day 28 (VFDs) [3]. Negative binomial regression models adjusted for baseline patient and ICU care characteristics were applied.
Results: Among 9,614 included patients (Fig. 1), 6,952 (72.3%) experienced a proportion of days with RASS mismatch > 0.5. Median age ranged from 65 to 66 years, and approximately 42% of patients were female. Patients with greater proportions of RASS mismatch had higher baseline APACHE II scores (23 (IQR: 19–27)) than those without RASS mismatch (20 (IQR: 17–24), ASD > 0.5). Higher mismatch was also associated with greater median propofol doses (7.3 g [IQR: 2.2–17.0] vs 2.4 g [IQR: 0.0–7.7]; ASD = 0.487) and a higher proportion of medical ICU admissions (84.2% vs 78.5%; ASD = 0.184). In adjusted analysis there was a 2.3% decrease in 28 day VFD (95% CI 1.3–3.3%; $p < 0.001$) per 10% increase in proportion of RASS mismatch. Predictive margins indicated that patients without RASS mismatch had 15.7 VFDs (95% CI 14.5–16.8), compared with 12.4 VFDs (95% CI: 11.9–13.0) in patients with RASS mismatch every day of MV (Fig. 2). In stratified analysis, RASS mismatch where sedation was deeper than target was associated with a 3.6% decrease in VFDs (95% CI 2.7–4.5%; $p < 0.001$) whereas RASS mismatch where sedation was lighter than target was associated with a 3.5% increase in VFDs (95% CI 2.3–4.7%; $p < 0.001$).
Conclusions: Sedation mismatch was associated with fewer VFDs, particularly when sedation was deeper than prescribed. This underscores the importance of sedation target adherence and the need for precision sedation strategies in patients where the goal of light sedation is difficult to achieve.

Intensive Care Medicine Experimental 2025,* 13(1)*:001177

Introduction: Septic shock is a leading cause of mortality in critically ill patients and the main indication for vasopressor therapy. Due to reduced vascular responsiveness to norepinephrine and a relative vasopressin deficiency, norepinephrine is used as the first-line agent.
Methods: We included all adult patients admitted to the ICU, between 1 January 2024–15 December 2024, with the diagnosis of septic shock according to SSC guidelines; who received noradrenalin alone and both noradrenalin with vasopressin as an adjunctive vasopressor. The primary endpoint was to evaluate the impact of vasopressin, used as a second-line agent, on hemodynamic and physiological parameters. The secondary endpoint was mortality.
Results: A total of 146 septic shock patients were included in the study, with 113 (77.4%) in the noradrenaline group and 33 (22.6%) in the adjunctive vasopressin-treated group. Patients in the vasopressin group had significantly higher severity of illness at at the time of septic shock. APACHE II scores were significantly higher in the vasopressin group compared to controls (26 vs. 19, $p = 0.007$), similarly, SOFA scores were higher (9 vs. 8, $p = 0.030$). Overall survival and 28-day survival were identical between groups. Overall survival: 24.2% in adjunctive vasopressin group vs. 24.8% in noradrenaline group ($p = 1.000$). The Kaplan–Meier survival curves was shown as Fig. 1. In terms of vasopressor requirements, the median norepinephrine dose decreased significantly from 0.55 mcg/kg/min (IQR: 0.44–0.84) at baseline to 0.43 mcg/kg/min (IQR: 0.27–0.72) by the 6th hour ($p = 0.010$), supporting a vasopressor-sparing effect of vasopressin. Change in physiological and hemodynamic parameters are also given in Table 1; Fig. 2).

Table 1 (abstract 001177) Comparison of time-dependent values after vasopressin *, †

Hours after vasopressin initiation				
	Hour 0	**2nd hour**	**6th hour**	**p value**
Heart rate – beat/min	110 (97,5–120)a	110 (100–123,75)a,b	97,5 (88,75–120,5)b	0,003
Systolic pressure – mmHg	80 (70–92,5)a	90 (80–105)b	95 (77,5–120)b	0,002
Diastolic pressure– mmHg	50 (40–50)a	50 (50–60)b	60 (50–60)b	0,001
Mean arterial pressure – mmHg	60 (54–66)a	70 (63.08–75.75)b	74 (61,75–83,5)b	< 0,001
pH	7.26 (7.19–7.32)a	7.28 (7.19–7.36)a	7.31 (7.17–7.37)a	0,07
Laktat – mmol/L	4,5 (3,55–7,05)a	4 (3.1–6.4)b	3.25 (2.7—7.45)b	< 0,001
Vazopressin dose – U/dak	0,01 (0,01–0,03)a	0,02 (0,01–0,03)a	0,02 (0,01—0,03)a	0,016
Noradrenalin dose – mcg/kg/dak	0,55 (0,44–0,84)a	0,55 (0,36–0,7)a,b	0,43 (0,27–0,72)b	0,010

* Upper letters donates statistically significant diffence within the group according to Related-Samples Friedman's Two-Way Analysis of Variance. † Data were shown as n (%)

The timing of adjunctive vasopressin initiation time was 14 h (IQR 5–25 h), and the initial norepinephrine dose at the time of vasopressin introduction was, 0.56 mcg/kg/min (IQR 0.445–0.880 mcg/kg/min).
Conclusions: This single center study with a limited number of patients is valuable as it reflects the first national experience with vasopressin use. In this study, no difference in mortality was observed between patients receiving norepinephrine alone and those receiving vasopressin in combination with norepinephrine. Adjunctive vasopressin was associated with an immediate noradrenaline sparing effect and a rapid reduction in, lactat levels, tachycardia and a notable hemodynamic improvement, characterized by a significant rise in mean arterial pressure.

Association of inhalation injury with ventilator-associated pneumonia and clinical outcomes in critically ill patients with burns: a retrospective study

T. Rech[1], T. Normann[1], B. Limeira[2], G. Dorneles[2], M. Oliveira[2], P. Bellaver[3]
[1]Post Graduate Program in Pneumological Sciences, Universidade Federal do Rio Grande do Sul, Porto Alegre, Brazil; [2]Burn Unit, Hospital de Pronto Socorro de Porto Alegre, Porto Alegre, Brazil; [3]Critical Care Division, Hospital de Clínicas de Porto Alegre, Porto Alegre, Brazil
Correspondence: T. Rech
Intensive Care Medicine Experimental 2025,* 13(1)*:001181

Introduction: Inhalation injury is a major indication for mechanical ventilation (MV) in patients with burns, contributing to prolonged MV and increased hospital costs (1).
Objectives: This study aimed to evaluate the impact of inhalation injury on the outcomes of patients with burns, especially ventilator-associated pneumonia (VAP) and mortality.
Methods: A single-center retrospective cohort study of patients admitted to the intensive care unit (ICU) with burn injuries. Data were obtained from medical records. The primary outcome was the incidence of VAP in patients with or without inhalation injury. Secondary outcomes included need and duration of mechanical ventilation (MV), incidence of acute respiratory distress syndrome (ARDS), need for prone positioning, rates of reintubation and tracheostomy, need for vasopressors and renal replacement therapy (RRT), length of ICU and hospital stay, hospital mortality, and comparison between survivors and nonsurvivors.
Results: From January 2017 to December 2022, a total of 242 patients with a median burn surface area of 23% (15%-37%) were included. Third-degree burns occurred in 64% of patients. The incidence of inhalation injury was 9.9% ($n = 24$). The overall incidence of VAP was 23%. VAP incidence was significantly higher in patients with inhalation injury than in those without inhalation injury (RR 2.1, CI 1.9–3.8) ($p < 0.012$). After adjustment for age, burn surface area, and duration of MV, the RR remained significant (2.1, CI 1.2–3.7) ($p = 0.009$). Patients with inhalation injury had higher rates of reintubation (12.5% vs. 2.8%, $p = 0.048$) and tracheostomy (54.2% vs. 21.6%, $p < 0.001$). The incidence of inhalation injury was similar in survivors and non-survivors (11.2% vs. 5.6%, $p = 0.305$), but non-survivors had a higher burn surface area than survivors (40% vs. 20%, $p < 0.01$).
Conclusions: The incidence of VAP was higher in patients with inhalation injury than in those without inhalation injury; however, the mortality rate was similar.

Unmasking the hidden threat: ventilator-associated pneumonia and gram-negative dominance

A. Sousa Lopes, J. P. Vinhal, E. Sousa, J. Alves, R. Pinho
Medicina Intensiva, Unidade Local de Saúde de Entre Douro e Vouga (CHEDV), Santa Maria da Feira, Portugal
Correspondence: A. Sousa Lopes
Intensive Care Medicine Experimental 2025,* 13(1)*:001182

Introduction: Ventilator-associated pneumonia (VAP), also known as pneumonia associated with intubation, is a severe nosocomial infection affecting critically ill patients under invasive mechanical ventilation. This complication is linked to significant morbidity and mortality, with reported mortality rates ranging from 20 to 70%. Frequently implicated pathogens include Gram-negative bacilli—notably *Klebsiella* spp. and *Pseudomonas aeruginosa*.
Objectives: To analyse cases of VAP in an adult mix intensive care unit (ICU) between 2022 and 2024, with a focus on the predominant microbial agents, patient mortality, and the duration of intubation and invasive mechanical ventilation.
Methods: A retrospective observational study was conducted in an adult mix Portuguese ICU, including all patients who developed VAP between January 2022 and December 2024. VAP was defined as pneumonia occurring after 48 h of endotracheal intubation, diagnosed based on clinical criteria (fever, leucocytosis or leukopenia, purulent secretions and new pulmonary infiltrates) and/or microbiological confirmation from respiratory cultures. Data collected included demographics, gravity scores, causative microorganisms, antibiotic therapy and outcomes (tracheostomy, duration of mechanical ventilation and ICU stay, ICU mortality). Data were analysed descriptively and survivors were compared to non-survivors.
Results: Among 23 VAP cases, the median age was 65 years (65% male), and 70% were medical admissions (30% trauma). Median SAPS II and SOFA scores on admission were 35 and 7, respectively, indicating moderate illness severity.
The diagnosis of VAP was typically established during the first two weeks of ventilation (median on day 8). Microbiological confirmation was obtained in 83% of cases, predominantly Gram-negative bacilli: *Klebsiella* spp. (39%) and *Pseudomonas aeruginosa* (26%). All patients received broad-spectrum antibiotics.
Median duration of mechanical ventilation was 29 days (with a maximum of 96 days), and 61% of patients required tracheostomy. The median ICU length of stay was 30 days (mean 43.6 ± 23.5). Other nosocomial infections occurred in 43% of patients (mostly bloodstream or urinary tract infections). ICU mortality was 35%, with no significant differences between years or by pathogen, and no association with

age or severity scores. No further in-hospital or 3-month mortality was recorded.
Conclusions: VAP remains a critical complication among ventilated ICU patients, predominantly involving Gram-negative pathogens and associated with significant mortality and prolonged durations of mechanical ventilation. These findings underscore the necessity for stringent preventive measures—such as ventilator care bundles—and early, targeted antibiotic therapy to improve clinical outcomes.

Clinical characteristics and outcomes of intensive care unit patients with acute poisoning: a 14-year retrospective cohort

A. Albuquerque, C. Cunha, O. Gomes, L. Pereira
Intensive Care Unit, Unidade Local de Saúde da Região de Leiria, Leiria, Portugal
Correspondence: A. Albuquerque
Intensive Care Medicine Experimental 2025,* 13(1)*:001184

Introduction: Acute poisonings remain a frequent cause of Intensive Care Unit (ICU) admission, often involving psychiatric comorbidities and requiring intensive supportive care. While polypharmacy with psychotropic drugs is increasingly common, pesticide-related exposures remain particularly severe and are frequently associated with worse outcomes in specific patient profiles. Understanding gender-related patterns and toxicological profiles may help guide targeted interventions.
Objectives: To describe the clinical profile of ICU patients admitted for acute poisoning, identify predictors of mortality, and examine associations between gender, type of intoxication and outcomes, with a dedicated analysis of pesticide-related cases.
Methods: We conducted a retrospective study of all adult patients admitted to a Portuguese ICU between 2010 and 2024 with acute poisoning. Variables included demographics, origin, APACHE II and SAPS II scores, psychiatric and alcohol-related history, previous intoxications, substances involved, organ dysfunctions, interventions (vasopressors, renal replacement therapy—RRT, gastric lavage, activated charcoal, antidotes), and outcomes. Statistical tests included chi-square, *t* test, and logistic regression. A dedicated subgroup analysis was performed for pesticide cases.
Results: A total of 106 ICU admissions were included (mean age 51.8 years; 50% male), mostly from the emergency department (92.5%). Psychiatric illness was documented in 56.6%, alcohol abuse in 19.8%, and 16.0% had previous intoxications. Most cases involved psychotropic drugs ($n = 42$), often combined with alcohol. Pesticide exposure was identified in 26 cases (24.5%), mainly organophosphates.
There was a significant association between gender and type of intoxication ($p = 0.013$), with 73.1% of pesticide cases in men and 86.8% of psychotropic intoxications in women. Neurological dysfunction occurred in 93.4%, cardiovascular in 33.0%, and renal in 15.1%. Interventions included vasopressors (22.6%), RRT (11.3%), gastric lavage (76.4%), activated charcoal (7.5%), and antidotes (43.4%). ICU mortality was 14.2%. Nonsurvivors were older (59.9 vs. 50.5 years, $p = 0.057$) and had higher APACHE II ($p = 0.011$; OR = 1.11, 95% CI 1.02–1.20) and SAPS II scores ($p = 0.017$; OR = 1.06, 95% CI 1.01–1.11). Other variables were not significantly associated with mortality.
Among pesticide cases, the mean age was 63.0 years, with 73.1% male. Mortality was 26.9%. These patients required vasopressors (50.0%), RRT (23.1%), lavage (92.3%) and antidotes (80.8%), reflecting greater clinical severity. Although time to medical contact was relatively short (mean: 3.6 h), outcomes remained poor.
Conclusions: ICU admissions for acute poisoning involve a clinically diverse population, frequently with psychiatric comorbidity and need for organ support. Gender was associated with the type of substance used, with psychotropic drugs more frequent in women and pesticides in older men. Pesticide-related poisonings showed higher severity and mortality. APACHE II and SAPS II were the strongest predictors of mortality, supporting their role in early risk stratification. These findings highlight the need for improved documentation, toxicovigilance and targeted public health strategies.

$ZnCl_2$ smoke-induced acute lung injury: mechanism and prevention

X. Fei
College of Pulmonary and Critical Care Medicine, Chinese PLA General Hospital, Beijing, China
Correspondence: X. Fei
Intensive Care Medicine Experimental 2025,* 13(1)*:001185

Introduction: Zinc chloride ($ZnCl_2$) smoke, a hazardous combustion byproduct generated during military and firefighting training exercises using smoke grenades, represents a significant etiological factor in acute lung injury (ALI). Despite the critical nature of this iatrogenic exposure, clinical management remains limited to supportive care, with no targeted prophylactic interventions currently available.
Objectives: This study aimed to explore the pathogenesis of ZnCl2 smoke-induced ALI, evaluate the protective efficacy of pulmonary surfactant vesicles (PSV), derived from natural bovine surfactants, administered via inhalation.
Methods: A murine model of ALI was induced by exposing mice to ZnCl2 smoke for 3 min in a sealed chamber. Animals were randomly divided into four groups: sham, $ZnCl_2$-exposed, ZnCl2 + PSV, and ZnCl2 + budesonide (BUD; positive control). PSV and BUD were respectively administered intratracheally 30 min prior to smoke exposure. After smoke exposure, the respiratory function of the mice was assessed 48 h later. Lung injury was assessed by histopathological analysis, quantification of proinflammatory cytokines (TNF-α, IL-6, IL-1β), oxidative stress markers (myeloperoxidase [MPO], malondialdehyde [MDA], and superoxide dismutase [SOD]), and apoptosis indicators (Bcl-2 expression and TUNEL staining). Ultrastructural alterations were examined using transmission electron microscopy. The integrity of the air-blood barrier was evaluated using Evans blue dye extravasation and three-dimensional magnetic particle imaging (3D-MPI).
Results: ZnCl2 smoke exposure led to severe alveolar collapse, inflammatory infiltration, oxidative damage, and apoptotic cell death, along with disruption of the air-blood barrier and pulmonary edema. Pre-treatment with PSV significantly reduced the levels of inflammatory cytokines, oxidative stress markers, and apoptosis. Notably, PSV preserved alveolar architecture, maintained barrier integrity, and improved both CT density and MPI ventilation signal. Compared to

BUD, PSV provided superior protection in preventing ZnCl2-induced damage and promoting lung function recovery.
Conclusions: This study reveals the critical role of air-blood barrier disruption in ZnCl2 smoke-induced ALI and supports the use of inhaled PSV as a promising prophylactic strategy. These findings provide translational evidence for non-invasive surfactant therapy in managing toxic inhalation-related respiratory injury.

Impact of telemedicine on reducing infections, response time of consultation, accuracy, and efficacy through real-time communication

A. Heikel[1], A. Abdelmaguid[2], S. Basma[3], A. El Haddad[4]
[1]Critical care, Royal commission hos, yanbu, Saudi Arabia; [2]Critical care, Dr. Hamid S. Al-Ahmadi Hospital-ITC, Madinah, Saudi Arabia; [3]Research, Kasr al -Aini, cairo, Egypt; [4]Critical care, Royal commission hosp, jubail, Saudi Arabia

Intensive Care Medicine Experimental 2025,* 13(1)*:001186

Introduction: Telemedicine has emerged as a transformative solution in modern healthcare, enabling remote consultation and care delivery through real-time communication technologies. As healthcare systems strive to improve efficiency, safety, and patient outcomes, telemedicine presents a promising approach to address key challenges, including infection control, clinical responsiveness, and care quality.
Objectives: The study aims to evaluate the impact of telemedicine on reducing healthcare-associated infections (HAIs), assess improvements in consultation response times through telemedicine, and compare the accuracy of clinical decisions between telemedicine and traditional consultations. It also seeks to examine patient satisfaction and overall care efficacy using telemedicine. Lastly, the study will identify key factors influencing telemedicine adoption and implementation in real-time care.
Methods: A mixed-methods design was used, combining quantitative and qualitative data collection.
Quantitative:A comparative observational study was conducted with 400 patients (200 telemedicine, 200 traditional care). The data from Electronic Health Records (EHRs) and hospital systems were analyzed to assess:

- Healthcare-associated infection (HAI) rates
- Consultation response times
- Diagnostic accuracy (based on follow-up outcomes)
- Patient satisfaction (5-point Likert scale)

Statistical analysis included chi-square tests for categorical data and independent t tests for continuous variables.
Qualitative: Semistructured interviews and focus groups were conducted with 15 healthcare providers and 20 patients**.** Thematic analysis was used to explore experiences, effectiveness, and barriers to telemedicine adoption.
Results: Data from 400 patients revealed the following key findings:

- HAIs were significantly lower in the telemedicine group (4%) compared to the traditional group (9%), $\chi^2(1, N = 400) = 12.5$, $p < 0.001$
- Average consultation response time was faster in the telemedicine group (15 min vs. 45 min), $t(398) = 8.9$, $p < 0.001$
- Clinical decision accuracy was higher with telemedicine (92% vs. 85%), $\chi^2(1, N = 400) = 10.8$, $p = 0.001$
- Patient satisfaction was significantly greater in the telemedicine group (4.7 vs. 3.8 out of 5), $t(398) = 6.7$, $p < 0.001$

Conclusions: This study provides robust evidence that telemedicine enhances healthcare delivery by reducing infection rates, improving response times, increasing diagnostic accuracy, and elevating patient satisfaction. These findings support the integration of telemedicine into routine clinical practice and inform healthcare policies aimed at expanding access and quality of care. Continued investment in technology, training, and regulatory support is essential to fully realize the benefits of telemedicine.

Prevalence of burnout syndrome, stress, anxiety and depression among in ICU healthcare professionals: Maracaibo, Venezuela

A. Mujica[1], J. M. Osio[2], N. Arraiz[3]
[1]ICU, Centro Clinico Universitario La Sagrada Familia, Maracaibo, Venezuela; [2]ICU, Clínica Guerra Méndez, Valencia, Venezuela; [3]Molecular Biology Department, University of Zulia, Maracaibo, Venezuela
Correspondence: A. Mujica
Intensive Care Medicine Experimental 2025,* 13(1)*:001187

Introduction: Mental health state in ICU workers determines quality of practicing and patient security. It is a challenge to keep mental balance between excessive workload and high demands of care and lack of medical resources and extremely poor conditions. ICU healthworkers are in high risk to develop Burnout Syndrome (BS), stress, anxiety and depression.
Objectives: The aims of this study was to assess the current prevalence of burnout syndrome, stress, anxiety and depression among ICU healthcare professionals in ICUs in Maracaibo, Venezuela.
Methods: A standarized questionnaire was administrated to doctors and nurses in 3 public ICUs and 1 private ICU in Maracaibo, Venezuela during March 2025, sent online. It was strictly confidential and anonymous. The survey consisted of 4 parts: sociodemographic information followed by 3 validated psychometric instruments: Maslach Burnout inventory-Human Services Survey (MBI-HSS) for burnout, Cohen Perceived Stress Scale (CPSS-14) for stress and Patient Health Questionnare Screening (PHQ-4) for anxiety and depression. Their reliability was assessed by Cronbach's alpha value.
MBI-HSS is a 22-item questionnaire that explores three dimensions: emocional exhaustation (EE), despersonalization (DP) and personal accomplishment (PA). Professional SB was defined by scores of EE $\geq$ 26pts and DE $\geq$ 9pts or EE $\geq$ 26pts and PA $\leq$ 34. CPPS-14 total score was categorized in low stress (0–18), moderate stress (19–37) and high stress ($\geq$ 38). In the PHQ-4, scores $\geq$ 3pts for the first two items-measure anxiety and scores $\geq$ 3pts for the last two-items measure depression.
Central tendency and dispersion measures means and standards desviations or medians and interquartile ranges were used, depending on variables distribution, according to the Kolmogorov–Smirnov test. Comparision was made using independent sample *t* test and ANOVA one way. IBM SPSS Software version 2024 was used. A *p* value of $\leq$ 0.05 was considered significant.
Results: The study population consisted in 105 participants, corresponded to a response rate of 61% (inicial number: 172 invited), including professionals between 18 and 60 years. Most of them, were women (76.2%), singles (62.9%) and involved nurses (71.4%) y doctors (28.6%) (Table 1).
Burnout syndrome was detected in 27.6% (29/105) in this population, showing higher prevalence in 18–40 years old participants compared to 40–60 years old (37.7% vs 17.3%, $p = 0.028$). The major components of BS in this study were emocional exhaustion (35.2%) and despersonalization (29.5%) (Table 2). In addition, professionals who had < 5 years of experience working in ICU exhibited higher prevalence of BS than groups who have worked in ICU 5–10 years and > 10 years (43.3% vs 28.2% vs 13.9%, $p = 0.029$). Doctors experienced increased levels of BS compared to nurses (43.3% vs 21.3%, $p = 0.023$). Marital status and type of institution were not associated to BS ($p = 0.42$ and $p = 0.09$).
Moderate stress was diagnosed in the study (21.06 $\pm$ 8.6). The 40–60 years group (18.7 $\pm$ 8.6, $p = 0.007$) and the one who had > 10 years of experience (16.1 $\pm$ 8.7, $p = 0.001$) showed less stress levels (Table 3).
Anxiety diagnose was more common in 18–40 years group than the oldest one but not significant (32.1% vs 17.3%, $p = 0.08$). As well, anxiety was highly observed in the group that had less experience in contrast > 10 years of experience professionals (46.7% vs 2.8%, $p = 0.001$). Similar behaviour for depression was found (33.3% vs 5.6%, $p = 0.012$) (Table 3), as shown highest scores in moderate and severe category in the less experience group ($p = 0.009$) (Table 4).Stress, anxiety and depression were associated to SB ($p = 0.001$, $p = 0.001$ and $p = 0.014$).
Conclusions: In our study, being younger and having less professional experience in ICU were associated to BS, stress, anxiety and depression. Doctors showed higher levels of BS than nurses. This is the first study in Venezuela to our knowledge, and results are important for creating programs to promote wellbeing and mental health in new generations ICU healthworkers. The sample size was a limitation of the study and it is not representative of all the country.

Impact of ICU design on staff burnout: a comprehensive investigation

A. Abdelmaguid[1], A. Heikel[2], A. El Haddad[3], S. Basma[4]
[1]Critical care, Dr. Hamid S. Al-Ahmadi Hospital-ITC, Madinah, Saudi Arabia; [2]Critical care, Royal commission hos, yanbu, Saudi Arabia; [3]Critical care, Royal commission hosp, jubail, Saudi Arabia; [4]Research, Kasr al-Aini, Cairo, Egypt

Intensive Care Medicine Experimental 2025,* 13(1)*:001188

Introduction: Intensive care units (ICUs) are high-stress environments where healthcare professionals, particularly nurses and physicians, are exposed to physically and emotionally demanding situations. Burnout in ICU staff is increasingly recognized as a major concern, impacting not only individual well-being but also patient safety and care quality. Although workload and patient acuity are commonly examined, the role of the physical design of the ICU—such as noise levels, lighting, and spatial layout—has received limited empirical attention. This study aims to explore how ICU design influences staff burnout and to identify key environmental factors that contribute to or mitigate stress.
Objectives: The primary objective was to investigate the relationship between ICU design and burnout among staff. Secondary objectives included assessing the correlation between specific design elements (e.g., lighting, noise, layout) and burnout levels, and exploring the mediating roles of perceived workload and job satisfaction in this relationship.
Methods: A mixed-methods design was employed, combining quantitative and qualitative data collection and analysis. The quantitative component involved a comparative observational study of 200 ICU nurses and physicians across multiple hospitals. Participants completed standardized questionnaires, including the Maslach Burnout Inventory (MBI) and ICU-specific environmental assessments. Data were analyzed using correlation and regression analyses to determine relationships between ICU design factors and burnout scores.
The qualitative component involved semi-structured interviews with 15 ICU staff and focus groups with 20 participants from both well-designed and poorly designed ICUs. Thematic analysis was used to identify perceptions of environmental stressors and suggestions for improvement.
Results: The average burnout score among participants was 30, indicating moderate burnout. There was a strong positive correlation ($r = 0.65$, $p < 0.001$) between poor ICU design and higher burnout levels. Specific findings include:

- Noise levels significantly predicted increased burnout ($\beta = 0.4$, $p < 0.01$).
- Natural lighting was associated with significantly lower burnout scores ($M = 24$) as compared to poorly lit environments ($M = 34$; $t(198) = 4.5$, $p < 0.001$).
- Efficient unit layout was associated with reduced perceived workload and burnout ($\beta = -0.35$, $p < 0.05$).

Qualitative data supported these findings, with staff citing noise, lack of privacy, poor lighting, and inefficient workspace arrangements as major contributors to stress and exhaustion. Many participants reported that better design would enhance their job satisfaction, performance, and emotional resilience.
Conclusions: This study provides strong evidence that ICU design plays a significant role in shaping staff burnout. By identifying specific

environmental stressors, the research offers actionable insights for healthcare planners and administrators seeking to redesign ICU spaces. Improvements in lighting, acoustics, and spatial efficiency could serve as strategic interventions to reduce burnout, improve staff retention, and ultimately enhance the quality of patient care. Future studies should examine the long-term effects of such design interventions and expand research across diverse healthcare settings.

Natural agent cynaropicrin alleviates sepsis-induced ARDS via covalent targeting NLRP3 in macrophages

H. Xu[1], X. Lingxiao[2], Z. Zhaocai[3]
[1]Department of Critical Care Medicine, The Second Affiliated Hospital of Zhejiang University School of Medicine, Hangzhou, China; [2]Production Company, Hangzhou Zhongmei Huadong Pharmaceutical Co., Ltd., Hangzhou, China; [3]Department of Critical Care Medicine, The Second Affiliated Hospital of Zhejiang University School of Medicine, Hang Zhou, China
Correspondence: H. Xu
Intensive Care Medicine Experimental 2025,* 13(1)*:001189

Introduction: The excessive activation of NOD-like receptor family pyrin domain containing 3 (NLRP3) inflammasome plays a critical role in the development of sepsis-induced acute respiratory distress syndrome (ARDS) by inducing the production of pro-inflammatory cytokines and driving pathological processes. Pharmacological inhibition of the NLRP3 inflammasome emerges as a discernible therapeutic strategy in the treatment of ARDS. However, FDA has authorized no NLRP3 inhibitor for therapeutic application in treating ARDS.
Objectives: Our laboratory commits to discovering potential NLRP3 inhibitors as effective drugs against sepsis-induced ARDS. Cynaropicrin inhibited the secretion of Caspase-1 and IL-1β, and suppressed NLRP3 inflammasome-mediated pyroptosis in macrophages. We hypothesize that Cynaropicrin is an effective drug against sepsis-induced ARDS. This study aims to investigate the therapeutic efficacy of Cynaropicrin in sepsis-induced ARDS and clarify its underlying pharmacological mechanism.
Methods: The therapeutic effect of Cynaropicrin was evaluated in murine LPS-induced ARDS models. Lung tissue and bronchoalveolar lavage fluid were collected for pathological examination. Immunoblotting and ELISA assays were performed for inflammatory detection. Proteomic analysis of lung tissue was performed to discover the pharmacological mechanism of Cynaropicrin. In vitro studies were conducted on primary mouse macrophages to investigate how Cynaropicrin inhibited the NLRP3 inflammasome.
Results: Cynaropicrin has an obvious therapeutic effect on the murine ARDS model through inhibiting the NLRP3 inflammasome pathway in alveolar macrophages. Cynaropicrin treatment significantly reduced lung tissue trauma and disruption of air–blood barrier. It also decreased total cell infiltration and neutrophil invasion after LPS challenge. The secretion of the crucial inflammatory factors and proteins; namely, IL-1β and Caspase-1, associated with the NLRP3 inflammasome pathway showed a notable decrease in response to Cynaropicrin administration. In contrast, the therapeutic efficacy of Cynaropicrin was abolished in GsdmdKO and Nlrp3KO mouse ARDS models. In vitro studies revealed Cynaropicrin specifically inhibited the activation of NLRP3 inflammasome in primary mouse macrophages and primary human peripheral blood monocytes. The assembly of NLRP3 inflammasome was interrupted under CYN treatment via inhibiting the complex of NLRP3–NEK7 and NLRP3–ASC. From a molecular structure perspective, Cynaropicrin directly bound to the NACHT domain of NLRP3, covalently bound to cysteine 417 (Cys415 in mouse) and reduced NLRP3 oligomerization via suppressing its ATPase activity.
Conclusions: Cynaropicrin, for the first time, was identified as a natural covalent inhibitor of NLRP3 and as a new lead compound for the treatment of NLRP3-mediated ARDS. Cynaropicrin has promising clinical applications and development potential for the treatment of ARDS.

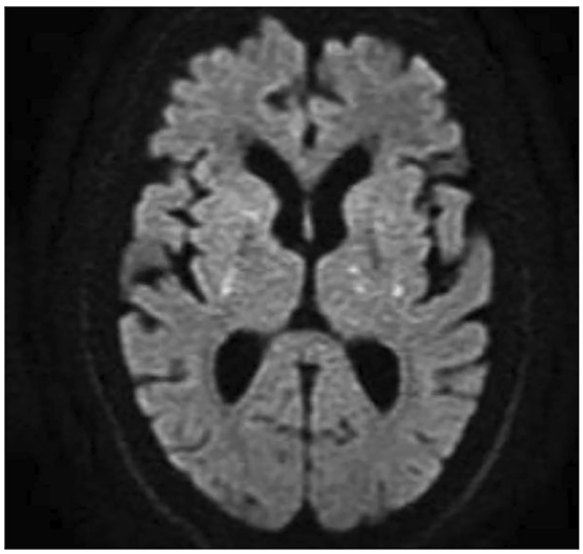
Disseminated cryptococcal meningitis in an immunocompetent patient: a diagnostic challenge

F. Ahmed[1], M. Rafi[1], A. Sabeen[2]
[1]Medicine, Aga Khan University, Karachi, Pakistan; [2]Internal Medicine, Aga Khan University Hospital, Karachi, Pakistan
Correspondence: F. Ahmed
Intensive Care Medicine Experimental 2025,* 13(1)*:001190



Introduction: Cryptococcal meningitis is the most common cause of fungal meningitis and typically affects immunocompromised hosts, particularly those with HIV/AIDS, solid organ transplants, or chronic immunosuppressive therapy. However, around 20% of cases occur in individuals without identifiable immunodeficiency. In such cases, clinical suspicion is often low, leading to diagnostic delays. Presentations may be atypical or subtle, contributing to morbidity and mortality. We report a case of disseminated cryptococcosis in LMIC in a previously healthy 55-year-old male, initially misdiagnosed despite multiple healthcare encounters, which eventually led to fatal outcomes.
Objectives: Cryptococcal meningitis, a life-threatening fungal infection, predominantly affects immunocompromised individuals. However, a rising number of cases have been reported in immunocompetent patients, where diagnosis is often delayed due to atypical presentations.
Methods: A 55-year-old male, with no known comorbidities, presented to the emergency department with a one-week history of flu-like symptoms, non-productive cough, and 15 h of palpitations. He denied fever, dyspnea, gastrointestinal symptoms, neck stiffness, photophobia, or recent infections. No history of chronic illness, immunosuppressive therapy, or substance use was reported.Two months earlier, he had presented with aphasia, left lower limb numbness, and jerky limb movements. MRI brain showed leptomeningeal enhancement, but CSF analysis was normal. He was discharged on antiepileptic medication. A follow-up MRI showed new multifocal infarcts, and his seizure regimen was adjusted.
On examination, he was alert, oriented, and hemodynamically stable, except for tachycardia (HR 109 bpm). Vitals: BP 103/58 mmHg, RR 20/min, SpO_2 99% RA. Neurological exam showed no focal deficits, and meningeal signs were absent. Chest X-ray showed subtle bilateral infiltrates, and CRP was elevated. ECG revealed sinus tachycardia.

Empirical antibiotics were initiated for suspected atypical pneumonia. Respiratory viral panels including COVID-19, influenza, and RSV were negative. He developed seizures (stiffening and staring spells) in the ED, followed by hypoxia requiring NIV, and was subsequently intubated.CT pulmonary angiography showed bilateral ground-glass opacities and a "tree-in-bud" appearance, with no pulmonary embolism. Repeat MRI brain revealed new lacunar infarcts. A lumbar puncture showed:• Opening pressure: Elevated• CSF glucose: < 2 mg/dL• Protein: 193 g/dL• WBC count: 20 cells/μL, 98% lymphocytesAFB smear and PCR for TB in CSF and tracheal aspirate were negative. However, India ink staining revealed budding yeasts, and cryptococcal antigen was strongly positive (1:2560 in CSF and serum). Blood cultures also confirmed *Cryptococcus neoformans*.

The patient was HIV, hepatitis B, and C negative. Workup for malignancy, sarcoidosis (ACE levels), and plasma cell dyscrasias was unremarkable. He was diagnosed with disseminated cryptococcosis, including pulmonary and CNS involvement.He was initiated on intravenous amphotericin B (1 mg/kg/day) and high-dose fluconazole (1200 mg/day). By Day 14, repeat CSF cultures and India ink were negative. His GCS improved and he was extubated, but later developed ventilator-associated pneumonia, necessitating re-intubation and tracheostomy. He remained septic and unfortunately succumbed to multiorgan failure.

Results: India ink staining and cryptococcal antigen testing confirmed cryptococcal meningitis with systemic dissemination. Despite antifungal therapy with amphotericin B and fluconazole, the patient developed ventilator-associated pneumonia and succumbed to sepsis. Cryptococcal infection must be considered in patients with subacute neurological symptoms, regardless of HIV status. Early lumbar puncture with fungal staining and antigen testing is crucial in CNS presentations.

Conclusions: This case highlights the growing need to consider cryptococcal infection in immunocompetent individuals presenting with neurological symptoms, especially in cases where initial workup is non-revealing. Early CSF testing and fungal diagnostics may be lifesaving. Consent to publish had been obtained.

Thromboembolic phenomenon in cryptococcal meningitis.

Early versus late initiation of second-line vasopressors with norepinephrine and short-term prognosis in septic shock: a retrospective cohort study

W. Song, M. Liao, H. Yuan, T. Yang, X. Ma, X. Guan, R. Shi, X. Si, J. Wu
Department of Critical Care Medicine, The First Affiliated Hospital, Sun Yat-sen University, Guang Zhou, China
Correspondence: W. Song
Intensive Care Medicine Experimental 2025,* 13(1)*:001191

Introduction: The current guidelines recommend combining second-line vasopressors with norepinephrine for patients experiencing refractory shock in the intensive care unit (ICU). However, there is limited evidence regarding the optimal timing for initiating second-line vasopressors. This study aims to evaluate the effects of early versus late initiation of second-line vasopressors in patients with septic shock.

Methods: This single-center, retrospective observational study examined patients with septic shock who were admitted to the ICU of the First Affiliated Hospital of Sun Yat-Sen University between June 2016 and December 2023. The inclusion criteria for the study were: (i) adult patients with septic shock admitted to our ICU within 48 h of onset, and (ii) patients requiring at least two vasopressors to maintain a mean arterial pressure (MAP). The primary outcome is the total dose of norepinephrine during first seven days of ICU stay. The secondary outcomes include ICU length of stay (LOS), hospital LOS, mechanical ventilation free days, fluid balance,7-day ICU mortality and hospital mortality. The second-line vasopressors considered in the study were epinephrine, metaraminol, and terlipressin. Patients were categorized into the early and late groups based on whether a second-line vasopressor was added to the norepinephrine treatment. The median time for initiating second-line vasopressors in our cohort served as the cut-off value to distinguish between these two groups. To compare the two groups, we used univariate and multivariate Cox regression proportional hazards analysis. Continuous variables were assessed using either a t test or a rank-sum test, while categorical variables were analyzed using Fisher's exact test. A two-sided p value of less than 0.05 was considered statistically significant.

Results: In total, 176 septic shock patients (71% male) were included with mean Sequential Organ Failure Assessment (SOFA) scores of 12 (10–14). The median time for initiating the second-line vasopressors was 9 (5–12) hours. The cohort was thus separated into two groups: early gourp (< 9 h, $n = 90$) and late group (≥ 9 h, $n = 86$). The mean dose of norepinephrine when the second-line vasopressors were initiated was 0.5 (0.1–1.1) mcg/kg/min in the early group and was 0.6 (0.3–1.0) mcg/kg/min in the late group ($p = 0.094$). There are no difference between two groups of patients except that there are more post-operation patients in early group than in late group (92.2% vs. 74.4%, $p = 0.001$). Besides, the lactate level was higher in the early group than in the late group (9.3 (3.8–15.0) vs. 5.2 (2.6–10.9), $p = 0.004$). Regarding the primary outcome, although the mean (early: 0.7 (0.3–1.1) *vs.* late: 0.5 (0.2–1.0) mcg/kg/min, $P = 0.069$) and maximal (early: 1.1 (0.6–1.8) *vs.* late: 0.8 (0.4–1.5) mcg/kg/min, $P = 0.027$) dose of norepinephrine was higher in the early group than in the late group during the first nine hours of ICU admission, the total dose of norepinephrine was less in early group compare to late group (249.1 (118.5–403.8) vs. 274.2 (149.5–594.8) mcg/kg/min, $p = 0.235$). The 7-day survival rate of the early group was higher than that of the late group throughout the entire observation period. The Log-rank test indicated that the difference in survival curves between the two groups was statistically significant ($p = 0.039$). The Cox regression analysis shows that late initiation of second-line vasopressors (Hazard ratio (HR): 3.25 (1.61–6.58),

$p = 0.001$), the lactate level at the ICU admission (HR: 1.03 (0.95–1.11), $p = 0.497$) and the mean dose of norepinephrine during the first nine hours of ICU admission (HR: 1.78 (1.14–2.79), $p = 0.012$) were the independent risk factors for the 7-day ICU mortality. There were no difference between early and late groups regarding ICULOS, hospital LOS, mechanical ventilation free days, fluid balance and hospital mortality.
Conclusions: In septic shock patients, early initiation of second-line vasopressors could significantly reduce the use of norepinephrine in the early phase and was associated with an improvement in 7-day ICU mortality.

An investigation of the relationship between disgust propensity and sensitivity and professional quality of life among intensive care nurses
B. Tosun[1], E. Dirgar[2], S. Berse[2], S. Gungor[3], I. Dusak[4]
[1]Faculty of Nursing, Hacettepe University, Ankara, Turkey; [2]Faculty of Nursing, Gaziantep University, Gaziantep, Turkey; [3]Vocational School of Health Services, Kahramanmaraş Sütçü İmam University, Kahramanmaraş, Turkey; [4]Palliative Care Department, Şanlıurfa Mehmet Akif İnan Eğitim ve Araştırma Hastanesi Haliliye Ek Binası, Şanlıurfa, Turkey
Correspondence: B. Tosun
Intensive Care Medicine Experimental 2025,* 13(1)*:001193

Introduction: Intensive care nurses frequently come into contact with the human body and bodily fluids due to the nature of their profession. This exposure may lead to disgust sensitivity in some nurses, potentially affecting their professional performance, job satisfaction, and psychological resilience.
Objectives: This study aimed to examine the relationship between disgust propensity and sensitivity and the subdimensions of professional quality of life among intensive care nurses.
Methods: This descriptive and correlational study was conducted using a snowball sampling method. An online questionnaire was initially distributed to intensive care nurses working in different geographical regions of Turkey. Participants were also encouraged to share the survey with other colleagues working in similar intensive care settings to increase sample diversity and reach. Although the questionnaire was sent to a larger pool of nurses, the study was completed with $n = 209$ intensive care nurses who fully completed the data collection form and correctly answered the control validation item, ensuring the accuracy and reliability of their responses. Descriptive statistics, Kruskal–Wallis and Mann–Whitney U tests were used for group comparisons, and Spearman correlation analysis was conducted to assess the relationships between variables.
Data were collected through two validated instruments: the Professional Quality of Life Scale (ProQOL), and the Disgust Propensity and Sensitivity Scale (DPSS), which assesses an individual's tendency to feel disgust and the intensity of the response.
Results: The mean age of the intensive care nurses was 31.33 ± 6.91 years, and 62.2% were female. Disgust sensitivity was positively correlated with compassion fatigue (secondary traumatic stress) ($r = 0.551$; $p < 0.01$) and burnout subdimentions. ($r = 0.376$; $p < 0.01$), and negatively correlated with compassion satisfaction subdimention ($r = -0.140$; $p < 0.05$). Nurses who were frequently exposed to disgust-inducing situations and reported that their performance was seriously affected had significantly higher levels of disgust sensitivity, burnout, and compassion fatigue ($p < 0.001$). Those who reported considering leaving the profession due to disgust had significantly lower compassion satisfaction and higher levels of burnout and compassion fatigue ($p < 0.001$). Statistically significant differences were also found by age, gender, years of experience, and education level. Older and more experienced nurses had higher compassion satisfaction and lower burnout levels ($p < 0.05$). Female nurses had significantly higher disgust sensitivity as compared to male nurses ($p = 0.011$).
Conclusions: Disgust propensity and sensitivity negatively affect various dimensions of professional quality of life among intensive care nurses. Structured training programs to strengthen coping skills and emotional resilience are recommended to support nurses in managing disgust-related stressors in clinical settings.

Intensive Care Medicine Experimental 2025,* 13(1)*:001194

Introduction: Switching from controlled to assisted ventilation is crucial in the trajectory of intensive care unit (ICU) stay, but no guidelines exist. We described current practices, analysed patient characteristics associated with switch success or failure, and explored the feasibility to predict switch failure.
Methods: In this retrospective study, we obtained highly granular longitudinal ICU datasets from three medical centers, covering demographics, severity scores, vital signs, ventilation, and laboratory parameters. The primary endpoint was switch success, considering a switch attempt to be successful if a patient remained on assisted ventilation for the next 72 h while alive, and to be failed otherwise. We compared the characteristics of patients with successful versus failed first switch attempts at ICU admission, immediately before, and three hours after the attempt. We trained LASSO logistic regression models to predict switch failure.
Results: In 4,524/6,715 (67%) patients attempting a switch, the first attempt failed. The first switch attempt, regardless of success or failure, was generally made at normalized PaCO2 and pH levels, with PEEP < 10 cmH2O and PaO2/FiO2 indicating mild injury. Despite very similar baseline disease severity, switch failure was associated with significantly worse outcomes, including a 28-day mortality of 27% vs. 16% and median ventilator-free days of 16 vs. 22 ($P < 0.001$). Failed attempts were initiated significantly earlier than successful ones

(median 1.8 vs. 1.3 days, $p < 0.001$). PaO2/FiO2 was lower before the switch in patients with switch failure (185 vs. 205 mmHg, $P < 0.001$) if measured at PEEP > 10 cmH2O (Fig. 1), and they experienced greater deterioration in gas exchange and minimal improvement in ventilatory parameters post-switch. Contrary to our hypotheses, however, patient characteristics for failed vs successful switches were surprisingly similar, resulting in prediction models with limited discriminative performance.

Conclusions: Approximately two-thirds of attempts to switch to assisted ventilator modes fail, which are associated with significantly worse clinical outcomes, despite similar baseline disease severity. Contrary to our hypotheses, patients with successful and failed attempts showed similar characteristics, making switch failure difficult to predict. These findings underscore the importance of preventing switch failures and, given the retrospective nature of our study, highlight the need for prospective studies to better understand the reasons for switch failure and when spontaneous breathing can be safely initiated.

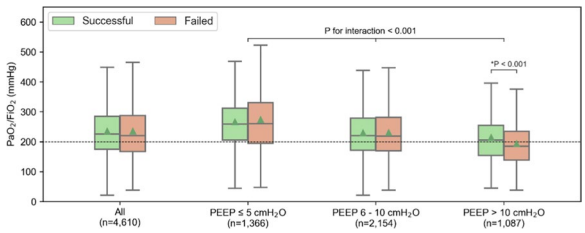

Fig 1 (abstract 001194) PaO2/FiO2 at the switch attempts, for patients with successful vs. failed switches, for all patients and stratified for the set PEEP at the time of measurement. The p value for interaction denote that PEEP significantly modified the association between the PaO2/FiO2 and switch success

Sivelestat sodium alleviates acute lung injury in heat stroke rats by protecting the endothelial glycocalyx

J. Wang[1], Z. Sun[1], Y. Zhang[1], R. Chi[2], F. Liu[3]
[1]Department of Critical Care Medicine, the Eighth Medical Center of Chinese PLA General Hospital, Beijing, China; [2]Graduate school, Hebei North University, Zhangjiakou, China; [3]Department of Endocrinology and Geriatrics, Pingchang County People's Hospital, Bazhong, China
Correspondence: J. Wang
Intensive Care Medicine Experimental 2025,* 13(1)*:001195

Introduction: Heat stroke (HS) represents a life-threatening systemic disorder characterized by rapid elevation of core body temperature resulting from exposure to extreme heat and humidity. This condition frequently leads to multiorgan dysfunction, including acute lung injury (ALI), and is often accompanied by neurological impairment with significantly high mortality rates. Based on the etiological factors, HS is clinically classified into two distinct forms: exertional heat stroke (EHS) and classic heat stroke (CHS). The escalating global temperatures coupled with demographic aging have precipitated a marked increase in CHS incidence among elderly populations. Advanced age confers particular vulnerability to CHS due to age-related deterioration in circulatory function and diminished capacity for thermoregulatory adaptation. The current therapeutic strategies for HS primarily focus on three key interventions: rapid core temperature reduction, systemic inflammatory response modulation, and comprehensive organ function support. Sivelestat sodium (SIV), a specific neutrophil elastase (NE) inhibitor, has demonstrated therapeutic potential through its dual mechanism of action: suppressing protease-mediated inflammatory cascades while preserving the structural integrity of the pulmonary vascular endothelial glycocalyx (EG). These pharmacological properties suggest SIV may offer protective effects against HS-induced ALI and pulmonary tissue damage. Notably, the potential efficacy of SIV in preventing or treating CHS-associated lung injury in aging populations remains unexplored in the current scientific literature.

Objectives: To investigate the effects of Sivelestat sodium (SIV) on acute lung injury in heat stroke (HS) rats and its potential mechanisms.

Methods: A total of 125 rats were randomly divided into five groups (25 rats/group): Control (Ctrl), Heat Stroke 12 h (HS-12 h), Low-dose SIV (HS + SIV 1.6 mg/kg), Medium-dose SIV (HS + SIV 4.8 mg/kg), and High-dose SIV (HS + SIV 10 mg/kg). SIV was administered via tail vein 2 h prior to modeling at respective dosages. The survival rates of all groups were recorded over 72 h. Histopathological changes were assessed using HE staining; lung vascular permeability was evaluated with Evans blue dye; pulmonary edema was measured by dry/wet weight ratio; TUNEL staining was used for apoptosis analysis; neutrophil counts in bronchoalveolar lavage fluid (BALF) were determined by Wright–Giemsa staining; ELISA was conducted to measure inflammatory mediators TNF-α, IL-6, IL-1β levels, and NE activity; serum NE activity and glycosaminoglycans (HA, HS, CS, SDC1) were quantified; Western blot (WB) was performed to evaluate the expression of HS, glypican-1, SDC1, Toll-like receptor 4 (TLR4), and Heparanase (HPSE) in lung tissues; immunohistochemistry was utilized to observe syndecan-1 expression in pulmonary endothelial cells; transmission electron microscopy was employed to assess the structure of the endothelial glycocalyx.

Results: SIV administration significantly increased survival rates in HS rats ($P < 0.01$) in a dose-dependent manner (Fig. 1). Lung tissue pathology, dry/wet weight ratios, vascular permeability, and apoptosis were markedly reduced in SIV-treated groups. Furthermore, levels of inflammatory factors (IL-1β, IL-6, TNF-α), neutrophil counts, and NE activity in BALF and serum were lowered (Fig. 2). Notably, expression of HS, syndecan-1, and glypican-1 in lung tissues increased significantly, while TLR4 and HPSE expressions decreased. Serum levels of HS, HA, CS, and SDC1 were significantly reduced(Fig. 3).Immunohistochemical and electron microscopy results demonstrated enhanced expression of syndecan-1 in pulmonary endothelium along with the progressive integrity of the endothelial glycocalyx with increased dosages of SIV (Fig. 4).

Conclusions: SIV alleviates HS-induced acute lung injury by inhibiting NE activity in lung tissue, reducing neutrophil release and inflammatory factor levels, and protecting the integrity of the endothelial glycocalyx, thereby mitigating vascular endothelial damage.

High-flow tracheal oxygenation: an alternative to T-tube oxygen therapy in tracheostomized patients during weaning from mechanical ventilation

A. Pérez-Madrigal, M. D. M. Fernandez, E. Piacentini, J. Trenado
Department of critical care medicine, Mútua Terrassa University Hospital, Terrassa, Spain
Correspondence: A. Pérez-Madrigal
Intensive Care Medicine Experimental 2025,* 13(1)*:001196

Introduction: High-flow nasal cannula oxygen has been proposed to facilitate weaning from mechanical ventilation [1]. High-flow oxygen can be also delivered through tracheostomy during the weaning process although its physiologic effects and clinical benefits have not been clearly established [2].
Objectives: To describe the characteristics of patients admitted to the intensive care unit (ICU) who required tracheostomy in the process of weaning from mechanical ventilation (MV) and to compare the T-tube disconnection strategy with high-flow tracheal oxygenation therapy (HFOT).
Methods: A retrospective observational study was conducted. Adults ≥ 18 years old admitted to a mixed ICU of a university hospital during the year 2022 for more than 24 h who required tracheostomy during the MV weaning process were included. Demographic variables (sex, age), past medical history, APACHE II, reason for admission, time of tracheostomy, time of start of disconnection and method used (T-tube oxygen vs. HFOT), time until definitive disconnection, ventilatory mode during reconnections and mortality were collected. A descriptive study was performed with percentages and medians and Mann–Whitney *U* test for the comparison of variables.
Results: In 2022, 208 patients admitted to the ICU required MV for more than 24 h, of whom 58 (28%) were tracheostomized. Among these subjects, 74% were men with an interquartile median age of 66 years (54–73) and APACHE II of 15 ± 6.7. One or more cardiovascular risk factors (hypertension, diabetes, dyslipemia, obesity) were present in 57% of the subjects, while 24% had immunosuppression/malignancy, 14% chronic renal failure, 17% chronic liver disease/enolism, 7% COPD and 7% previous coronary artery disease. The reason for admission was septic shock in 31%, stroke in 14%, SARS-COV-2 pneumonia in 12%, TBI in 9%. The average length of stay in the ICU was 37 days (28–57). Six patients died (10% mortality), 4 of them before the start of weaning from MV. Among the included subjects, 7 (13.4%) underwent direct disconnection and the rest followed a progressive longer periods of unassisted breathing strategy. The average time until tracheostomy was performed was 14 days (9–18) since admission and it took an average of 5 more days (3–13) to initiate the unassisted breathing periods. T-tube oxygen therapy was the disconnection strategy chosen for 46 patients (88%), whereas 6 patients (12%) were disconnected from the beginning with HFOT. Pressure support was the most used modality during reconnections (85%). The average time until definitive disconnection was 4 days in the T -tube group (2–6) and 1 day in the HFOT group (0–2, $p = 0.015$). Among the patients who initiated T-tube therapy, 22% switched to HFOT, with an average disconnection time for these patients of 8 days (4–15). Including this group, the mean time to definitive disconnection was 3,75 days (2–6) in the T group and 4,25 days in HFOT group (2–13, $p = 0.028$).
Conclusions: High-flow oxygenation therapy in tracheostomized patients during mechanical ventilation weaning process is a reasonable alternative to T-tube oxygenation therapy, although more studies are needed to define the target subject who can benefit most from this therapy.

Introduction: The pathophysiology of sepsis involves a complex interplay between the infectious agent and the host immune system. Early detection and treatment of sepsis are critical to improve patient outcomes, but biomarkers have not yet demonstrated clinical utility for early diagnosis of sepsis. A better understanding of the dynamics and kinetics of the inflammatory response and its interaction with the diagnosis of sepsis and the severity of organ dysfunction would help to develop better diagnostic tools and improve outcome prediction.
Objectives: We aimed to evaluate the effect of the diagnosis of sepsis on the kinetics of inflammatory biomarkers and the effect of the severity of organ dysfunction on the values of biomarkers measured at three times during the first 24 h.
Methods: We conducted a prospective observational cohort study of patients with suspected infections at high risk of developing sepsis (measured by a NEWS scale $\geq$ 3). Sepsis was defined according to the Sepsis 3 definition by two blinded investigators. Samples were collected between 0 h, 4 h and 24 h after admission to the emergency department. SOFA score was calculated at the same time. Biomarker trajectories (IL-10, IL-6, IL-8, IL1-RA, MCP.1 and TNF.RI) over time were analysed using general mixed model analysis, where a linear regression model was fitted to logarithmically transformed data, with group (sepsis or no sepsis), time and their interaction as fixed effects, and patient-specific intercept and slope of time as random effects. For severity of organ dysfunction a mixed model analysis was fitted to logarithmically transformed data, with SOFA score and time as fixed effects and patient-specific intercept and slope of time as random effects.
Results: We included 176 patients, of whom 139 (78%) developed sepsis within the first 24 h. The median SOFA score was 1 (IQR 1–1) for those without sepsis and 3 (IQR 2–5) for those with sepsis. For all biomarkers except IL-6, the SOFA score has a significant positive effect on the mixed models. Figure 1A shows the fitted prediction of biomarker levels according to SOFA score at the three time points. IL-6 was the only biomarker where mixed models showed a significant interaction between diagnosis of sepsis and time, observing a significant difference in slope over time (Fig. 1b).
Conclusions: Higher SOFA score increased levels of biomarkers differently at three time points, and the diagnosis of sepsis only altered the dynamics of IL-6 during the first 24 h.

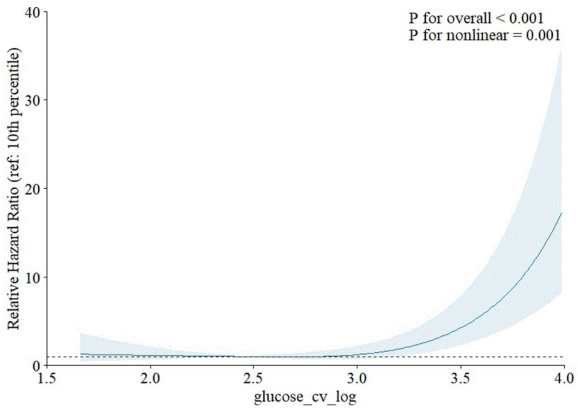
Association of glycemic variability with mortality among septic patients with cardiovascular disease: a multicenter cohort study

H. wang
Intensive Care Unit, The Second Hospital Of Tianjin Medical University, Tianjin, China
Correspondence: H. wang
Intensive Care Medicine Experimental 2025,* 13(1)*:001198



Introduction: Septic patients with cardiovascular disease (CVD) face elevated mortality risks, potentially exacerbated by glycemic variability (GV). This study aimed to investigate the association between GV and in-hospital and 1-year mortality in septic patients with CVD.
Methods: We conducted a retrospective analysis using data from the Tianjin Health and Medical Database Platform (THMDP) as the validation cohort. Patients with sepsis and CVD who had at least three blood glucose measurements during their ICU stay were included. Glycemic variability was defined as the coefficient of variation (CV) of blood glucose levels, categorized into quartiles (Q1–Q4). The primary outcome was in-hospital mortality, with 1-year mortality as a secondary outcome. Cox proportional hazards models were used to assess the association between GV and mortality.
Results: In the cohort, higher GV was also associated with in-hospital mortality (adjusted HR 1.56, 95% CI 1.25–1.93, $P = 0.001$) but not 1-year mortality (adjusted HR 0.17, 95% CI 0.85–3.24, $P = 0.134$). A meta-analysis of both cohorts confirmed a significant association with in-hospital mortality (adjusted HR for Q4 vs. Q1: 1.65, 95% CI 1.34–2.03, $P = 0.001$), while the association with 1-year mortality was weaker (adjusted HR 1.24, 95% CI 0.89–1.73, $P = 0.204$). RCS analyses in the discovery cohort revealed a nonlinear relationship between GV and in-hospital mortality (P for nonlinearity < 0.001). KM survival curves showed reduced survival probability in the highest GV group for the whole discovery cohort.
Conclusions: Higher GV is independently associated with increased in-hospital and 1-year mortality in septic patients with CVD. These findings suggest that stabilizing GV may be a critical therapeutic target in this population. Monitoring and managing GV may improve outcomes in this patient population.

Introduction: Infections after liver transplantation (LT) account for the main cause of mortality and morbidity. This study analyzes the incidence, burden, and immediate risk factors associated with infections within the first year after LT.
Methods: Retrospective, single-center cohort study including adult patients who underwent LT between January 2021 and October 2023. Patients were classified into two groups based on whether they presented bacterial infections during the first year after LT. Demographic and evolutionary variables were collected. The results are presented as median (IQR) or %, with differences analyzed using the *U* Mann–Whitney test or chi-square test, respectively. Multivariate logistic regression analysis was performed to identify independent predictors of infections

within the first year after LT. Kaplan–Meier curve was plotted to explore the influence of bacterial infection during the first year on graft survival at 1 year. A $p < 0.05$ was considered statistically significant.

Results: We included 82 LT procedures. Risk factors for infections are shown in Table 1 and 2. Bacterial infections occurred in 25 patients (30%) with a total of 53 episodes of infection (respiratory infections, 30.2%; urinary tract infections, 20.75%; bacteremia, 9.43% and cholangitis 13.2%, among others). MDRB were isolated in 11 infections (20.7%). *Klebsiella pneumoniae* (11.3%), *Escherichia coli* (5.6%) and *Enterococcus* (5.6%) were the most frequently isolated microorganisms. In multivariate analysis, there were no factors identified as independent predictors of bacterial infections during the first year (Table 1). There was a significant decrease in graft survival at 1 year (defined as absence of graft failure requiring re-transplantation or patient death) in patients with bacterial infections (Fig. 1).
