Introduction: Capillary refill time (CRT) is a noninvasive vaso-occlusive test (VOT) used to assess skin perfusion and microcirculatory function (1,2). A VOT induces transient ischemia, resembling the mechanism of ischemic preconditioning (3). Prolonged CRT indicates impaired capillary perfusion and has been associated with increased organ dysfunction and mortality among intensive care unit (ICU) patients (4–7). Moreover, normalization of CRT following resuscitation in patients with septic shock has been linked to better outcomes (8). Consequently, frequent CRT assessments are recommended in the management of septic shock (9). Given that CRT measurement entails a brief, localized vascular occlusion, we hypothesized that repeated assessments might trigger an ischemic preconditioning response.

Objectives: This study aimed to determine whether consecutive CRT measurements induce a preconditioning effect.

Methods: This interventional study was conducted in the Department of Intensive Care at Erasme University Hospital (Brussels, Belgium). Thirty healthy volunteers were evaluated in a quiet, temperature-controlled room after resting for 15 min before each experimental session. On day 1, CRT was measured twice on the index and middle fingers of the dominant hand and the index finger of the non-dominant hand at 15-min intervals. On day 2, CRT was assessed twice on the same fingers at 30-min intervals. CRT was measured by applying firm pressure to the ventral surface of the distal phalanx using a glass microscope slide until blanching occurred, maintained for 10 s, and then released. The time taken for the skin to return to baseline color was recorded with a chronometer. Heart rate (HR) and respiratory rate (RR) were also monitored noninvasively.
Results: The median age of participants was 34 (IQR: 30–46), and 13 of 33 (43.3%) were males (Table 1). No statistically significant differences in CRT were observed following repeated measurements at either 15- or 30-min intervals (Table 2). Baseline CRT values did not differ significantly between fingers of the dominant and nondominant hands on either study day (Table 2).
Conclusions: In healthy volunteers, repeated CRT assessments at intervals commonly used in clinical practice do not appear to induce a detectable preconditioning effect in the fingers.

Variable	Experiment Day
Subjects (n)	30
Men (n, %)	13 (43.3)
Age (years)	34 (30-46)
Body mass index (Kg/m²)	23.8±3.0

Main characteristics of the cohort of healthy volunteers.

	Day 1= 15 min			Day 2= 30 min		
	Finger 1	Finger 2	Finger 3	Finger 1	Finger 2	Finger 3
Before	0.60 (0.55 - 0.65)	0.59 (0.54 – 0.65)	0.59 (0.54 – 0.64)	0.62 (0.57 – 0.67)	0.62 (0.57 – 0.68)	0.63 (0.57 – 0.68)
After	0.60 (0.55 – 0.65)	0.61 (0.56 – 0.66)	0.59 (0.54 – 0.64)	0.62 (0.57 – 0.67)	0.64 (0.58 – 0.69)	0.63 (0.57 – 0.68)

Data are reported as mean and 95% confidence interval.
Finger 1= index of the dominant hand; Finger 2= middle of the dominant hand; Finger 3= index of the non-dominant hand.
Significant at 5%: * vs Finger 1, [&] vs Finger 2.

Changes in repeated CRT measurements and comparisons of baseline CRT between the fingers of the dominant and nondominant hands for each study-day experiment.

Prognostic significance of POCUS in ICU patients with community-acquired pneumonia

P. Khanna, V. Gandhi
Anaesthesia,pain medicine & critical care, All India Institute Of Medical Sciences, New Delhi, New Delhi, India
Correspondence: P. Khanna
Intensive Care Medicine Experimental 2025,* 13(1)*:001201

Introduction: Early identification of high-risk patients with sepsis due to community-acquired pneumonia (CAP) is vital for enhancing outcomes through timely and aggressive treatment strategies that can reduce length of ICU stay and improve survival (1). Point-of-Care Ultrasound (POCUS) has emerged as an essential tool for assessing lung pathology and predicting mortality in critically ill patients (2).
Objectives: To evaluate the prognostic significance of POCUS in predicting mortality among patients with sepsis due to CAP.
Methods: A retrospective observational study was conducted at a tertiary care center in India, reviewing the medical records of patients with sepsis due to CAP admitted to the ICU from January 2021 to December 2023. Patients meeting Sepsis-3 criteria aged 18 years or older were included, while those with incomplete records were excluded. Demographic and clinical data were collected, along with POCUS findings, which included the Cumulative Lung Ultrasound Score (CLUS), lung consolidations, pleural effusions, and cardiac function parameters. Statistical analyses were performed to identify predictors of mortality.
Results: A total of 345 patients were assessed for eligibility, with 314 included in the analysis. The overall mortality rate was 36%. Significant differences were observed between survivors and nonsurvivors in terms of respiratory rate and SOFA score, with higher values in nonsurvivors ($p = 0.001$). Multivariate logistic regression identified respiratory rate, SOFA score, CLUS, and male sex as independent predictors of mortality ($p < 0.05$ for all).
Conclusions: POCUS, particularly the CLUS, is a valuable prognostic tool for predicting mortality in patients with sepsis due to CAP. Key independent predictors include male sex, respiratory rate, SOFA score, and CLUS. Incorporating POCUS findings into routine clinical

assessments could enhance risk stratification and guide treatment strategies for high-risk CAP patients.

Association between pan-immune inflammation value (PIV), system inflammation response Index (SIRI) and 28-day mortality in sepsis patients: evidence from MIMIC-IV database

H. wang
Intensive Care Unit, The Second Hospital of Tianjin Medical University, Tianjin, China
Correspondence: H. Wang

Intensive Care Medicine Experimental 2025,* 13(1)*:001202

Introduction: The system inflammation response index (SIRI) and pan-immune inflammation value (PIV) have been applied as a new predictor in pneumonia, cardiovascular diseases, and cancers. However, the role of them in predicting all-cause mortality in patients with sepsis has not been evaluated. Therefore, this research aimed to probe the connection of SIRI, and PIV with clinical prognosis in sepsis patients based on the Medical Information Mart for Intensive Care IV (MIMIC-IV) database.
Methods: The data of patients with sepsis admitted to an intensive care unit (ICU) were extracted from the MIMIC-IV database. Different models were created to explore the relationship between SIRI and PIV and 28-day mortality of sepsis patients. The two-segment linear regression model and the fitting analysis of the smooth curve were used to identify the threshold effect of SIRI and PIV on their clinical prognosis.
Results: This research calculated the SIRI of 15277 sepsis patients and PIV of 15349 sepsis patients. Among the sepsis patients whose SIRI were recorded, the 28-day mortality was 14.50% (2219/15277); among those PIV recorded the 28-day mortality was 14.60% (2250/15349). After adjustment of covariates, we observed a significant nonlinear association between SIRI/PIV and 28-day mortality (nonlinear $P < 0.001$).
Conclusions: The index of SIRI/PIV was associated with the 28-day mortality of sepsis patients. the measurement of SIRI/PIV could be employed to predict the clinical prognosis of sepsis.

Intensive Care Medicine Experimental 2025,* 13(1)*:001203

Introduction: Females are often underrepresented in intensive care unit (ICU) admissions (1). However, the impact of sex on ICU-related outcomes remains unclear, with often contradictory results in the literature. Most studies focus on specific indications for ICU admission and relatively short-term mortality (2,3). Although females have a higher life expectancy than males in the general population (4), long-term survival differences after ICU admission remain underexplored.
Objectives: To identify the impact of sex on long-term survival in a large general cohort of ICU patients.
Methods: In this retrospective analysis, we included all adult patients admitted to the ICU of the University Medical Center Groningen (UMCG) between 2001 and 2020, irrespective of ICU admission indication. Long-term survival data were obtained from the hospital database and the national personal records database. Kaplan–Meier analysis was performed to assess the long-term survival, and a log-rank test was used to compare the two cohorts.
Results: A total of 54,919 patients (38% female) were admitted to the ICU during the study period. The mean age was comparable in the groups (60.0 vs 59.7 years). The median survival time (95% CI) after ICU admission was 9.8 years (9.6–10.0) for males and 9.5 years (9.3–9.7) for females. The Kaplan–Meier curves showed a linear, persistently decreasing trend for both sexes. The log-rank test showed a significant difference in long-term survival between males and females ($P = 0.021$).
Conclusions: Although fewer females were admitted to the ICU, their long-term survival after ICU admission was slightly worse. This suggests that the survival advantage females have in the general population disappears once they are admitted to the ICU. This finding highlights potential sex-related differences in both ICU admission patterns and long-term outcomes, emphasizing the need for further research into these differences.

Kaplan–Meier curve of cumulative survival in males and females in 15-year follow-up.

Limitations of the PaO_2/FiO_2 ratio during V–V ECMO: the role of FiO_2,pulmonary shunt, and the blood flow-to-cardiac output ratio

M. Delle Vergini[1], D. Tonetti[1], B. Fumagalli[1], M. Frazzei[1], M. Ravasi[1], A. Nova[1], M. Bombino[2], G. Foti[1], R. Fumagalli[1], M. Giani[1], E. Rezoagli[1]

Intensive Care Medicine Experimental 2025,* 13(1)*:001204

Introduction: The PaO_2/FiO_2 ratio is widely used for diagnosing, monitoring and severity assessment of acute respiratory distress syndrome (ARDS). However, the Berlin definition of ARDS does not require standardization of the FiO_2 level when assessing the PaO_2/FiO_2 ratio, which may affect the reliability and consistency of hypoxemia severity classification—a key determinants of ARDS severity. In patients supported with venovenous extracorporeal membrane oxygenation (V–V ECMO),

the assessment of the PaO_2/FiO_2 ratio is further complicated by the complex interaction between mechanical ventilation and extracorporeal oxygenation.

Objectives: This study aims to compare PaO_2/FiO_2 ratio measured at clinical FiO_2 versus at FiO_2 of 1.0 in patients receiving V–V ECMO for ARDS. In addition, we evaluated the impact of pulmonary shunt and the ratio of extracorporeal blood flow to cardiac output (BF/CO) on the observed differences between the two measurements.

Methods: We conducted a retrospective analysis of prospectively collected data from ARDS patients supported with V–V ECMO in the ICU of IRCCS San Gerardo Hospital (Monza, Italy) between 2003 and 2024. According to the institutional practice, during mechanical ventilation both the ventilator and extracorporeal oxygenator are maintained at the same FiO_2 level throughout ECMO support. To standardize oxygenation assessment and minimize the impact of ventilation–perfusion mismatch, FiO_2 is increased to 1.0 every morning prior to arterial and mixed venous blood sampling for intrapulmonary shunt calculation. For this study, paired PaO_2/FiO_2 measurements at clinical FiO_2 and at FiO_2 1.0 were compared using the paired Student's t test, with stratification by clinical FiO_2 level. Multivariable linear regression was then performed to identify independent predictors of the variation in PaO_2/FiO_2 values at clinical FiO_2 and FiO_2 1.0, including clinical FiO_2, pulmonary shunt, and BF/CO ratio. Inizio moduloFine modulo.

Results: A total of 242 patients were included, contributing 2282 paired PaO_2/FiO_2 measurements. The median age was 52 years [IQR 43–59], 84 patients (34.7%) were females, and 194 (80%) were referred from other centres. Pneumonia was the predominant cause of ARDS, accounting for (88%), followed by autoimmune disease (6%), trauma (3%), septic shock (1%), and other causes (2%). The median clinical FiO_2 was 60% [IQR 50–70]. The mean PaO_2/FiO_2 ratio was significantly higher at FiO_2 1.0 (258 ± 120) as compared to clinical FiO_2 (137 ± 49), ($p < 0.001$). As shown in Fig. 1, this difference remained statistically significant across all strata of clinical FiO_2 ($p < 0.001$), with a clear trend toward a greater discrepancy at lower FiO_2 levels.

Multivariable analysis confirmed that lower clinical FiO_2 was the strongest independent predictor of greater discrepancies between PaO_2/FiO_2 measured at clinical FiO_2 and at FiO_2 1.0. Other predictors included pulmonary shunt and BF/CO ratio ($p < 0.001$). The increase in shunt reduced the difference between PaO_2/FiO_2 measured at clinical FiO_2 and at FiO_2 1.0, while the increase in BF/CO ratio enlarged this difference.

Conclusions: In patients with ARDS receiving V–V ECMO, the PaO_2/FiO_2 ratio is a highly variable and potentially misleading index of hypoxemia severity. As expected this value is significantly influenced by FiO_2 settings, pulmonary shunt, and the ratio of extracorporeal blood flow to cardiac output, underscoring the need for cautious interpretation in this setting.

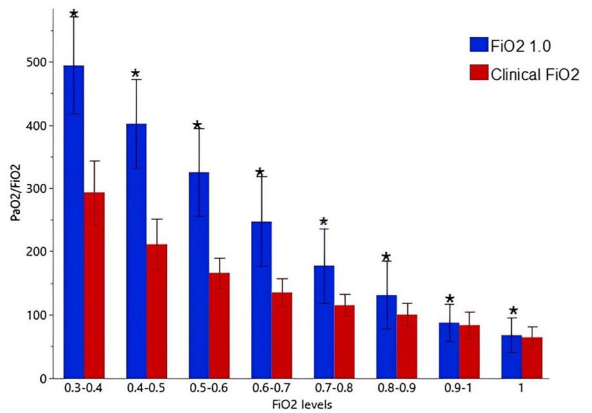

Fig. 1 (abstract 001204) PaO_2/FiO_2 ratio at clinical FiO_2 and FiO_2 1.0, stratified by clinical FiO_2 levels. *$p < 0.001$

CRRT weaning in French ICUs: discrepancy between perceived and actual practices: insights from the PROSECO survey and the multicenter DISCORT study

A. Orieux[1], L. Stephan[1], S. Bodot[2], A. Auvet[3], J. Nicolas[4], Collaborative Group Proseco-Discort[5], D. Gruson[1], R. Prevel[1], A. Boyer[1]

Intensive Care Medicine Experimental 2025,* 13(1)*:001205

Introduction: Acute kidney injury (AKI) is a common and severe complication in critically ill patients, with up to 10% requiring renal replacement therapy (RRT) during their ICU stay. Continuous renal replacement therapy (CRRT) is the preferred modality in hemodynamically unstable patients. Although the recent guidelines and trials have clarified when to initiate CRRT, optimal weaning strategies remain poorly defined. CRRT discontinuation is highly variable in daily practice and primarily based on clinical judgment (1).

Objectives: To better characterize CRRT weaning practices in French ICUs, we combined two complementary studies: PROSECO, a national survey on perceived practices, and DISCORT, a multicenter cohort assessing real-life weaning trajectories. The main objective was to compare stated weaning criteria with actual patient conditions. The secondary objective was identifying gaps between perceived thresholds and clinical scenarios at CRRT discontinuation.

Methods: The PROSECO study was conducted between August and October 2023 via a 45-item electronic questionnaire distributed to 230 ICUs. It explored, among other topics, physician experience, CRRT weaning criteria, fluid balance management, urine output thresholds, and the use of urinary biomarkers. A total of 243 intensivists from 87 ICUs responded. The DISCORT study is a multicenter retrospective cohort including the last 2–5 consecutive adult patients per center admitted for severe septic AKI (KDIGO stage 3, SEPSIS-3 criteria), initiated on CRRT, and subsequently weaned. CRRT weaning was defined as the first discontinuation with the intent to stop, whether or not RRT was resumed later. D0 was defined as the CRRT weaning day. Data were collected from 21 ICUs across France, including detailed clinical, hemodynamic, renal, and fluid parameters over the five days preceding CRRT discontinuation.

Results: In PROSECO, 93% of respondents cited the return of spontaneous diuresis as the main trigger for CRRT discontinuation, with a reported threshold of 612 ± 328 mL/day. Seventy-four percent reported reassessing CRRT continuation daily. Sixty percent used urinary biomarkers, mainly urinary urea, creatinine, or UV/P clearance, and 69% transitioned to intermittent RRT before complete withdrawal. Only 3% reported a formal weaning protocol, while 60% believed delayed CRRT discontinuation could impair renal recovery. The study also revealed variability in the definition of successful weaning: 34% considered it effective after 7 days without CRRT resumption, while others used ICU or hospital discharge as endpoints. Notably, although 81% stated that cost did not influence their decision, nearly

half acknowledged continuing CRRT until filter lifespan completion, even when clinical criteria for weaning were met. In DISCORT, the 111 patients had a mean age of 62 ± 12 years, a mean SAPS II score of 63 ± 22, and a mean SOFA score of 11 ± 4. The median duration from CRRT initiation to final discontinuation was 5 [3–8] days. At D0, 50% of patients remained on vasopressors, with a median norepinephrine dose of 0.15 [0.06–0.30] µg/kg/min. Median urine output on the day before CRRT discontinuation (D-1) was 122 [17–562] mL and 121 [30–630] mL two days before (D-2), well below the self-reported thresholds in PROSECO (Figure). A positive fluid balance was present in 70% of patients on the day of CRRT discontinuation (median: + 4888 [−568 to + 8624] mL). Diuretics were frequently administered on the day of weaning (21%) (D0), and ultrafiltration practices varied considerably across days and centers.

Conclusions: This combined analysis reveals a marked discrepancy between perceived and actual CRRT weaning practices in French ICUs. Although most physicians report relying on objective criteria (urine output, hemodynamic stability, fluid balance), real-life data show frequent discontinuation despite persistent oliguria, ongoing vasopressors, and positive fluid balance. The near-total absence of standardized protocols in PROSECO mirrors the heterogeneity of clinical trajectories in DISCORT. These findings highlight the gap between intention and practice, and the challenge of applying theoretical thresholds in real-world settings. Developing and validating reproducible weaning protocols, including diuresis, vasopressor use, fluid status, and urinary biomarkers, should be a research priority to improve safety and outcomes in septic AKI.

Correspondence: F.J. Lapi Cerezo
Intensive Care Medicine Experimental 2025,* 13(1)*:001209

Introduction: Extracorporeal membrane oxygenation therapy has evolved greatly in the recent years, providing supportive treatment for respiratory, cardiac and cardiopulmonary insufficiency, highlighting in our case its use in respiratory insufficiency with veno-venous configuration.

Objectives: To describe the characteristics and evolution of patients with severe respiratory insufficiency and need for assistance with extracorporeal membrane oxygenation (ECMO) veno-venous (VV) admitted to the intensive care unit (ICU).

Methods: A descriptive and retrospective analysis of the patients who were admitted to the Respiratory/Multipurpose Unit of the ICU of the University Hospital of Gran Canaria Dr. Negrín from December 2016 to September 2024, which consists of 16 beds, who needed ECMO-VV support. Demographic data, clinical data and ECMO-related eigenvalues, major complications, as well as ICU survival data were collected at 3 and 6 months. The descriptive statistical analysis was carried out using absolute frequencies for categorical variables, while continuous variables were summarized by means and standard deviation (SD).

Results: 53 patients with ECMO-VV were included. The mean age was 48.4 years (SD 12.1). 39 (73.5%) patients were male, a third (35.8%) had hypertension and only 13.2% and 18.8% diabetes mellitus and dyslipidemia, respectively. 22 patients (41.5%) were obese and 16 (30.1%) were smokers. Only 9 patients had some form of immunosuppression. The main cause of ECMO use was community acquired pneumonia (CAP) (56.5%), followed by SARS-CoV2 infection (26.4%). The average of the indices collected were: APACHE II 18.2 (DS 8.2), CHARLSON 1.8 (DS 2.2) and SOFA 8.9 (DS 3.8). The average hospital stay was 59.5 (SD 36.7), in the ICU 38.2 (SD 20.8) and with ECMO 17.1 (SD 11.9) being 5.8 (SD 8.4) the average of days in the ICU until ECMO placement. Plateau and PEEP ECMO pressure values averaged 31.1 (SD 5.7) and 10.4 (SD 3.4), respectively. Despite this, 43.3% died (23), 95.6% within the hospital. 94.3% were ECMO-femoroyugular configuration. Of the 53 patients included, 9 (16.9%) were transferred from other hospitals in the Canary Islands. During use, almost two-thirds (62.2%) presented complications, the most frequent being overinfection (54.7%) and bleeding (52.8%), followed by thrombocytopenia (50%) and acute renal failure (48.1%). 32 patients (59.3%) were discharged from ICU and 55.6% survived at 3 and 6 months.

Conclusions:CAP was the most frequent cause of ECMO. With an average duration of use of 17 days, noting that overinfection and bleeding were the most frequent complications. Allowing hospital survival around 50%.

Introduction: Inhaled sedation with isoflurane is emerging as a preferred sedative option for patients requiring deep analgosedation in the intensive care unit (ICU). This technique necessitates the use of an

additional device, the SedaConda ACD-S®, which functions as a heat and moisture exchanger with antiviral and antibacterial properties. The device is typically connected between the Y-piece of the ventilator and the endotracheal tube (proximal configuration), resulting in an estimated additional dead space of 50 mL.
Objectives: The aim of this study is to describe the changes in dead space, ventilation, oxygenation, and pulmonary mechanics in ARDS patients undergoing inhaled sedation during the initial hours following device connection.
Methods: This is a prospective, observational, descriptive study including patients over 18 years of age admitted to a multidisciplinary ICU with a diagnosis of ARDS requiring deep analgosedation, and considered candidates for inhaled sedation using the Sedaconda ACD-S® system.
Following the adjustment of protective ventilation parameters and the establishment of optimal PEEP, we recorded epidemiological, clinical, and gasometric variables both before and after the initiation of inhaled sedation.
Results: A total of 31 patients were included, 84% of whom were male ($n = 26$), with a mean age of 66 years (± 14). The initial SOFA score was 8.4 (± 3.4), and the initial APACHE II score was 28.7 (± 7.3). According to ARDS severity classification, 35.5% ($n = 11$) had mild ARDS, 52% ($n = 16$) moderate, and 13% ($n = 4$) severe.

	PREISO	POST ISO (1H)	POST ISO (24H)	*P*
VT/kg	6,57 (± 0.52)	6,79 (± 0.51)		< 0,05
Pplateu	22,70 (± 3,0)	22,26 (± 3,22)		0,17
Driving Pressure (DP)	13,06 (± 6,82)	13,26 (± 6,94)		0,4
Dead Space (VD)	115,36 (± 29,93)	161,61 ± 35,40)		< 0,05
Ventilatory ratio (VR)	1,61 (± 0,369)	1,87 (± 0,45)		
Compliance (C)	41,13 (± 18,62)	48 (± 25,23)		0,12
Resistence (R)	15,06 (± 4,96)	18,52 (± 5,45)		< 0,05
pH	7,37 (± 0,07)	7,35 (± 0,06)		0,5
PC02	44,84 (± 6,54)	47,26 (± 6,38)		< 0,05
Pa02/Fi02	173 (± 59,75)	216 (± 94,80)		0,08

Conclusions: The use of inhaled sedation in proximal settings has been shown to be safe for patients with acute respiratory distress syndrome (ARDS). This approach allows for the maintenance of protective ventilation parameters, with an observed increase in dead space of 46 ml, while demonstrating no significant changes in pH and pCO2 levels. Furthermore, an improvement in compliance and the PaO2/FiO2 ratio was noted, which persisted for 24 h following the initiation of inhaled sedation. However, larger studies are needed to confirm these findings.

Topic: Acute respiratory failure and mechanical ventilation

Introduction: In skeletal muscle, clock genes regulate function and metabolism in a time-of-day-dependent manner. BMAL1 is a central component of the molecular clock network in skeletal muscle and is necessary for the maintenance of muscle homeostasis [1]. In healthy mice, skeletal muscle-specific *Bmal1* knockout causes muscle atrophy, impaired glucose metabolism, and reduced muscle strength [2,3]. Similarly, critical illness requiring treatment in the intensive care unit (ICU) often leads to critical illness myopathy (CIM), including skeletal muscle atrophy, weakness, and impaired glucose metabolism [4]. However, it remains unclear whether the expression of core clock genes in skeletal muscle is altered in critically ill patients with and without CIM.
Objectives: To investigate differential expression of clock genes in skeletal muscle of critically ill patients at risk of developing critical illness myopathy, compared to healthy controls.
Methods: Clock gene expression was compared in skeletal muscle biopsies from $n = 7$ critically ill patients in the ICU (CIM: $n = 3$; no-CIM: $n = 4$), and $n = 6$ control patients who underwent elective orthopedic surgery. These patients represent a subgroup of a previous study cohort for whom transcriptomic exon array data from *M. vastus lateralis* biopsies were available [5]. In the prior prospective clinical study (Ethics vote: Charité EA2/061/06), mechanically ventilated patients with a SOFA Score ≥ 8 were included and received electrophysiological CIM diagnosis [4,5]. Skeletal muscle biopsies were obtained during daytime in critically ill and control patients.
Results: Mean age was 70 years in the CIM group, 55 years in the no-CIM group, and 71 years in the control group. In critically ill patients, the following clock genes were significantly differentially expressed compared to controls (Fig. 1): *BMAL1* (official gene symbol: *ARNTL*, $p = 0.002$), *CRY2* ($p = 0.04$), *NR1D1* ($p < 0.001$), and *CLOCK* ($p = 0.01$). *BMAL1* expression was increased 5.38-fold in critically ill patients. Within the ICU cohort, *BMAL1* expression was decreased 3.67-fold in CIM patients as compared to no-CIM patients. (Fig. 2, $p = 0.005$).
Conclusions: Differences in clock gene expression may be influenced by diurnal variation, which could not be accounted for due to single time-point biopsies taken at non-standardized hours. However, *BMAL1* expression was strongly upregulated in critically ill patients, exceeding the expected range of physiological circadian variation. Interestingly, CIM patients showed significantly lower *BMAL1* expression than those without CIM. Our findings suggest that while *BMAL1* upregulation may reflect a general stress response or compensatory mechanism, a relative reduction could be linked to CIM development. We are currently conducting experimental studies to assess whether circadian rhythm dysregulation in skeletal muscle contributes to the development of muscle atrophy during critical illness.

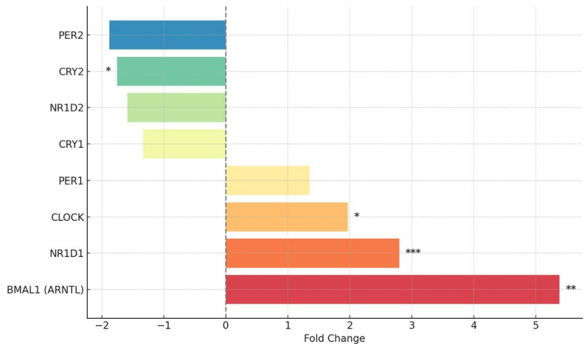

Fig. 1 (abstract 001215) Fold change of core clock gene expression in skeletal muscle. Gene expression in critically ill patients was compared to non-critically ill controls. *BMAL1* (official gene symbol: *ARNTL*). *$p < 0.05$, **$p < 0.01$, ***$p < 0.001$

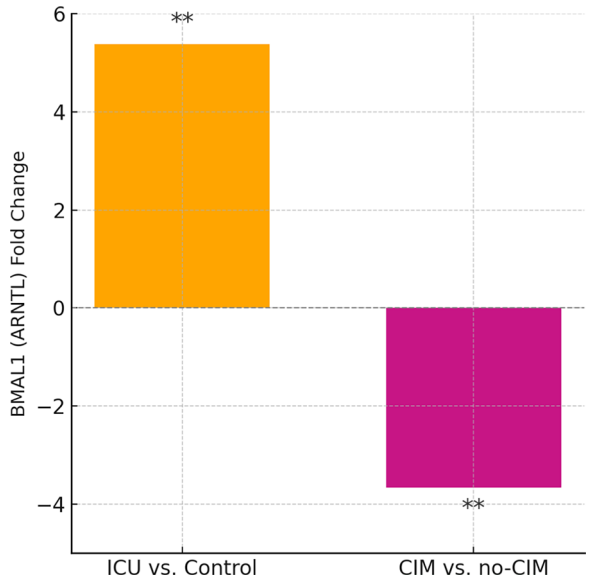

Fig. 2 (abstract 001215) Fold change in *BMAL1* expression in skeletal muscle. Shown are comparisons between critically ill patients and healthy controls (orange), and within the ICU group between CIM and non-CIM patients (magenta). *BMAL1* expression was increased 5.38-fold in critically ill patients compared to controls, but decreased 3.67-fold in CIM patients compared to those without CIM. $^{**}p < 0.01$. *ICU* intensive care unit, *CIM* critical illness myopathy, *BMAL1* (official gene symbol: *ARNTL*)

Predictive ability of transcranial Doppler to detect vasospasm in patients with spontaneous subarachnoid haemorrhage

R. Ruiz Cacho, A. Candela Fernandez, C. Frías Gatell, A. San José Sebrango, P. Garcia-Olivares, E. Bermejo López, J. C. Sotillo Díaz
Intensive Care Unit, H.G.U Gregorio Marañón, Madrid, Spain
Correspondence: R. Ruiz Cacho
Intensive Care Medicine Experimental 2025,* 13(1)*:001216

Introduction: Late cerebral ischaemia is known to be a major cause of morbidity and mortality in patients who have suffered a subarachnoid haemorrhage (SAH). Transcranial Doppler (TCD) helps in its diagnosis, with a lower sensitivity than other tests such as angioCT or arteriography.
Objectives: To analyze the ability to detect angiographic vasospasm and/or cerebral oligohaemia of TCD in patients diagnosed with SAH.
Methods: Prospective, observational study conducted in patients with SAH admitted to the ICU of the HGU Gregorio Marañón (Madrid) between August and December 2024. Epidemiological, clinical and analytical variables, prognostic scales, need for organ support and clinical outcomes were collected. Patients were followed up by daily TCD and imaging tests (simple CT, angio-CT and perfusion CT) according to the unit's protocol (24 h, 5th day, 9th day and any day in case of suspicion) in search of vasospasm and/or late cerebral ischaemia.
In the descriptive analysis, qualitative variables were expressed as percentage and quantitative variables as mean (SD) or median (RIC). The association of presence of TCD vasospasm (Vmed $\geq$ 120 mm/sec with Lindegaard index > 3) with angiographic vasospasm and/or cerebral oligohaemia was performed using Chi-Square. Sensitivity (S), specificity (S), positive predictive value (PPV) and negative predictive value (NPV) of TCD as a diagnostic method were calculated.
Results: 17 cases were included. Age 50 $\pm$ 8 years. Women 59%. Severity scales: APACHE 7 (3–7), SOFA 1 (0–4), H&H 1 (0–2), WFNS 0 (0–1), Fisher 2 (2–3). Aneurysm in anterior circulation 88%. Endovascular treatment 38% and surgical treatment 31%, with an elapsed time of 2 (1–5) days. 53% fulfilled the diagnosis of vasospasm in TCD and 65% in angio-CT and CT perfusion. 47% showed ischaemia on plain CT. ICU stay 17 days (7–34) and hospital stay 36 days (17–47). Poor functional status (Rankin 4–5) 33%, with 12% mortality.
In the analysis performed, there was a significant association between high TCD velocities and vascular involvement and/or CT perfusion (RR 17.50; 95% CI 1.22–250.36), as well as for established ischaemic brain injury (RR 42.00; 95% CI 2.14–825.71). Diagnostic quality indices for TCD were: S 78%, E 83%, PPV 88% and NPV 71%.
Conclusions: Based on the diagnostic indices obtained, transcranial Doppler could allow selection of patients at high risk of vasospasm.

Impact of early-phase inhaled sedation on pulmonary mechanics in mechanically ventilated patients

C. Vera Ching, R. S. Palacios, A. Castillo Niell, C. Murcia Gubianas
Intensive Care Medicine, Hospital Universitari de Girona Doctor Josep Trueta, Girona, Spain

Intensive Care Medicine Experimental 2025,* 13(1)*:001218

Introduction: In the recent years, inhaled sedation with isoflurane has been increasingly adopted in intensive care units (ICUs) as a preferred option for patients requiring deep analgosedation. Several studies suggest that isoflurane-based sedation may reduce the need for opioids and neuromuscular blockers, and has been associated with potential secondary benefits, such as shorter duration of mechanical ventilation and faster awakening times.
Preclinical research indicates that isoflurane may exert lung-protective effects through mechanisms potentially relevant to the pathophysiology of Acute Respiratory Distress Syndrome (ARDS).

The use of inhaled sedation requires the integration of an additional device (SedaConda ACD-S®), which functions as a heat and moisture exchanger and possesses antiviral and antibacterial properties. This device is typically placed proximally, between the Y-piece of the ventilator circuit and the endotracheal tube. This configuration appears to add approximately 50 mL of instrumental dead space, thereby increasing the physiological dead space in mechanically ventilated patients.
Objectives: To describe the changes in pulmonary mechanics, ventilation, oxygenation, and dead space (VD) during the first hour of inhaled sedation using the SedaConda ACD-S® device in a proximal configuration, in patients requiring deep sedation admitted to our Intensive Care Unit between November 2023 and November 2024.
Methods: This was a prospective, observational, descriptive study including patients over 18 years of age admitted to the Intensive Care Unit at Hospital Universitari Dr. Josep Trueta, who required deep analgosedation and were considered candidates for inhaled sedation using the Sedaconda ACD-S® system.
After setting protective ventilation parameters and determining optimal PEEP, epidemiological, clinical, and blood gas variables were recorded prior to the initiation of inhaled sedation and again one hour after its onset. All data were entered into a dedicated database for subsequent analysis.
Results: A total of 42 patients were included, 80.95% of whom were male. Obesity was present in 42% of the cohort, with a mean BMI of 28.65 (± 4.17). The median age was 64 years (± 15.4), with an initial SOFA score of 8.9 (± 3.60) and an APACHE II score of 27.83 (± 8.12).

Results

	PREISO	POSTISO	*P*
VT/Kg	6,55 (± 0,5)	6,82 (± 0,74)	< 0,05
Pplateu	21,76 (± 3,48)	21,62 (± 3,60)	0,9
Driving Pressure (DP)	12,52 (± 6,15)	12,55 (± 6,11)	0,5
Compliance (C)	44,76 (± 22,29)	49,58 (± 28,10)	0,09
Resistances (R)	14,93 (± 4,4)	18,31 (9,12)	< 0,05
Dead Space (VD)	117,07 (± 39,8)	157,24 (± 37,51)	< 0,05
pH	7,37 (± 0,06)	7,35 (± 0,06)	< 0,05
pCO2	42,86 (± 6,8)	45,55 (± 6,59)	< 0,01
paO2/fiO2	219,09 (105,51)	246,05 (± 100,04)	0,1

Conclusions: The use of inhaled sedation in the proximal section of the respiratory circuit with the SedaConda ACD-S® device appears to be safe in terms of pulmonary mechanics, allowing for the maintenance of protective ventilation parameters (Vt 6.82 ± 0.74 mL/kg, plateau pressure 21.62 ± 3.60 cmH_2O, and driving pressure 12.55 ± 6.11 cmH_2O). Dead space (VD) increased by an average of 40.17 ± 34 mL, without significant changes in $PaCO_2$ or pH. Additionally, its use was associated with improvements in oxygenation and pulmonary compliance, although these changes did not reach statistical significance.

Intensive Care Medicine Experimental 2025, **13(1)**:*001219*

Introduction: Sepsis remains a leading cause of morbidity and mortality in ICUs. Early diagnosis is crucial for prompt treatment, especially with antibiotics. While PCT is a widely accepted infection biomarker, emerging parameters like MDW—derived from standard complete blood count—are gaining attention. MDW represents the standard deviation of monocyte size, reflecting heterogeneity of monocyte function and morphology in immune response to infection.
Objectives: To assess the validity of the hematological parameter monocyte distribution width (MDW) as a diagnostic test for infection in the ICU, determine the optimal MDW cutoff value, evaluate its discriminative capacity, and compare it with procalcitonin (PCT).
Methods: This was a prospective, observational, single-center study including all ICU admissions from March 1 to May 31, 2024. Collected data encompassed demographics, admission cause, clinical and laboratory parameters, and prognostic scores. MDW was measured from whole blood in K3-EDTA within four hours of collection.
Patients were stratified into three groups: noninfectious medical conditions (NIMC), noninfectious surgical conditions (NISC), and infectious conditions (IC). Classification relied on clinical, laboratory, and imaging findings consistent with standard ICU practice.
The diagnostic performance of MDW and PCT was evaluated by calculating sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV) at various thresholds. The clinical diagnosis of infection at ICU discharge served as the gold standard. Receiver operating characteristic (ROC) curves were generated and area under the curve (AUC) was calculated to estimate discriminative ability.
Results: An MDW threshold of ≥ 23 demonstrated the best balance of sensitivity and specificity (Youden index), with sensitivity of 82.1%, specificity of 93%, NPV of 97%, and PPV of 63.9%. In comparison, the optimal PCT cutoff was ≥ 0.17 ng/mL, with sensitivity of 79.3%, specificity of 84%, NPV of 96.2%, and PPV of 44.2%. (See Tables 1 and 2 of results).
The AUC for MDW was 0.935 (SD 0.024; 95% CI 0.889–0.982; $P < 0.0001$), while for PCT it was 0.898 (SD 0.032; 95% CI 0.836–0.961; $P < 0.0001$).
Conclusions: MDW showed high diagnostic accuracy for infection in ICU patients, surpassing PCT in sensitivity, specificity, NPV, and PPV. An MDW cutoff of ≥ 23 was superior to the manufacturer-recommended ≥ 21.5 (this cutoff has been validated for the Emergency department patients), offering better specificity (93%) and PPV (63.9%). With an AUC of 0.935, MDW exhibited strong discriminative power, suggesting it is a robust biomarker for early infection diagnosis in critically ill patients.

Intensive Care Medicine Experimental 2025,* 13(1)*:001220

Introduction: High-flow nasal oxygen (HFNO) is used post-extubation to prevent reintubation. The physiological benefits of HFNO during the first 24 h after extubation as compared to conventional oxygen therapy (COT) are incompletely understood.
Objectives: The aim of this study was to compare the effect of HFNO to COT on respiratory effort and ventilation distribution in the first 24 h post-extubation.
Methods: Adult patients ($n = 42$) invasively ventilated for > 48 h were randomized between HFNO 60L/min or COT for 24 h post-extubation. Esophageal pressure (PES) measurements and electrical impedance tomography (EIT) were performed before and 2, 4, and 24 h post-extubation. Primary endpoint was change in ΔPES at 24 h after extubation as compared to baseline. Secondary endpoints were simplified PES pressure–time product (sPTPES), and EIT-derived parameters of ventilation within 24 h post-extubation.
Results: The change in ΔPES from baseline to 24 h after extubation in the COT group was 1.5 [0.0; 5.1] and −1.3 [−2.8; 2.2] cm H_2O in the HFNO group ($P = 0.11$, Fig. 1A). The change in sPTPES/min from baseline to 24 h in the COT group was 66 [−7; 111] and 0 [−47; 43] cm H2O ·s/min in the HFNO group ($P = 0.04$, Fig. 1B). Higher baseline ΔPES and sPTPES were correlated with decreasing levels of ΔPES and sPTPES post-extubation until 24 h (both ΔPES and sPTPES/min $r = -0.6$, $P < 0.01$) in HFNO, but not in COT group (both $P > 0.05$). No significant differences in EIT-derived ventilation parameters were observed except a lower ventral-to-dorsal tidal ventilation ratio in HFNO at 2 h ($P = 0.045$).
Conclusions: HFNO has a limited but sustained stabilizing effect on respiratory effort as indicated by a lower sPTPES.

(abstract 001220) Effect plots of the linear mixed models with 95% confidence intervals, intention-to-treat analysis. **A**: ΔPES. *P* value for difference between groups at T2: 0.54, T4: 0.06 and T24: 0.11. **B**: sPTPES/min. *P* value for differences between the groups at T2: 0.08, T4: 0.07 and T24: 0.04. Intensive Care Medicine Experimental 2025,* 13(1)*:001221

Introduction: Down syndrome (DS), or Trisomy 21, is defined by the existence of an additional chromosome 21. Various physiological considerations in DS patients might lead to challenges in adequate pain management and sedation after surgery. The aim of this systematic review and meta-analysis is to evaluate the variations of the requirement needed for pain management and sedation in patients with DS who have undergone surgery compared to patients without DS.
Methods: A systematic review and meta-analysis of studies were conducted, focusing on critically ill patients with DS who were admitted to Intensive care units (ICUs) post-surgery and received opioids and/or benzodiazepines. Searches were conducted in four databases from their inception to November 18, 2023 (Pubmed, Scopus, Cochrane Library, and Web of Science). The primary outcome measured was the dosage of Oral Morphine Equivalent (OME) administered in the days following surgery. Fixed-effect models were used, an approach advisable when only a limited number of studies are available.
Results: Out of the 992 studies initially screened, the systematic review included ten studies, encompassing 730 patients, while the meta-analysis consisted of seven studies, encompassing 533 patients. Of the seven studies included in the analysis, 298 patients were identified to have DS, and 235 patients served as controls. Patients with DS showed a slight increase in OME needs on the first day, but this increase was not statistically significant (mean difference [MD] = 0.09; 95% Confidence Interval [CI] [−0.02, 0.20]; $P = 0.11$). There was also no significant difference in the requirement for Midazolam on the first day among DS patients (MD = 0.01; CI [−0.16, 0.19]; $P = 0.88$). In addition, the duration of mechanical ventilation was not statistically significant in patients with DS when compared with the control group (MD = −1.46 h; 95% CI [−9.74, 6.82]; $P = 0.73$).
Conclusions: Patients with Down syndrome did not require more sedation or analgesia in the first three days after surgery than patients without Down syndrome. In addition, the two groups showed no significant difference in the duration of mechanical ventilation.

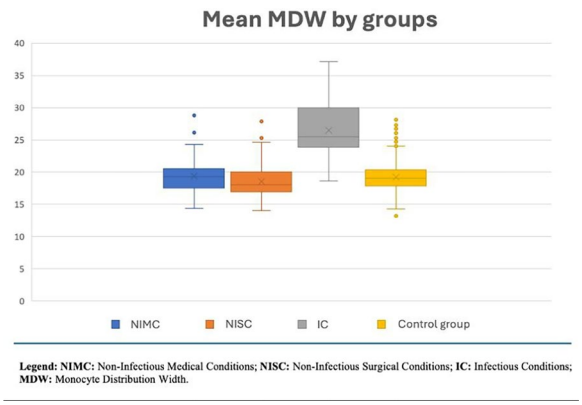
Intensive Care Medicine Experimental 2025,* 13(1)*:001222



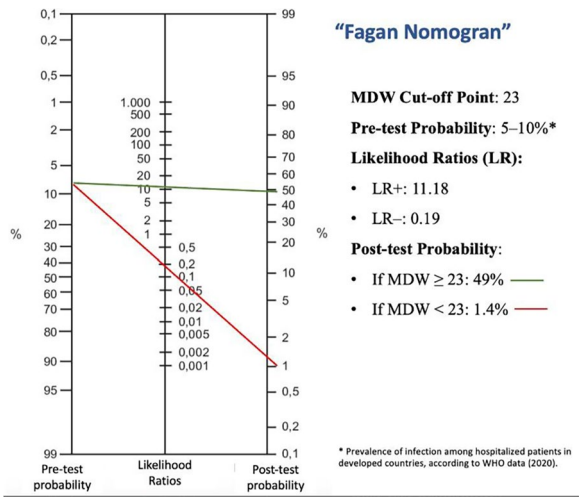
Introduction: Sepsis remains a major cause of morbidity and mortality among hospitalized patients, especially in intensive care units (ICUs). Timely detection is critical, as early initiation of appropriate treatment—primarily antibiotic therapy—has been proven to reduce mortality. However, early diagnosis remains challenging, prompting ongoing research into reliable diagnostic tools.
Procalcitonin (PCT) has long been considered the biomarker with the highest diagnostic accuracy for infection. Recently, new biomarkers have been studied, including monocyte distribution width (MDW), a parameter derived from the complete blood count. MDW reflects the standard deviation of monocyte size and indicates cellular heterogeneity in response to infectious stimuli.
Objectives: To analyze the clinical utility of monocyte distribution width (MDW) as a diagnostic test for infection in the intensive care unit (ICU).
Methods: This was a prospective, observational, single-center study. All patients admitted to the ICU between March 1 and May 31, 2024, were consecutively included. Data collected included demographics,

reason for admission, clinical parameters, laboratory tests, and prognostic scores. MDW was measured from whole blood samples in K3-EDTA, analyzed four hours post-collection.

Sensivity, specificity, positive and negative predictive values and standard descriptive statistics were calculated. MDW means from the overall sample and the various subgroups were compared using the independent samples *t* test, assuming equal variances after performing the *F* test for equality of variances.MDW utility was evaluated by calculating positive and negative likelihood ratios (LR + and LR–), based on the current consensus that a LR + > 10 and a LR– < 0.1 provide strong evidence for confirming or excluding infection. A Fagan nomogram was applied to determine how MDW modifies pretest probability.

Results: No significant differences were found between the MDW means of the NIMC (noninfectious medical conditions) and NISC (noninfectious surgical conditions) groups compared to the total sample or the control group.The IC group (patients with confirmed infection) showed a significantly higher MDW mean ($p < 0.001$) than the total sample and all other subgroups. No significant differences were found between infected patients with and without sepsis.An MDW ≥ 23 was the first value to yield a positive LR above 10 (11.2), but its negative LR was 0.19, not optimal. The first value with a negative LR < 0.1 was MDW ≥ 20.5.According to the Fagan nomogram, an MDW ≥ 23 (LR + 11.2) increases the pretest probability of infection from 5–10 to 49%.

Conclusions: MDW is a useful test for diagnosing infection in ICU patients. Values < 20.5 may help to rule out infection, showing a high negative predictive value (98.6%), while values ≥ 23 support infection detection with a moderate positive predictive value (63.9%).An uncertainty zone remains between 20.5 and 22.5, where additional testing is recommended.



Mean MDW by groups.

MDW	LR+	LR-	PPV	NPV
≥ 20,5	4,4	0,09	41,2%	98,6%
≥ 21	4,9	0,17	43,6%	97,3%
≥ 21,5	6,6	0,16	51%	97,5%
≥ 22	7,2	0,16	53,3%	97,5%
≥ 22,5	9,7	0,20	60,5%	97%
≥ 23	11,2	0,19	63,9%	97%

Legend: LR+: positive likelihood ratio; LR-: negative likelihood ratio; PPV: positive predictive value; NPV: negative predictive value

Results for key cutoff points of MDW.

Fagan Nomogran.

Mortality-related factors in critically ill patients with *Legionella pneumophila* pneumonia: a retrospective observational study

V. Bődi[1], A. Z. Kerekes[2], V. M. Lovász[2], K. Kristóf[3], E. Ludwig[4], A. Kállai, B. Mogyoródi[1]
[1]Department of Intensive Therapy, Semmelweis University, Budapest, Hungary; [2]Faculty of Medicine, Semmelweis University, Budapest, Hungary; [3]Department of Laboratory Medicine, Semmelweis University, Budapest, Hungary; [4]Heart and Vascular Center, Semmelweis University, Budapest, Hungary
Correspondence: B. Mogyoródi
Intensive Care Medicine Experimental 2025,* 13(1)*:001223

Introduction: Pneumonia caused by *Legionella pneumophila* reaches a mortality rate up to 40% in the critically ill population. Prognostic factors related to mortality need to be evaluated in order to improve outcome.
Objectives: The aim of our work was to investigate the factors influencing mortality in critically ill patients with *Legionella pneumophila* pneumonia.
Methods: A retrospective observational study was conducted at the intensive care unit (ICU) of the Department of Anesthesiology and Intensive Therapy, Semmelweis University, Hungary. All patients treated with *Legionella pneumophila* pneumonia between 2016 and 2023 were included. Patients were grouped based on ICU survival (ICU survivors [S +] and ICU non survivors [S-]). Data analysis was performed using clinical biostatistical methods. Variables associated with mortality were examined using multivariate Cox regression analysis and Kaplan–Meier analysis.
Results: A total of 50 patients were admitted to the ICU with *Legionella pneumophila* pneumonia during the 7-year period. The median age of the represented population was 64 (interquartile range [IQR] 50–73) years, and 62% were male. Based on the origin of infection, 29 patients (58%) had community-acquired, while 21 patients (42%) had nosocomial infections. The overall mortality was 42% ($n = 21$). Immunosuppression, higher APACHE II score, and higher SOFA score were significantly more common in the S- group. Multivariate analysis identified higher SOFA score (hazard ratio 1.22, 95% confidence interval 1.06–1.41, $p = 0.01$) and immunosuppression (hazard ratio 3.03, 95% confidence interval 1.25–7.14, $p = 0.01$) as risk factors for mortality. Furthermore, higher mortality rates were observed in patients with nosocomial infections and those who received delayed empirical antibiotic therapy, although these differences were not statistically significant given the sample size. The importance of these factors is underscored by the fact that in the group with the best survival, 75.0% received appropriate empirical antibiotic therapy, while only 37.5% did so in the group with the worst survival. Similarly, the rates of nosocomial infections were 25.0% and 50.0% in these groups, respectively.
Conclusions: Our findings suggest that mortality in severely ill, immunosuppressed patients with *Legionella pneumophila* pneumonia could be improved with the timely initiation of appropriate empirical antibiotic therapy. Based on our observations, empirical antibiotic therapy covering *Legionella pneumophila* is typically omitted in cases of nosocomial infection, highlighting a potential intervention identified in this study.

Intensive Care Medicine Experimental 2025,* 13(1)*:001224

Introduction: Mechanical power (MP) is the energy delivered to the respiratory system over time during mechanical ventilation, and integrates the variables related to the development of ventilator-induced lung injury; it is usually calculated using a formula obtained from the geometricreference method (MP F) (1); however, it does not differentiate the components involved in respiratory impedance and requires constant flow. Using the equation of motion (EM), we could calculate the total ventilator work of breathing and its resistive and elastic components in any ventilator mode.
Objectives: To calculate the MP as the inspiratory work of the ventilator partitioned using the equation of motion (MP EM), comparing it with MP F; and its relationship with hospital mortality, ventilator days and ICU stay in postoperative lung transplant patients (LT) mechanically ventilated (MV) for at least 48 h.
Methods: Prospective observational study, from December 2023 to January 2025, included in an original clinical study approved by the local ethics committee (Musc-Txp23). We studied a group of consecutive postoperative LT with MV for more than 48 h without ECMO. During controlled MV with constant flow. Flow signals (V´), airway pressure (Paw), and esophageal pressure (Pes) were recorded. Sampling 1126 Htz. Measurements: 1- Elastance and total respiratory system resistance (Ers, Rrs) were calculated using multiple linear regression. 2- MP E. Using EM, total Paw = Ers * Volume + Rrs * V´ + PEEPt. Integrating Paw * V´ over the inspiratory time for each component we obtained the partitioned work of breathing, expressed in J/min. 3- MP F was calculated according to (1), MP F (J/min) = 0,098 × V T × RR × (Ppeak—DP/2). RR:respiratory rate. Vt: tidal volume, liters. DP: driving pressure. The data are expressed as means (SD) or medians (IQR 25–75%). Comparisons with nonparametric tests. Concordance analysis and linear regression relationships. Relative risk (RR) of mortality, 95% CI.
Results: Patients: N 22. Male 12 (54.50%). Age 57.14 ± 9.75 years. Double LT 19 (86.36%). PaO2 /FiO2 335 (296.77–326.31); PaCO2 41.50 (37.25–51); pH 7.42 (7.38–7.48). ICU stay 56 (19.50–95), days of MV at inclusion 8.5 (7–15.5), Total days of MV 54 (15.50–82). Deaths 7 (31.82%). Respiratory parameters: Ers 24.68 ± 7.06 cmH2O/L; Rrs 11.81 ± 4.31 cmH2O/L/s. P Plateau 21.14 ± 3.53 cmH2O; PEEP 5 (5–7.25) cmH2O; DP 14.07 ± 3.08 cmH2O. Vt 5.86 (4.24–6.74) ml/Kg. RR 19.51 (18–22)/min.
MP EM, J/min: Total 19.36 ± 4.54 (Elastic: dynamic 6.61 ± 3.03, static 6.67 ± 2.67; Resistive 6.22 ± 2.03). The MP by MP EM vs MP F were highly correlated, R^2 0.95; mean differences 0.24 ± 1.3, 95% CI −0.34 to 0.84; coefficient of variation 13.69%.

MP EM < 20 > J/min: Risk of death (RR) 3,33 (95% CI 1.29–8.59); p = 0.001. Stay ICU 20.50 (10.00 −79.00) vs 68.50 (49.00–104.75); p = 0,023, MV 20.00 (8.50–55.50) vs 65.00 (45.50–98.75) days; p = 0.006.
Conclusions: The agreement between MP EM and MP F was excellent. MP EM higher than 20 J/min is associated with increased risk of death, ventilator days, and ICU stay. The elastic partition represents the most implicated component.

Table 1 (abstract 001224) ...

	Survival	Non Survival	P
Pplateau (cmH_2O)	20.65 (18.15-25.00)	23.00 (20.00-24.00)	0.358
ΔP (cmH_2O)	14.00 (11.50-16.64)	15.56 (14.95-16.00)	0.290
MP_Total Elastic (J/min)	11.69 (10.57-12.75)	15.25 (14.21-9.48)	0.003
MP_Static (J/min)	5.65 (4.23-6.91)	7.84 (7.00-8.28)	0.008
MP_Resistive (J/min)	4.96 (4.50-5.93)	7.98 (5.68-9.80)	0.057
MP_{EM}. Total (J/min)	16.62 (16.07-19.40)	21.47 (20.91-25.60)	<0.001

Clinical characteristics and outcomes in patients aged 80 years or older in intensive care units of a large multispecialty hospital in the capital city of Poland

W. Bogdanski, M. Szeląg, M. Jankowski, K. Szułdrzyński
Department of Anaesthesiology and Intensive Care, Państwowy Instytut Medyczny MSWiA w Warszawie, Warszawa, Poland
Correspondence: M. Jankowski
Intensive Care Medicine Experimental 2025,* 13(1)*:001225

Introduction: Life expectancy has risen in the recent decades, causing a rapidly aging population. Consequently, intensive care units (ICUs) are increasingly admitting elderly patients with multiple health issues, making it challenging to determine their prognosis and the benefit of intensive care.
Objectives: We aimed to clinically characterise patients aged ≥ 80 years admitted to the ICUs of an ~ 800-bed multispecialty hospital in Warsaw, Poland, taking into account comorbidities, prognostic scores, treatment and outcomes, with a focus on mortality and its determinants.
Methods: We retrospectively analysed patients aged ≥ 80 years admitted to the Department of Anaesthesiology and Intensive Care (3 ICUs with a total of 30 beds) of the National Medical Institute of the Ministry of the Interior and Administration in Warsaw between 1 January 2018 and 31 December 2022, comparing survivors and nonsurvivors. The data were collected on demographics, admission diagnosis, previous place of care, comorbidities, prognostic scores (APACHE, SAPS and SOFA), organ support during ICU stay and its duration, decisions to limit life sustaining therapy and mortality. The Clinical Frailty Scale (CSF) score was calculated retrospectively from the available data and assessed as a predictor of death using multiple logistic regression models adjusting for age, sex and either APACHE or SAPS or SOFA.
Results: We included 476 patients (median age 84 years, range 80–103 years, female 54%, COVID-19 17%, median ICU stay 8 days; 11.8% of the ICU population of the analysed period) with a high incidence of comorbidities (e.g. coronary artery disease, diabetes, renal failure, cancer and chronic obstructive pulmonary disease in 38%, 33%, 26%, 19% and 10% of patients, respectively). ICU mortality was very high (76% vs 37% in the younger patients over the same period, p < 0.001) but independent of sex and age. Advanced frailty was common, as indicated by CFS score (median 7, n = 189), which was identified as a significant risk factor for death independent of age, sex and APACHE score (odds ratio for the 1-point increase in CFS 1.08, 95% CI 1.01–1.15, n = 103), but not SAPS and SOFA scores; APACHE, SAPS and SOFA were predictors of death independent of age, sex and CFS. Organ support techniques were frequently used (invasive mechanical ventilation in 91%, pharmacological cardiovascular support in 83%, and renal replacement therapy in 14% of patients), with significant differences between nonsurvivors and survivors (95% vs 78%, 86% vs 74%, and 16 vs 7%, respectively; all $p \leq 0.015$) and high mortality rates (80%, 79%, and 88%, respectively). A protocol to limit futile therapy was implemented in 66 patients (14%).
Conclusions: Our findings support the usefulness of prognostic scales used upon ICU admission, while also pointing out the importance of individualized assessment for the anticipated benefit of ICU treatment in elderly patients, considering specific comorbidities, prior treatment effects, and frailty.

Intensive Care Medicine Experimental 2025,* 13(1)*:001226

Introduction: Cardiac surgeries constitute complex procedures involving diverse clinical and surgical profiles. This study aims to describe the demographic, clinical, surgical and postoperative characteristics of patients undergoing cardiac surgery between 2017 and 2023 in a tertiary hospital.
Methods: A prospective analysis of patients after undergoing cardiac surgery between 2017 and 2023 was performed. Demographic (age, sex), clinical (comorbidities, preoperative diagnoses), surgical (duration of surgery, extracorporeal circulation and aortic clamping times) and postoperative (complications, mortality, readmissions) variables were assessed. Quantitative variables were expressed as means and

standard deviation (± SD), or median with interquartile range (IQR) and qualitative variables as frequencies.
Results: 2,459 patients were analysed. The mean age of the patients was 64 ± 12 years, 72.3% being male. The most frequent comorbidities included HT (68.5%), diabetes mellitus (36.4%) and AF (19.2%). The predominant preoperative diagnosis was valve involvement (63.7%) followed by ischemic heart disease (41.7%). Of all procedures, the most frequent was valve surgery (43.7%) with biological aortic valve replacement (16.9%), followed by coronary surgery (36.9%) and combined surgery (11.3%). Urgent cases accounted for 38%, emergent cases for 13%, with the majority being planned surgery (49%). From a surgical point of view, the median duration of surgery was 180 min (IQR: 150–210), with mean extracorporeal circulation times of 91 ± 28 min and aortic clamping of 63 ± 19 min. Postoperatively, the most common complications included arrhythmias (15%), thrombopenia (10%), need for polytransfusion (16%) and reintubation (4%). In-hospital mortality was 4.3%, while hospital readmissions occurred in 3.5% of cases.
Conclusions: Our sample patient is a 64 ± 12 year-old male, hypertensive (68.5%) who underwent mostly valve surgery (43.7%) followed by coronary surgery (36.9%), with biological aortic valve replacement being the most frequent (16.9%). Our most frequent complications are arrhythmias and polytransfusion, with a readmission rate of 3.5% of cases and a mortality rate of 4.3%. These data are comparable to other series, highlighting adequate perioperative management and results consistent with national standards.

Introduction: The immune response to infection is highly dynamic and complex. In sepsis, this response frequently becomes dysregulated, disrupting the balance between pro-inflammatory and anti-inflammatory mechanisms. If not promptly controlled, this dysregulation may result in excessive inflammation, immunosuppression, and a failure to restore immune homeostasis.
SeptiLoop® is a novel in vitro diagnostic test that uses lipopolysaccharide (LPS) to stimulate immune cells in heparinized whole blood. It quantifies Tumor Necrosis Factor-alpha (TNF-α) release using a lateral flow assay, enabling rapid assessment of immune dysregulation and the patient's immunological state.
Objectives: To assess immune suppression using SeptiLoop® in a cohort of Emergency Department (ED) patients with suspected bacterial bloodstream infection and an elevated risk of sepsis (NEWS score ≥ 3). Specifically, we aimed to: evaluate the persistence of immune dysregulation over time (0 h, 4 h, and 24 h); explore associations between immune status, clinical outcomes; and, characterize the immune profile over time.
Methods: We conducted a prospective observational cohort study of emergency department patients with suspected infection and high risk of sepsis (NEWS ≥ 3). All patients received standard care in accordance with the Surviving Sepsis Campaign guidelines. Whole blood samples were collected at 0 h, 4 h, and 24 h following ED admission. SeptiLoop® negative results were considered indicative of immune dysregulation when TNF-α release after LPS stimulation was < 200 pg/mL. Statistical analyses were performed using appropriate tests (*$p < 0.05$; **$p < 0.01$).
Results: A total of 193 patients were included. Of these, 128 (66.3%) were classified as immunodysregulated at baseline (0 h) based on a negative SeptiLoop® result. Among these patients, 91.6% remained immunodysregulated at 4 h, and 85.4% at 24 h, indicating persistent immune suppression in most cases. In addition, 23.3% of initially non-immunodysregulated patients transitioned to immunodysregulation at 4 h, and 34.3% did so at 24 h. Patients classified as nonimmunodysregulated at baseline showed a significantly higher rate of SOFA score worsening between 0 and 4 h (36.9% vs. 18.8%, $p < 0.01$). Nonimmunodysregulated patients showed higher TNF-α and IL-10 plasma levels at 0 h and 4 h ($p < 0.05$), while cytokine levels declined in both groups by 24 h. Note that ICU admissions were more frequent in the nonimmunodysregulated group (23.1% vs. 11.3%, $p < 0.05$). Kaplan–Meier survival analysis revealed a nonsignificant differences between groups (Log-rank $p = 0.34$). No significant differences were observed between groups in age, sex, BMI, height, weight, leukocyte count, lymphocyte/neutrophil levels, CRP, lactate, comorbidities, or chronic medications.
Conclusions: SeptiLoop® provides a rapid and functional tool to assess immune status in patients with suspected sepsis. The test detects immune cell dysfunction and may serve as a real-time indicator of host response. Our findings support the value of immune profiling to identify patients at risk for adverse outcomes and to inform personalized therapeutic strategies. Immune stratification should be further explored in future sepsis management protocols.

A) Individual SOFA score trajectories at 0 h, 4 h, and 24 h in patients stratified by SeptiLoop® result at 0 h. Patients with a negative SeptiLoop® result (left) were classified as immunodysregulated. Arrows indicate the percentage of patients showing ΔSOFA score worsening between 0 h–4 h and 4 h–24 h in each group. B) Mean values with standard error of the mean (SEM) for plasma cytokine levels (TNF-α, IL-10) at 0 h, 4 h, and 24 h, stratified by SeptiLoop® result at baseline (0 h). Statistical comparisons between immunodysregulated and nonimmunodysregulated groups were performed at each time point using unpaired *t* test (*$p < 0.05$; **$p < 0.01$).

Euglycemic ketoacidosis after cardiac surgery: Is SGLT2 inhibition the trigger?

J. Ginestal-Calvo[1], J. L. Flordelís Lasierra[2], L. Campos-Bermejo[3], C. Coso-Garrido[4], L. Blanco[5], C. Galiano[1], L. J. Terceros Almanza[1], J. L. PerezVela[3]

Introduction: Postoperative ketoacidosis is rarely considered in cardiac surgery. However, the growing use of sodium-glucose cotransporter-2 inhibitors (SGLT2i) raises concern due to reports of euglycemic diabetic ketoacidosis (euDKA) in noncardiac surgery.
Objectives: To assess the incidence of postoperative ketoacidosis in elective cardiac surgery and its association with SGLT2i use, along with clinical and analytical implications.
Methods: A prospective observational study was conducted in a cardiac ICU. Adult patients undergoing elective cardiac surgery between June 2024 and March 2025 were included. Arterial blood gases and ketone levels were obtained at ICU admission, 20:00 h, and 06:00 h the next day. Ketoacidosis was defined as pH < 7.30 and ketonemia ≥ 0.6 mmol/L, in the absence of preoperative ketoacidosis. Clinical, surgical, and laboratory data were analyzed using chi-square, Fisher's exact test, Mann–Whitney *U*, and repeated measures analysis.
Results: 103 patients were included; 53% were males, 67% had hypertension, 29% diabetes, and 59% dyslipidemia. Median age was 66 years (IQR 57–73), BMI 26.4 kg/m^2 (IQR 24.38–30.16). The most frequent surgical category (37.9%), included combined procedures (e.g., aortic ± valve, coronary ± valve), followed by CABG (16.5%), aortic valve (16.5%), and mitral valve surgery (12.6%).
Postoperative ketoacidosis occurred in 24 patients (23.3%). Among patients on SGLT2i (n = 28), 16 (57.1%) developed ketoacidosis vs. 8 of 75 (10.6%) in the non-SGLT2i group (p < 0.001) (Table 1). Ketoacidosis was also associated with diabetes (p = 0.001), but not with sex, hypertension, or dyslipidemia. No differences were found in age, BMI, EUROSCORE II, or cardiopulmonary bypass time. Repeated measures analysis showed lower mean arterial pH in the ketoacidosis group (7.31 vs. 7.35, p < 0.001), more negative base excess (–4.2 vs. –2.6, p = 0.001), and lower bicarbonate (21.57 vs. 22.86 mmol/L, p = 0.001). Lactate values did not differ significantly (1.4 vs. 1.8 mmol/L, p = 0.093) (Table 2). No significant differences were observed in ICU length of stay (p = 0.3), duration of mechanical ventilation (p = 0.5), or in-hospital mortality (p = 0.46).
Conclusions: Ketoacidosis, often euglycemic, was observed in nearly one-quarter of patients undergoing cardiac surgery and was strongly associated with SGLT2i use. These findings support the need for increased perioperative awareness and further research in this population.

Table 1 (abstract 001228) Association between SGLT2 inhibitor use and postoperative ketoacidosis

	Ketoacidosis (+)	Ketoacidosis (–)	Total	% with Ketoacidosis	P value
SGLT2i: Yes	16	12	28	57.1%	<0.001
SGLT2i: No	8	67	75	10.6%	
Total	24	79	103	23.3%	

Table 2 (abstract 001228) Comparison of analytical parameters between patients with and without postoperative ketoacidosis

Parameter	No Ketoacidosis (n = 79)	Ketoacidosis (n = 24)	p-value
Mean arterial pH	7.35	7.31	< 0.001
Base excess (mmol/L)	−2.6	−4.2	0.001
Bicarbonate (mmol/L)	22.86	21.57	0.001
Lactate (mmol/L)	1.8	1.4	0.093

A pilot, randomized, double-blinded, controlled study of hemodynamic and acid–base effects of 0.5 m sodium lactate and 3% saline solutions in septic shock patients

M. Kříž[1], M. Nalos[1], P. Vintrych[2], J. Raděj[1]
[1]Intensive care unit, 1st Department of Internal Medicine, University Hospital in Pilsen, Pilsen, Czech Republic; [2]Clinic of Cardiology, University Hospital in Pilsen, Pilsen, Czech Republic

Intensive Care Medicine Experimental 2025,* 13(1)*:001229

Introduction: Intravenous fluid resuscitation is a common treatment for hemodynamic instability in patients with septic shock. Excessive accumulation of fluids and chlorides are independent predictors of increased morbidity and mortality and are associated with organ dysfunction. [4, 8] In light of the recent paradigm shifts in lactate metabolism [2, 3], the concept of low-volume therapy using hypertonic sodium lactate solution appears to be an attractive alternative. [1, 5, 6, 7, 9].
Objectives: In a blind fashion, we compare the hemodynamic and acid–base effects of intravenous bolus administration of 0.5 M sodium lactate solution (HSL) versus 3% sodium chloride (SAL) solution in adult patients with septic shock.
Methods: In a proof-of-concept, prospective, randomized, controlled study we compare a change in cardiac stroke work (SW = SV x MAP) assessed by means of transthoracic echocardiography (SV—stroke volume) and arterial pressure transducer system measured at time of start of infusion, at 30 and at 60 min from the start of the respective fluid bolus (3 ml/kg over 30 min; HSL or SAL). A number of secondary outcomes are assessed (inflammatory markers, vasopressor requirement, renal function, shock resolution).
Results: This pilot study enrolled 7 thus far and will include up to 40 patients. This small-scale preliminary study will be conducted to check the feasibility and improve the research design for a planned larger study. The primary endpoints will be analysed by a mixed model of repeated measures with baseline value SW as covariate and treatment, and time-point as fixed factors and patient as random effect with a two-sided α = 0.05. Treatment groups will be compared overall and additionally per time-point. The primary efficacy analysis will be

performed per "intention to treat" on the full analysis set with missing data and per-protocol set will be used as sensitivity analysis.
We present preliminary blinded data from the first 7 enrolled patients, analyzed as a mixed cohort from both treatment groups. Hemodynamic variables (stroke volume, mean arterial pressure, cardiac stroke work) were assessed using paired *t* tests and reported as mean ± SD (Fig. 1). Acid–base and electrolyte parameters (pH, lactate, sodium, chloride, potassium) were analyzed with Wilcoxon tests and presented as median [IQR], min–max (Fig. 2). These early findings suggest a favorable safety profile and will be re-evaluated after unblinding and upon completion of the full protocol-defined analysis following target sample enrollment.
Conclusions: This study will verify the effect and safety of two hypertonic crystalloid solutions in providing intravascular fluid replacement with the potential to eliminate harmful fluid overload and the consequences of chloride–liberal infusion therapy.
The results of the study could impact the choice of resuscitation fluid in this indication in the future and should contribute to solving the question whether chloride or lactate is the preferred anion for sodium based hypertonic solutions in the resuscitation of patients with septic shock.

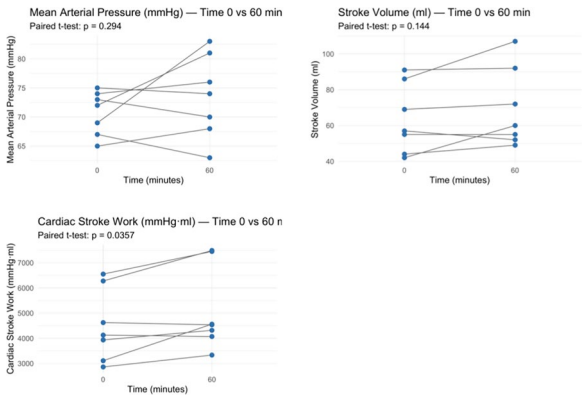

Fig 1 (abstract 001229) Changes in mean arterial pressure, stroke volume and cardiac stroke work in 7 patients treated with HSL or SAL at preinfusion and 60 min after infusion

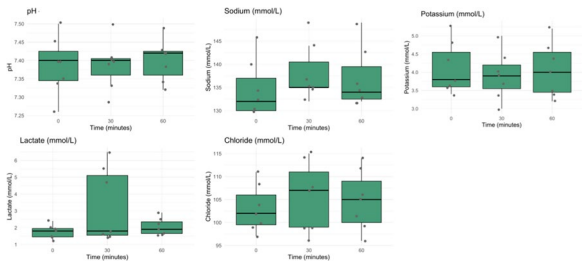

Fig 2 (abstract 001229) Changes in pH, plasma lactate, sodium, chloride and potassium in 7 patients treated with HSL or SAL at preinfusion, 30 min after infusion and 60 min after infusion reported with the median, IQR and maximum and minimum value

To wrongly assume: a retrospective study of ICU readmission

S. Ashkenazy[1], N. Licht[2]
[1]Genral Intensive Care Unit, Hadassah Medical Center, Jerusalem, Israel; [2]General Intensive Care Unit, Hadassaah Medical Center, Jerusalem, Israel
Correspondence: S. Ashkenazy
Intensive Care Medicine Experimental 2025,* 13(1)*:001230

Introduction: A low rate of early readmission after 48 h of discharge is widely recognized as an important quality indicator of care in the ICU. ICU readmissions are often linked to poorer clinical outcomes[1]. In practice, clinicians often rely on assumptions and generalizations, such as discharge timing and the complexity of nursing care required, to guide decisions about when patients are ready to be transferred from the ICU to a hospital ward.

Objectives: This study aims to characterize patients who are readmitted to the ICU, assess the clinical assumptions influencing discharge decisions, and develop targeted interventions to improve the quality of care.
Methods: a retrospective study that characterized patients readmitted to the ICU 48 h after discharge. Demographic data, physiological, and nursing parameters were collected and analyzed from electronic medical records.
Results: A total of 109 patients were readmitted to the ICU within 48 h and hospitalized for at least 24 h. The majority of the readmitted patients had a short ICU stay ≤ 3 days. A high Apache II score (22), Sofa score (7) ($r = 0.767$, $p = 0.001$), and a BMI ≥ 40, which was correlated with Apache II score ($r = -0.345$, $p = 0.004$). Most were without a tracheostomy (90%) and a pressure sore (87%). However, 65% were discharged during the week. Statistically, no significant differences in the characteristics of the patients were observed between the time the patients were discharged on the days of the week; only a higher readmission Sofa Score was observed during a weekday ($U = 454$, $p = 0.041$). In addition, readmitted patients to the ICU with tracheostomy and CVC decreased over the years.
Conclusions: Patients with significant comorbidities are at a higher risk of ICU readmission. Assumptions regarding discharge timing and nursing care complexity were not found to be reliable predictors of readmission. To improve patient outcomes and reduce readmission rates, hospital wards must implement targeted educational programs focused on managing complex conditions training. In addition, early identification of clinical deterioration postdischarge is a critical component in ensuring patient safety and continuity of care.

Introduction: To determine independent risk factors for acute respiratory failure (ARF) in a cohort of postoperative cardiac surgery patients in a coronary ICU.
Methods: A prospective observational study of a cohort of patients undergoing cardiac surgery between 2017 and 2023 was conducted in a 10-bed cardiovascular ICU in a tertiary hospital. We collected demographic and clinical variables, comorbidities, prognostic scales, type of surgery performed, need for vasoactive amines or other cardiac assist devices, need for mechanical ventilation or continuous extrarenal depuration technique and other risk factors for the development of AKI, such as postoperative complications, length of hospital stay and mortality. Univariate and multivariate analyses were performed using logistic regression to identify significant associations between these variables and the development of AKI. Results were expressed as odds ratios (OR) with 95% confidence intervals.
Results: After analysing 2,458 cases, 15.1% of patients ($n = 370$) had postoperative AKI. Of all variables studied, only a high APACHE-II value (OR: 1.10; CI95%: 1.08–1.13; $p < 0.001$), history of smoking (OR: 1.56; CI 95% 1.16–2.10; $p = 0.004$) and combined surgery (OR: 1.73; CI 95% 1.26–2.36; $p < 0.001$) were considered independent factors for the development of AKI. Other associated factors included obesity (16.2%; $p < 0.001$), presurgical chronic renal failure (17%; $p = 0.015$) and postsurgical complications. 015) and specific postsurgical complications such as pneumothorax (7.6%; $p < 0.001$), haemothorax (4.9%; $p <$ 0,001), need for multiple transfusions (19,5%; $p > 0.001$), delirium (12.7%; $p > 0.001$), acute renal failure (43.5%; $p > 0.001$) and infectious complications (the most relevant being bacteraemia (8.4%; $p > 0.001$), pneumonia (8.1%; $p > 0.001$), surgical wound infection (4.3%; > 0.001), urinary tract infection (2.7%; $p > 0.001$) and postoperative mediastinitis 2.4%; $p > 0.001$).
Likewise, aortic dissection surgery was more frequently associated with AKI (6.2%; $p < 0.001$), with a multifactorial origin.
Conclusions: According to the obtained results, the main independent risk factors associated with post-extubation AKI include higher APACHE II score, smoking and combined surgeries. Identifying and monitoring patients with these risk factors will allow for more appropriate and personalised management, which could reduce the incidence of AKI and improve outcomes.

Exploring innovative applications of EEG in the ICU environment

B. Hbibi[1], M. Lamine[2], N. Baffoun[3], M. Abdelkader[1]
[1]Physics, University of Tunis El Manar, ROMMANA, Tunisia; [2]Bradley Department of Electrical & Computer Engineering, Virginia Tech Research Center—Arlington, Arlington, United States of America; [3]Anesthesia and intensive care unit, National institute of neurology, Tunis, Tunisia

Intensive Care Medicine Experimental 2025,* 13(1):*001233

Introduction: For a century, electroencephalography (EEG) has delivered remarkable results in the investigation and diagnosis of diseases, as well as in the evaluation of cognitive and neuronal activities of the human brain [1]. Its application in the ICU has been particularly impactful, showing significant value in the monitoring and evaluation of various patient conditions [2]. In recent decades, fractal analysis has emerged as a powerful tool to study brain electrical activity [3]. In particular, EEG has revealed the multifractal nature of brain electrical activities and uncovered correlations between these multifractal states and their properties, offering deeper insight into the complexities of brain function [4].
Objectives: This research aims to explore the multifractal properties of EEG signals in ICU patients, focusing on two groups of patients with known Glasgow coma scale and the effects of sedative drugs on the multifractal formalism of the EEG data [5].
Methods: In this research work, we used a wireless Emotiv EPOC 14 headset to record EEG signals from 36 ICU patients at the National Institute of Neurology, Mongi Ben Hmida, Tunis, Tunisia [6]. Six of the patients were sedated during the recording, and 30 others with a known Glasgow Coma Scale (GCS). We considered sedated patients as the first group (S), we selected 6 other patients with GCS = 3 as the second group (D), and group L is the group of patients with GCS = 7. To analyze the data, we utilized multifractal analysis based on wavelet leader techniques to explore the properties of EEG signals in ICU patients.
Results: The singularity spectrum of three patient groups presents distinctive graphical patterns, varying in both shape and location, with significant features identified in the sedated patient group, as illustrated in Fig. 2 of [7]. Figure 1 illustrates the average peak values of the singularity spectra across these groups: the sedated group has the lowest average score of 0.11, while the group with a Glasgow Coma Scale (GCS) score of 3 shows an average of 0.2, and the group with a GCS score of 7 exceeds an average of 0.3. Applying the same methodology, combined with the dominant wave band analysis, revealed a significant correlation between the proposed EEG-MFA-based coma scale and the GCS scores. These findings are detailed in Fig. 2.

Conclusions: The singularity spectrum yielded fascinating results, especially in classifying the vigilance states of comatose patients. An EEG-based coma score could overcome many limitations of the classical coma scales. Upon further investigation, we discovered that carefully selecting specific EEG channels, in conjunction with brain rhythm analysis, could serve as the foundation for developing a novel EEG-based coma scale. The use of EEG could emerge in the ICU. Although our work has shown promising results, it is constrained by the limited number of patients involved. Future studies should be conducted across multiple ICU departments to ensure broader applicability. Furthermore, utilizing advanced EEG headsets with a higher number of electrodes could improve the accuracy and depth of the findings.

Intensive Care Medicine Experimental 2025,* 13(1)*:001234

Introduction: Randomized clinical trials have demonstrated the superiority of mechanical thrombectomy plus best medical treatment over best medical treatment in patients with large vessel occlusion ischemic stroke. However, very old patients (≥ 80 years of age) were under-represented in randomized trials of endovascular thrombectomy. Though there are uncertaintiesabout the clinical benefit of the intervention in this growing population.
Objectives: This study aims to identify predictors at hospital admission for favorable outcome after endovascular thrombectomy in very old patients.
Methods: Cohort retrospective study analyzing the group of very old patients (aged 80 years or older) with acute ischemic stroke who underwent endovascular thrombectomy of the anterior circulation admitted to the neurocritical care unit of a tertiary hospital, between January 2017 and December 2024. We collected demographic data, degree of disability/dependence pre-stroke (modified Rankin Scale—mRS), admission stroke severity (National Institutes of HealthStroke Score—NIHSS), comorbidities, severity scores (APACHE II), intravenous thrombolysis (rT-PA), mortality and functional outcome (mRS) at hospital discharge and at 3 months after the procedure. We defined favorable as 3-month mRS equal or less than 3. Statistical analysis was performed with SPSS, version 23. We performed Chi-square and Fisher's exact tests; Mann–Whitney and Kruskal–Wallis tests. Significance was set at < 0.05.
Results: During the referral period, 147 patients who were admitted to the neurocritical care unit with acute ischemic stroke underwent a thrombectomy, and 19 (13%) of them were very old patients. Median age was 87 years (IQR 82.0–89.0). The median admission mRS was 0 (IQR:0.0–1.0) and the median NIHSS was 15.0 (IQR 5.0–20.0). The utilization of rT-PA was 47% (9/19). 28-day mortality was 13% (3/19), and was associated with APACHE II (p 0.022), but not with admission NIHSS (p 0.62) or rT-PA utilization. We did not find significant association-between 3 month-mRS and APACHE II (p 0.081), admission NIHSS (p 0.12), or rT-PA (p 0.52).A favorable outcome at 3 months was seen in 47% (9/19 patients), with a decrease in mRS of −3 (IQR −1, −4) in the overall population, and no association with age was seen.
Conclusions: In this cohort, APACHE II was associated with 28-days mortality, but neither NIHSS nor thrombolysis was associated with short term mortality or 3-month functional outcome after

endovascular thrombectomy. Against the literature stroke severity did not predict poststroke outcomes. Age did not influence the outcome. Mortality is lower than historical or thrombolysis controls, therefore thrombectomy should be considered despite age.

Intensive Care Medicine Experimental 2025,* 13(1)*:001235

Introduction: Out-of-hospital cardiac arrest (OHCA) affects around 3.8 million people annually worldwide. Early initiation of cardiopulmonary resuscitation and prompt access to defibrillators are crucial, but despite improved care systems, mortality remains high. Prognostic indicators like no-flow time (NFT), low-flow time (LFT), and Glasgow Coma Score (GCS) after return to spontaneous circulation (ROSC) are often associated with outcomes, but specific cut-off values are lacking in evidence.
Objectives: To establish a correlation between NFT, LFT and GCS after ROSC and all-cause mortality.
Methods: Retrospective, observational, single-center study on patients admitted to an intensive care unit (ICU) unit of a tertiary hospital following OHCA between 2017 and 2019. Data were collected from clinical registries, receiving operating characteristic analysis was used to assess the impact of LFT, NFT and GCS after ROSC in predicting all-cause mortality (ACM). Kaplan–Meier survival analysis was performed.
Results: Among the 79 participants considered, 32.9% were female, with a mean age of 59.3 ± 15.1. The majority of OHCA were witnessed (84.8%), and basic life support was administered in 72.2% of cases. However, only 25.3% of these interventions involved the use of an automated external defibrillator.
A total of 59 patients (74.7%) died during follow-up (FUP). Mean FUP time in surviving patients was 3.9 years. Mean NFT was 4.1 ± 3.1 min and LFT was 22.7 ± 12.3 min. There was not a correlation between NFT and ACM. However there was a strong correlation between increasing LFT and ACM. Specifically, the use of a 15-min cutoff demonstrated the highest sensitivity and specificity in predicting mortality. Patients that face a LFT greater than 15 min had 2.1 times the risk of death when compared to patients with LFT of less than 15 min (HR: 2.07, CI 95% 1.124–3.34, $p = 0.045$).
Median GCS after ROSC was 3. It was found that GCS of 6 was the best cutoff value in terms of sensitivity and specificity to discriminate mortality risk. Patients with a GCS inferior to 6 had a statistically significant greater risk of mortality than patients with a GCS of at least 6 (HR: 4.43, CI 95% 1.73–11.32, $p < 0.001$).
Conclusions: Our study underscores the importance of time and neurological status in OHCA cases. NFT cannot be used to predict ACM as it is difficult to ascertain. In contrast, a LFT beyond 15 min and a GCS below 6 serve as key indicators associated with increased mortality risk.

GCS and LFT—All Cause Mortality.

Intensive Care Medicine Experimental 2025,* 13(1)*:001236

Introduction: Early identification of high-flow nasal oxygen (HFNO) failure in COVID-19 related acute hypoxemic respiratory failure is critical to prevent delayed intubation and improve outcomes. Traditional tools like the ROX index have limited early-stage accuracy.Artificial intelligence (AI) offers a promising approach to enhance predictive performance and support clinical decision-making in real time.
Objectives: To compare the predictive performance of multiple machine learning (ML) models with the ROX index in forecasting HFNO failure in critically ill COVID-19 patients.
Methods: This retrospective study included 386 adult COVID-19 patients treated with HFNO. HFNO failure was defined as the need for invasive mechanical ventilation or death under HFNO therapy. Patients were randomly divided into training (80%) and testing (20%) sets. Four ML algorithms, Logistic Regression (LR), Random Forest (RF), Extreme Gradient Boosting (XGBoost), and K-Nearest Neighbors (KNN) were trained using demographic, clinical, and biological features. Hyperparameterswere optimized using GridSearchCV. Performance was assessed using accuracy, recall, precision, specificity, area under the curve (AUC), and F1 score. The ROX index at Day 2 and Day 3 served as clinical benchmarks.
Results: XGBoost outperformed all other models with an AUC of 0.842, accuracy of 74.3%, recall of 62.5%, precision of 74.1%, specificity of 83.3%, and F1 score of 0.678. This model demonstrated excellent discrimination in identifying patients at high risk of HFNO failure. Random Forest achieved similar accuracy (74.3%) but had a lower AUC (0.743), recall (60.0%), and F1 score (0.612), reflecting slightly inferior but still robust performance. KNN yielded moderate results (accuracy 64.9%, AUC 0.640, F1 score 0.536), while Logistic Regression was the least effective (accuracy 59.5%, AUC 0.656, F1 score 0.464), highlighting the added value of non-linear, ensemble-based approaches in handling complex clinical datasets.

The ROX index, used as a reference standard, showed an AUC of 0.798 at Day 2 and 0.865 at Day 3. Although the Day 3 ROX score exhibited the highest AUC overall, XGBoost was superior at earlier timepoints, where clinical decision-making is most critical. Notably, the precision of XGBoost exceeded that of the ROX index at Day 2 (74.1% vs. 67.5%), suggesting improved ability to avoid false-positive predictions in early management.
Comparative ROC curve analysis emphasized the strong discriminatory capacity of XGBoost and RF over conventional logistic regression and the ROX index at early phases (Fig. 1). These findings support the integration of ML models, particularly XGBoost, to complement traditional tools and assist clinicians in early risk stratification and therapeutic planning.
Conclusions: Machine learning models, especially XGBoost, offer superior early prediction of HFNO failure as compared to traditional approaches, including the ROX index. Its incorporation into critical care workflows could enhance real-time clinical decision-making, optimize timing of intubation, and personalize management strategies in patients with severe COVID-19.

Cerebral vasospasm after neurosurgery: beyond subarachnoid hemorrhage

F. Rodríguez-Lucci, N. Wainsztein, P. Maskin
Neurocritical Care Unit, Fleni, Buenos Aires, Argentina
Correspondence: P. Maskin
Intensive Care Medicine Experimental 2025,* 13(1)*:001237

Introduction: Cerebral arterial vasospasm is commonly encountered after aneurysmal subarachnoid hemorrhage, and it is associated with delayed cerebral ischemia. However, it is not the only cause of cerebral vasospasm, under certain circumstances it can be developed in post-neurosurgical patients. Neurological deficit secondary to cerebral vasospasm following tumor resection can be a catastrophic event. Pathophysiological mechanisms underlying postoperative vasospasm are complex and multifactorial.
Objectives: The main objective of this study is to describe the characteristics of patients with vasospasm after tumor resection in a referral center and seach for probable predictors.
Methods: Cohort retrospective study analyzing consecutive patients who presented post-surgical vasospasm between January 2017 and May 2024 at an neurocritical care unit of a tertiary hospital. We collected demographic data, tumor features, surgical characteristics, vasospasm diagnosis and management. ANOVA and Chi-square tests were used accordingly. Statistical analysis wasperformed with SPSS, version 23. Significance was set at < 0.05.
Results: Twenty-two patients were enrolled, median age was 41 years, and 41% were female. The incidence is extremely low, 0.24% (2.4 events/1000 tumor brain surgeries). The most frequent location of lesions was in thesellar/suprasellar space (73%), and pituitary tumors were the most common pathology. The average time to develop vasospasm was 3 days and mostly was diagnosed using transcranial Doppler (86%). Almost all patients had anterior circulation compromised (91%). All patients needed pharmacological and supportive treatment, and more than half needed nimodipine. Incomplete recovery after vasospasm was reported in 13 patients (59%), and 3 patients (14%) died. No association was seen between outcome and the probable causative factors.
Conclusions: Cerebral vasospasm due to tumor resection is a rare but challenging complication with remarkably high morbidity and mortality in reported cases. A high index of suspicion is required for early diagnosis and prompt management. It should be considered in post-surgical patients with neurological impairment without evident cause.

Mismatch between attending's and residents' perceptions on diagnoses and care goals after intensive care unit rounds

L. U. Taniguchi, P. V. Mendes, B. Besen, L. A. Hajjar
Emergency Medicine Discipline, Hospital das Clínicas FMUSP, Sao Paulo, Brazil
Correspondence: L.U. Taniguchi
Intensive Care Medicine Experimental 2025,* 13(1)*:001238

Introduction: Intensive care unit (ICU) rounds are frequently performed in academic hospitals to discuss information on diagnoses and care goals of admitted patients. However, experienced attending physicians might have different perceptions about this information compared with junior residents.
Objectives: To measure how much and which type of information were different between attendings and postgraduate year-1 residents after an ICU round, to evaluate the attending physician's and trainees' impressions of the residents' preparedness for patient care, and whether this perception mismatch might be associated with the quality of information misalignment.
Methods: A cross-sectional study was performed at an academic ICU at a large university-affiliated hospital in Sao Paulo, Brazil during twelve months. A standardized questionnaire was applied to residents and attending physicians immediately after an ICU round. No formal tool (e.g., checklists, standardized presentations, handoffs) was employed during the study period. Residents' preparedness for patient care was evaluated with a 10-point Likert scale separately by the attending physician and the trainee.
Results: Six hundred eighty-six case comparisons during 57 rounds were evaluated. Residents correctly identified 783 of 1,191 diagnoses reported by the attending physician (65.7%, 95% confidence interval [95% CI] 61–68). Residents also identified 868 of 1,329 goals and objectives mentioned by the attending physician (65%, 95% CI 62–68). Discordance in perceived perceptions of residents' preparedness did not influence the misinformation rate.
Conclusions: Information about diagnoses and care goals are similar between attendings and junior residents in only two of every three

opportunities after an ICU round. Mismatched information occurs in all aspects of care, including diagnoses, goals, procedures and code status, and is not influenced by divergent perceptions of the resident' readiness after the round. Our results might have implications for patient safety and quality of care in academic ICUs.

Comparison of two citrate concentrations for regional anticoagulation of continuous renal replacement therapy: an observational study

L. U. Taniguchi, A. A. Carvalho, J. D. J. Souza, M. T. G. Almeida, N. Balestra, M. E. A. Carvalho
Intensive care unit, Hospital Sirio Libanes, Sao Paulo, Brazil
Correspondence: L.U. Taniguchi
Intensive Care Medicine Experimental 2025,* 13(1)*:001239

Introduction: Regional citrate anticoagulation (RCA) is the preferred approach for continuous renal replacement therapy (CRRT), and different protocols with distinct citrate concentrations are available. However, if a higher citrate concentration is associated with longer filter lifespan as compared to a lower citrate concentration is poorly understood.
Objectives: Our objective was to study the effect of RCA with a higher citrate concentration (citrate 4%) compared with a lower citrate concentration (citrate 0.5%) on filter life span during CRRT.
Methods: A retrospective study was performed at a private tertiary medical-surgical intensive care unit (ICU) in Sao Paulo, Brazil. All adult (> 18 years old) patients who required CRRT with RCA were included. Patients with severe hepatic disease, with COVID-19 or requiring extracorporeal membrane oxygenation were excluded. A mixed Cox regression was used to analyze the association of two citrate concentrations (citrate 4% group and citrate 0.5% group) and take into account the influence of confounders that could also affect the outcome (filter life span) and the clustering effect (the same patients could receive more than one CRRT session). Observations were censored when CRRT was interrupted for any reason other than failure due to clotting at 72 h.
Results: From 2023 to 2024, one hundred twenty-nine patients (mean age was 73.8 years; 66.7% were men; median SAPS3 was 59; 81% received vasoactive drugs) received 596 CRRT sessions in our ICU (median 4 session per patient (IQR 4–10). All sessions were continuous venovenous hemodiafiltration. In the citrate 4% group ($n = 66$ patients with 253 sessions) vs citrate 0.5% group ($n = 63$ patients with 343 sessions), median filter life span was 69 h (IQR 46–72 h) vs 70 h (IQR 60–72) (unadjusted absolute difference, 4 h [95% CI 0.8–7.3 h]; $p = 0.08$ with Mann–Whitney test). Mixed Cox regression did not show an association between these two RCA groups with longer filter lifespan ($p = 0.43$), after adjustment for confounders (SAPS3, venous access type, year of ICU admission, post-filter hematocrit, use of vasoactive drugs during dialysis, and membrane type).
Conclusions: Among critically ill patients receiving continuous kidney replacement therapy, anticoagulation with a RCA protocol with citrate 4% compared with citrate 0.5% was not significantly associated with longer filter life span.

EELV-associated phenotypes reveal the effect of different SBT methods on patients at high risk of extubation failure

S. Zhang, S. Yuan, Y. Chi, S. Longxiang, H. Huaiwu, Y. Long
ICU, Peking Union Medical College Hospital, Beijing, China
Correspondence: S. Zhang
Intensive Care Medicine Experimental 2025,* 13(1)*:001240

Introduction: Spontaneous breathing trial (SBT) is typically conducted with pressure-support ventilation (PSV) or T-piece. Identifying potential extubation failure and selecting the optimal SBT method are still challenging. This study aimed to assess the effect of end-expiratory lung volume (EELV) on weaning outcome during different SBT methods.
Methods: Patients were conducted with pressure support of 8 cmH2O and positive end-expiratory pressure of 0 cmH2O for 30 min, and then replaced with a T-piece for 30 min if they passed the PSV-SBT, and were divided into T-piece SBT success and failure group. We acquired three 2-min EIT records at baseline (T0), after 30 min of PSV-SBT (T1) and after 30 min of T-piece SBT (T2). △EELVT0-1—△EELVT1-2 > 50 ml was defined as the P-derecruitment phenotype, △EELVT0-1—△EELVT1-2 < -50 ml was classified as the T-derecruitment phenotype.
Results: A total of 67 patients after cardiac surgery were included in the study of which 60 patients passed the PSV-SBT and 7 patients did not (10.4%). Of these 60 patients, 17 failed the T-piece SBT (28.3%) and 43 patients succeeded the weaning finally. Compared with T-piece SBT success ($n = 43$), the failure group ($n = 17$) showed a higher incidence of pendelluft (52.9% vs. 23.7%, $p = 0.033$) and a greater changes in tidal impedance variation (ΔTIV%: 38.8% vs. 27.8%, $p = 0.011$). No significant changes in EIT variables were observed between the PSV-SBT success and failure groups ($p > 0.05$). Meanwhile, the T-piece SBT failure group showed a greater reduction of ΔEELVT1-2 than ΔEELVT0-1 (400 [293, 436]ml vs. 199 [166, 269]ml, $p < 0.001$), while this reduction was lower in the success group (186 [129, 311]ml vs. 322 [247, 459]ml, $p < 0.001$). T-derecruitment phenotype represented the majority of the T-piece SBT failure group (64.7%) and had worse dorsal ventilation at baseline (40[39,46]% vs. 44[41,50]%, $p = 0.047$) than the P-derecruitment phenotype, which accounted for the majority of the success group (72.1%).
Conclusions: P-derecruitment and T-derecruitment phenotypes were related to the weaning outcome. Moreover, T-derecruitment phenotype was characterized by poor dorsal ventilation at baseline. The significant reduction of EELV during the T-piece SBT revealed the effect of lung collapse.

P-derecruitment phenotype was △EELVT0-1—△EELVT1-2 > 50 ml, T-derecruitment phenotype was △EELVT0-1—△EELVT1-2 < -50 ml; A represents a patient with better dorsal ventilation (56%) at baseline (T0) succeed the T-piece SBT and his lung collapse occurred mainly at T0-1; B represents a patient with worse dorsal ventilation (29%) at baseline (T0) failed the T-piece SBT and his lung collapse occurred mainly at T1-2. EELI, end-expiratory lung impedance.

Intensive Care Medicine Experimental 2025,* 13(1)*:001241

Introduction: Acute abdominal pain accounts for 4–9.1% of all emergency department visits. Clinical investigation of patients with acute abdominal pain is critical to guide further evaluation with laboratory tests and imaging studies. Acute abdomen patients are at high risk for complications and death, and patients with actual or impending organ failure or life-threatening disability due to severe comorbidities are typically admitted to an intermediate or intensive care unit (ICU) for real-time monitoring of organ function, management of associated sepsis, or optimization of perioperative hemodynamics for emergency or elective surgery.
In the aging society, surgery for acute abdomen in the elderly population is increasing, and studies have been conducted on the elderly and their impact in each disease group, but not much has been reported on the impact in the intensive care unit. In particular, there is only limited review of the emergency abdominal surgery population. Therefore, this study aims to identify the clinical characteristics and outcomes of advanced age in critically ill patients undergoing surgery for sexual abdominal disease.
Methods: 372 patient charts were retrospectively reviewed from 2018 to 2023 underwent abdominal surgery and critical care in National Health Insurance Ilsan Hospital (NHISIH) whom were diagnosed with surgical abdomen in Emergency Room. 89 patients were excluded due no ICU admission or no abdominal surgery. The patient was divided into three groups, young elderly patient group (YEPG), patients over eighty (POE) and nonelderly patient group. Also risk factor of mortality of critically ill surgical abdomen patients was analyzed.
Results: The average age of nonelderly, elderly and patients over eighty(POE) were 49.4 ± 9.6, 71.5 ± 6.0 and 85.1 ± 3.9 ($p < 0.001$) respectively. The proportion of hypertension increased between age groups with 25.4%, 56.3% and 71.4% and the frailty rate also increased with age of 7.5% 7.1% and 25.7% ($p < 0.001$) respectively. Severe complication rate of these groups was 10.4%, 19.5% and 25.7% ($p = 0.02$) respectively. The mortality of the three groups were 4.5%, 5.4% and 14.3% ($p = 0.02$) respectively. The risk factors of mortality of critically ill surgical abdomen patients was analyzed and POE were 6.68 more like to die compared to non elderly group (6.68, 1.18–37.66, $p = 0.03$). Other risk factors with significance was SOFA score (OR 1.32, 1.15–1.52, $p < 0.001$), and use of antifungal agent (OR 12.68, 3.15–51.08, $p < < 0.001$).
Conclusions: Pateints over eighty group was more likely to have poorer outcomes in critically ill surgical abdomen patients in ICU.

Intensive Care Medicine Experimental 2025,* 13(1):*001244

Introduction: Central venous catheterization (CVC) via the subclavian vein is a standard procedure in medicine. Ultrasound guidance is increasingly recommended to improve success rates and reduce complications. The *Microconvex In-plane Subclavian Puncture* (MISP) technique represents a refined approach which yields advanced imaging capabilities and allows precise needle placement and visualization of surrounding structures (Fig. 1) [1]. In contrast, the *Landmark with Ultrasound Prescan* (LP) method relying on anatomical landmarks is associated with high operator variability and higher complication rates [2,3].

We therefore hypothesized that the ultrasound-guided MISP technique provides a higher success rates and less complications than the Landmark Prescan (LP) technique.

Methods: In this randomized controlled trial, 101 patients scheduled for elective surgery were enrolled and randomly assigned to either the MISP or LP technique. The primary endpoint was an a priori created risk-based complication score. Secondary and exploratory endpoints included success rates, complication rates, and procedural times. We performed two-sided Student's *t* tests, Chi-square tests and the Mann–Whitney *U* test with a significance level of 0.05. Data are presented in mean ± standard deviation.

Results: We randomized 51 patients to the MISP and 50 patients to the LP technique (Fig. 2). Patient characteristics were well balanced between the treatment groups (Table 1).

The overall risk score was significantly lower in the MISP group (6.4 ± 5.9 vs. 11.6 ± 10.8; $p = 0.028$; Table 2). In addition, the MISP technique demonstrated significantly higher as-treated overall success rates (86% vs. 71%, $p = 0.046$) and significantly reduced the risk of arterial punctures (1.9% vs. 12%, $p = 0.047$).

After failure with the LP technique, CVC placement was successfull in all patients with the MISP technique, whereas a single failure with the MISP technique remained unsuccessful after switching to the LP technique (Fig. 2). First-pass success with a single skin puncture and no change in needle direction was also more frequent in the MISP compared to the control group (20 out of 51 versus 4 out of 50, $p < 0.001$). Average procedural time was five minutes longer in the MISP group ($p < 0.001$).

Conclusions: The ultrasound-guided MISP technique for subclavian CVC placement significantly reduces risk for complications and increases success rates compared to the LP technique. This clearly outweighs an increase in procedural time by only 5 min with the MISP technique. Further studies should evaluate the implementation of the MISP technique as a standard approach for subclavian vein catheterization.

Table 1 (abstract 001244) Biometrics of participants

Intensive Care Medicine Experimental 2025,* 13(1)*:001245

Introduction: An ideal screening and diagnostic tool for malnutrition risk in ICU patients is still lacking. Malnutrition is a major contributor to poor clinical outcomes in critically ill patients.
Objectives: In this study, we aimed to screen and diagnose malnutrition in critically ill patients using m-NUTRIC scores and GLIM criteria, and to determine the relationship between malnutrition and mortality in high-risk patients.
Methods: The study was prospective in design and included 250 patients over the age of 60 who were hospitalised in the Medical ICU for more than 72 h. The m-NUTRIC score and the GLIM criteria were assessed within the first 24 h of admission to the ICU.
Results: The median age of the patients was 71 (IQR: 65–77) years and 55% were male. Overall, 64% of patients were malnourished according to the mNUTRIC score, and 68% according to the GLIM criteria. The GLIM criteria were significant ($p < 0.001$) in ROC analyses for predicting 28-day ICU mortality. The m-NUTRIC score and the GLIM criterion were significant in ROC analyses for the prediction of 90-day mortality in the ICU. The m-NUTRIC score was found to predict 28-day mortality in our population with the best sensitivity and specificity at a cut-off of 5.5 points. The m-NUTRIC score was found to predict 90-day mortality in our population with the best sensitivity and specificity at a cut off of 4.5 points.
Conclusions: Malnutrition is common among elderly critically ill patients and is strongly associated with increased mortality. Both the m-NUTRIC score and GLIM criteria are effective tools for early identification of nutritional risk and prediction of 28- and 90-day mortality. Incorporating these tools into routine practice may support timely nutritional interventions and improve patient outcomes.

Intensive Care Medicine Experimental 2025,* 13(1)*:001246

Introduction: Tracheostomy is a commonly performed procedure in critically ill patients requiring prolonged ventilatory support. It can be performed percutaneously or surgically, offering advantages such as improved patient comfort, reduced sedation, and earlier weaning. Despite these benefits, it carries risks of both early (e.g., infection, bleeding, pneumothorax) and late complications (e.g., tracheal stenosis, tracheomalacia, dysphagia, tracheoesophageal fistula).
Objectives: To describe the complications related to the performance of tracheostomies (TQ) and analyze their frequency based on whether they are performed using a PDT in the ICU or ST by surgical team.
Methods: A retrospective observational study that includes all patients admitted to the ICU over a 4-year period (08/20–11/24) who underwent TQ. Clinical and demographic variables were collected, as well as those related to the performance of TQ (percutaneous or ST) and associated complications (bleeding (SE) or stoma infection, intratracheal SE, development of tracheobronchitis (TKB), dysphagia). Quantitative variables are expressed as means ± standard deviation. Qualitative variables are expressed as proportions of the total. Statistical analysis of the data was performed using Chi-square.
Results: 336 patients, 67.56% male, mean age 60 ± 12 years. 79.7% of tracheostomies were performed percutaneously in the ICU, while the remaining 20.3% were performed surgically. Complications related to the percutaneous technique included: 39.9% hemorrhagic (33.5% stoma SE, 66.5% intratracheal SE), 14.2% infectious (97% TKB, 3% stoma infection), and 16.4% dysphagia. In the surgical technique, complications were: 73.5% hemorrhagic (48% stoma SE, 52% intratracheal SE), 30.8% infectious (57% TKB, 43% stoma infection), and 23.5% dysphagia. Statistical analysis showed that the ST technique had a higher rate of hemorrhagic complications ($p = 0.0009$) and infectious complications ($p = 0.0004$) compared with the percutaneous technique, with no significant differences in the risk of dysphagia ($p = 0.172$).
Conclusions: The study shows that TQ performed using the percutaneous technique has a more favorable complication profile. ST presents more hemorrhagic and infectious complications compared to percutaneous ones, with these differences being statistically significant. There were no differences in the risk of dysphagia between the two techniques.

Intensive Care Medicine Experimental 2025,* 13(1)*:001247

Introduction: Dissociation between the macro- and microcirculation and the lack of specific markers to indicate tissue hypoxia complicate septic shock resuscitation. A newly developed non-invasive method of measuring mitochondrial oxygen tension (mitoPO2) may be the most downstream bedside marker of tissue oxygen balance and perfusion. As such, mitoPO2 might be a superior signal of inadequate tissue perfusion than conventional markers.
Objectives: To investigate the relation between mitoPO2 and organ dysfunction and mortality of septic shock, as well as the utility of mitoPO2 to trigger fluid resuscitation.
Methods: This was a multicenter observational study in three large mixed ICU's in the Netherlands. 72 septic shock patients were included between 2019 and 2022. The mitochondrial oxygen tension was

sequentially measured every 2 h during the first 24 h of ICU admission. The time course of mitoPO2 was investigated in relation to other hemodynamic variables and parameters of tissue oxygenation, delta SOFA score, and mortality. In total 43 crystalloid fluid boluses of 500 cc were administered in between two sequential mitoPO2 measurements as part of standard of care. The response of mitoPO2 and other parameters of deranged physiology to a crystalloid fluid bolus was evaluated based on baseline values. Using mathematical modelling we identified an a priori threshold of abnormal mitoPO2 of lower than 40 mmHg.

Results: In survivors, mitoPO2 improved from 54(39–64) mmHg to 78(43–88)mmHg (p = 0.022) whereas in nonsurvivors, mitoPO2 decreased from 48(35–56)mmHg at baseline to 39(35–69)mmHg within the first 24 h. A mitoPO2 increase from 65(53–84)mmHg to 85(80–103) mmHg was also observed in patients whose SOFA score improved. In contrast, a high lactate did not decrease in patients with good outcome. In addition, (a-v)pCO2 gap and ScvO2 did not change during the study period and did not differ between mortality and delta-SOFA.

In response to fluid therapy (Fig. 1), mitoPO2 increased only in patients with a baseline mitoPO2 < 40 mmHg from a mean of 24 to 34 mmHg (p = 0.009) but not in patients with mitoPO2 > 40 mmHg. In contrast, patients with an abnormal lactate (> 2 mmol/L), low ScvO2 (< 65%) or high (a-v)pCO2 gap (> 0.8 kPa) did not show an improvement after fluid therapy, nor an increase in mitoPO2.

Conclusions: Septic shock patients with persistently low mitoPO2 during the first day of ICU admission had a higher mortality and more organ dysfunction whereas adequate mitoPO2 was indicative of recovery. Furthermore, low mitoPO2 is improved by fluid therapy, whereas conventionally used markers such as lactate and ScvO2 are not. Overall, mitoPO2 could be a new trigger of septic shock resuscitation.

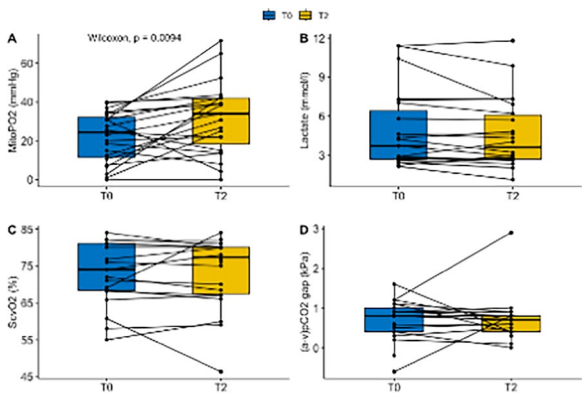

Fig. 1 (abstract 001247) Boxplots of **A** low mitoPO2, **B** High lactate, **C** ScvO2 and **D** (a-v)pCO2 gap before and after 500 cc fluid bolus. Change in individual patients shown with lines. Only p values of statistically significant differences shown. Tested with Wilcoxon signed rank test

Aortic pulse pressure more accurately reflects stroke volume and its variation better predicts preload responsiveness during passive leg raising

A. Goury[1], A. Henry Chebiri[1], Z. Djerada[2], D. Chemla[3], M. Caplan[1], O. Ticos[1], L. Pradignac[1], J. L. Teboul[4], O. Hamzaoui[1]

Intensive Care Medicine Experimental 2025,* 13(1)*:001249

Introduction: Pulse pressure (PP) primarily depends on stroke volume (SV) and arterial stiffness [1]. For a given vascular compliance within the same patient, variations in PP (ΔPP) reflect changes in SV. While this relationship holds true for aortic pulse pressure (aoPP), it is less accurate for peripheral PP due to pulse wave amplification. Recently, Chemla et al. validated a novel formula to estimate aortic systolic blood pressure (aoSBP) using mean arterial pressure (MAP) and diastolic arterial pressure (DBP): aoSBP = MAP^2/DBP [2]. Based on this new formula, aoPP = aoSBP-DBP.

Objectives: To assess the correlation between aoPP and SV, and to evaluate the ability of aoPP variation (ΔaoPP) to predict preload responsiveness during a passive leg raise (PLR) maneuver.

Methods: This was a retrospective analysis of a multicenter prospective database including patients who underwent PLR to assess fluid responsiveness. Patients were classified as preload responsive if the velocity–time integral of the subaortic flow (VTI) increased by ≥ 15% during PLR. Correlations between ΔaoPP and PLR-induced changes in VTI were analyzed. The global performance of ΔaoPP and peripheral ΔPP in predicting preload responsiveness was compared by calculating their area under the receiver operating characteristic curves (AUC), adjusted to baseline VTI mean. Then, the optimal cutpoints of ΔaoPP were given with the Youden test for 3 ranges of VTI, after 1000 bootstraps iterations.

Results: A total of 100 patients were included, with a median age of 63 years [IQR, 56–72]. Septic shock was the primary diagnosis in 51% of cases, with a median SAPS II score of 52 [IQR, 38–65]. All patients were spontaneously breathing, and 29% were receiving mechanical ventilation. At inclusion, 74% were on norepinephrine with a median dose of 0.2 µg/kg/min [IQR, 0.1–0.5], and 49% were preload responsive. VTI mean was 19.0. A significant correlation was found between ΔaoPP and PLR-induced changes in VTI (R^2 = 0.48; p = 0.009), whereas no such correlation was observed for peripheral ΔPP (R^2 = 0.00096; p = 0.334) (Fig. 1). In the whole population, after adjusted for VTI mean, ΔaoPP demonstrated superior predictive value for preload responsiveness (adjusted AUC = 0.865 for a cutpoint of 8%; sensitivity = 84%, specificity = 80%; p = 0.001), unlike peripheral ΔPP (adjusted AUC = 0.591 for a cutpoint of 7%; sensitivity = 49%, specificity = 76%; p = 0.4) (Fig. 2). For specific ranges of VTI, the optimal cutpoints of ΔaoPP were given as follow; for VTI < 14 cm, AUC = 1 for a cutpoint of 4%, sensitivity = 78%, specificity = 100%; for VTI between and 22 cm, AUC = 0.966 for a cutpoint of 8%, sensitivity = 86%, specificity = 100%; for VTI > 22 cm, AUC = 0.929 for a cutpoint of 14%, sensitivity = 86%, specificity = 90% (Table 1).

Conclusions: In spontaneously breathing critically ill patients, ΔaoPP is more closely correlated with SV estimated by subaortic VTI and more accurately predicts preload responsiveness than peripheral ΔPP.

Intensive Care Medicine Experimental 2025,* 13(1)*:001250

Introduction: ICU readmission occurs when a patient's condition falls unexpectedly after discharge. It is linked to higher mortality, prolonged hospitalization and increased costs. As up to 42% of ICU readmissions are preventable, identifying modifiable risk factors is essential. This study examines risk factors for ICU readmission within 48 h and 7 days post-discharge.
Methods: A retrospective review was conducted on SICU patients at National Insurance Service Ilsan Hospital from January 2020 to December 2023. Patients who stayed more than 24 h in the SICU were included. Exclusion criteria were patients who expired in the ICU, were transferred to other facilities, were discharged directly from ICU, were under 20 years old, or pregnant. Demographic variables, APACHE II scores, mechanical ventilator use, inotropic use, vital signs before SICU discharge, and laboratory results were collected.
Results: Among 2,199 patients analyzed, 158 were readmitted within 48 h and 212 within 7 days. Both groups had higher APACHE II scores, mechanical ventilation and norepinephrine use at discharge. Critical vital signs, such as low blood pressure and oxygen saturation were significantly more prevalent. In-hospital mortality was significantly higher in ICU readmitted patients: 60 (38%) within 48 h and 83 (39.2%) within 7 days, compared to 266 (13%) and 243 (12.2%) in non-readmitted patients, respectively. Norepinephrine use, RR > 30/min, SpO2 < 90%, WBC > 10,000, platelet < 150,000, and sodium > 145 mEq on the discharge day, along with mechanical ventilator use, were associated with both 48-h and 7-day readmission. SBP < 90 mmHg was identified as a risk factor for 7-day readmission.
Conclusions: This study identifies key contributing factors for ICU readmission in surgical patients. Recognizing these factors can aid decision-making, reduce readmissions and improve patient outcomes. Addressing modifiable risks through targeted interventions may optimize ICU care and resource utilization.

Introduction: Continuous noninvasive monitoring systems, e.g. ClearSight®, are increasingly used in the anesthesia field in place of the standard invasive arterial catheter allowing early hypotensive events prediction through the algorithm "hypotension prediction index" (HPI) promoting a timely intervention [1].
Feasibility of continuous noninvasive monitoring in patients with moderate-to-high surgical risk remains controversial [2], [3]. We aimed to assess the agreement between invasive arterial monitoring and Clearsight® in patients undergoing cardiac and vascular surgery. HPI performance in predictive arterial hypotension was also evaluated.
Methods: 40 consecutive patients undergoing cardiac or vascular surgery were prospectively enrolled over 12 months: they were simultaneously equipped with an invasive monitoring and Clearsight® with HPI algorithm. Systolic, diastolic and mean arterial pressures (SAP, DAP, MAP) from both systems were recorded every 5 min during surgery and values compared (unpaired Student's *t* test). Limits of agreement between methods were established as the mean difference ± 1.96 SD of the differences, as described by Bland and Altman. Agreement and Lin's concordance correlation coefficient (CCC) was calculated. The HPI's predictive ability was evaluated by annotating the hypotensive events (e.g. MAP < 65 mmHg at 5 and 10 min from an HPI value of 100 or 2 consecutive values between 85 and 100).
Results: Surgery mean duration was 97 min (20–310 min), bringing to approximately 808 concurrently invasive and noninvasive arterial pressure measures. Clearsight® SAP was significantly lower compared to invasive SAP (mean diff −8.5 mmHg, $p < 0.001$), while DAP was equivalent. As shown in Fig. 1, the agreement between the methods was poor (CCC 0.69[0.66–0.73] for both SAP and DAP). HPI predicted 152 hypotensive events; of these, 81 real hypotensive events were observed at 5 and 10 min at the Clearsight®. However, considering the invasive arterial monitoring, only 10 and 7 real hypotension occurred (Fig. 2).
Conclusions: No reliable agreement between invasive arterial monitoring and Clearsight® was observed in cardiovascular surgical patients. Thus, HPI values suggestive of arterial hypotension may be misleading and could result in overtreatment.

As shown in Fig. 1, the agreement between the methods was poor (CCC 0.69[0.66–0.73] for both SAP and DAP): Clearsight® SAP was significantly lower compared to invasive SAP (mean diff −8.5 mmHg, $p < 0.001$), while DAP was equivalent.

HPI predicted 152 hypotensive events; of these, 81 real hypotensive events were observed at 5 and 10 min at the Clearsight®. However, considering the invasive arterial monitoring, only 10 and 7 real hypotension occurred **(**Fig. 2).

Intensive Care Medicine Experimental 2025,* 13(1)*:001255

Introduction: To assess the outcomes of a heart transplantation program at Dr. Negrín University Hospital, Canary Islands, from December 2019 to November 2024. The program, conducted in the ICU of this tertiary hospital, compares the results of using brain death (BD) donors versus controlled donation after circulatory death (cDCD) donors.
Methods: This investigation includes a combined retrospective and prospective analysis of heart transplantation (HT) cases at a 10-bed cardiac ICU and cardiac surgery unit of a regional tertiary referral hospital from December 2019 to November 2024. Demographic data, clinical data, and specific heart transplant-related metrics, along with outcomes and complications, were extracted from the clinical registry. Descriptive statistical analysis was conducted using absolute frequencies for categorical variables. Continuous variables were summarized using means and standard deviations (SD) when the data followed a normal distribution, and medians and interquartile ranges when the distribution deviated from normality. Statistical significance was set at 0.05. The data were analyzed using the R software package, version 4.2.1 (R Development Core Team, 2022).
Results: During the analyzed period, a total of 95 consecutive patients who underwent heart transplantation (HT) were reviewed. Of these, 78 were from brain death donors (BD) (82.1%) and 17 from controlled donation after circulatory death (cDCD) (17.8%). There were no statistically significant differences between the groups regarding preexisting comorbidities of the recipients such as chronic kidney disease (CKD), prior atrial fibrillation (AF), pulmonary hypertension, or previous cardiac surgery.
During the analyzed period, a total of 95 consecutive patients who underwent heart transplantation (HT) were reviewed. Of these, 78 were from brain death donors (BD) (82.1%) and 17 from controlled donation after circulatory death (cDCD) (17.8%). There were no statistically significant differences between the groups regarding preexisting comorbidities of the recipients such as chronic kidney disease (CKD), prior atrial fibrillation (AF), pulmonary hypertension, or previous cardiac surgery.
Postoperatively, 5.2% (5/95) of patients required circulatory support with ECMO, with a higher percentage in the cDCD group (2/17, 11.8%) ($p = 0.60$). A total of 23.2% (22/95) of patients developed right ventricular dysfunction: 15/78 in the BD group and 7/17 in the cDCD group ($p = 0.06$). Renal failure developed in 51.2% of patients, with 26.3% (26/95) requiring continuous renal replacement therapy, showing no differences between BD and cDCD. Lactic acidosis was observed in 80% (76/95) of patients, with a higher percentage in the HT with cDCD group (16/17, 94%) ($p = 0.18$). After coming off cardiopulmonary bypass, 15 out of 95 patients needed IABP, with similar frequency in both groups (15.4% BD vs. 17.6% cDCD). The ischemic time was shorter in HT with cDCD, 126 min (107; 165) $p = 0.06$. Survival in both groups was over 94%.
Conclusions: No selection of recipients was made based on the donor type, as demonstrated by the homogeneity of the preoperative data. The morbidity and mortality outcomes are comparable regardless of the donor type.
In our experience, heart transplantation in the Canary Islands with donors after circulatory death is as effective as transplantation from brain-dead donors and enhances the quality of life for many patients.

What happens after ICU discharge? Insights from a multidisciplinary post-ICU clinic

G. J. M. Giménez[1], C. Gómez Gordo[2], C. Cañete Santiago[3], R. Rosario[4]
[1]UCI, Hospital Universitario Clínico San Cecilio, Granada, Spain; [2]Intensive Care, Hospital Universitario Clínico San Cecilio, Granada, Spain; [3]Intensive Care Unit, Hospital Universitario Clínico, Granada, Spain; [4]Intensive medicine, San cecilio, Grana, Spain
Correspondence: G.J.M. Giménez
Intensive Care Medicine Experimental 2025,* 13(1)*:001256

Introduction: After prolonged ICU stays, many patients experience significant sequelae that hinder their return to baseline health. These physical, psychological, or cognitive impairments are collectively known as post-intensive care syndrome (PICS). Post-ICU follow-up clinics aim to detect these complications early and provide targeted interventions.
Objectives: To analyze our post-ICU follow-up clinic data and compare findings with the existing literature.
Methods: A retrospective, descriptive observational study was conducted on patients seen in the post-ICU follow-up clinic from October 2022 to December 2024. Data collected included sex, age, diagnosis, APACHE II score, need for mechanical ventilation and tracheostomy, ICU length of stay, and complications assessed through physical examinations and validated tests.
Results: A total of 96 patients were included; 37 (38.54%) were female, with a mean age of 59.19 ± 12.02 years. Diagnoses were: cardiac (25%), respiratory (21.87%), gastrointestinal (18.75%), neurological (12.5%), infectious (9.37%), nephrological (4.17%), trauma (4.17%), and others (4.17%). The mean APACHE II score was 19 ± 4.24. Mechanical ventilation was required in 74 patients (77.08%) for an average of 16.11 ± 22.63 days; 29 patients (30.21%) underwent tracheostomy. Mean ICU stay was 19.9 ± 2.12 days. ICU complications included delirium in 40 patients (41.67%), critical illness polyneuropathy in 50 (52.08%), and pressure ulcers in 23 (23.97%). Post-ICU clinic assessments revealed neuromuscular sequelae in 20 patients (20.83%), PTSD in 36 (37.5%), cognitive impairment in 7 (7.29%), anxiety in 27 (32.93%), depression in 21 (25.61%), and both anxiety and depression in 19 (23.17%). Family burden, measured by the Zarit scale, averaged 36.02 ± 6.36, with overload observed in 13 cases (22.03%).
Conclusions: Half of the patients exhibited critical illness polyneuropathy, and 20.83% had persistent neuromuscular sequelae 30 days post-discharge. PTSD (37.5%), anxiety (32.93%), and depression (23.17%) rates were consistent with existing literature, while cognitive impairment (7.29%) was lower than reported in other studies.

Introduction: Deciding whether a patient with acute respiratory distress syndrome (ARDS) requires veno-venous extracorporeal membrane oxygenation (vv-ECMO) is highly complex and time-sensitive, especially in hospitals without ECMO capabilities. Artificial intelligence (AI)-driven models may help improve early risk stratification and guide timely referral decisions.
Objectives: This study aimed to develop and validate machine learning-based models—using clinical data and quantitative CT features—to predict the future need for vv-ECMO therapy in ARDS patients at ICU admission.
Methods: In this retrospective single-center cohort study, patients with COVID-19-associated ARDS admitted to the ICU between March 2020 and April 2022 were included. Lung segmentation and quantitative feature extraction were performed using a convolutional neural network (CNN), yielding 592 radiomic features from thoracic CT scans. Five clinical parameters—age, mean airway pressure (Pmean), lactate, and C-reactive protein (CRP)—were selected based on clinical relevance. Three logistic regression models were trained and evaluated: (1) an imaging model, (2) a clinical model, and (3) a combined model integrating both feature sets. Model performance in predicting the need for ECMO was assessed using area under the receiver-operating characteristic curve (AUROC), overall accuracy, sensitivity, and specificity. In addition, to assess cumulative event differences, Kaplan–Meier curves were generated, and statistical significance was evaluated using the log-rank test.
Results: A total of 375 patients were included: 172 in the training cohort and 203 in the validation cohort. In the training cohort, AUROC values were 0.743 (Imaging Model), 0.828 (Clinical Model), and 0.842 (Combined Model). In the validation cohort, the Combined Model yielded an AUROC of 0.705, outperforming the Clinical (0.674) and Imaging (0.639) Models. Overall accuracy in the validation cohort was 64.0% for the Combined Model, 66.5% for the Clinical Model, and 59.1% for the Imaging Model in the validation cohort. Sensitivity and specificity of the combined model were 68.1% and 58.9%, respectively. Kaplan–Meier curves (Fig. 1) demonstrated a significantly higher cumulative incidence of ECMO therapy in patients predicted as ECMO-positive (log-rank $p < 0.001$), confirming the model's discriminatory power across the 60-day observation period. Applied to the validation cohort, the combined model correctly identified 77 of 113 ECMO patients (positive predictive value: 67.5%) while avoiding unnecessary referral in 53 of 90 patients not requiring ECMO (negative predictive value: 59.6%). These findings suggest potential for clinical benefit in triage and early transfer decisions.
Conclusions: A machine learning approach integrating objective clinical and radiological parameters enables early prediction of ECMO necessity in ARDS patients at ICU admission. The combined model showed the best predictive performance and may serve as a decision-support tool to improve timing and appropriateness of ECMO referrals, especially in nonspecialized settings. Survival analysis supports its prognostic relevance in real-world ICU conditions.

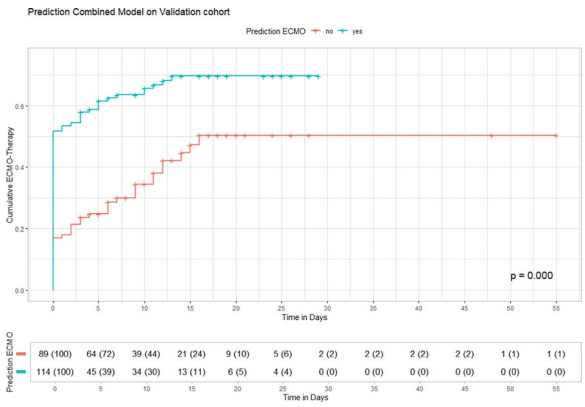

Fig. 1 (abstract 001257) Kaplan–Meier curve for cumulative incidence of ECMO therapy in the validation cohort, stratified by prediction of the combined model. The figure illustrates the estimated cumulative probability of receiving ECMO therapy over 55 days following ICU admission, stratified by ECMO prediction from the combined model. Patients predicted to require ECMO are shown in turquoise; those predicted not to require ECMO are shown in red. Cross marks indicate censored observations (discharge, transfer, or death). A statistically significant difference between the groups was observed (log-rank test, $p < 0.001$). The risk table below shows the number of patients at risk at each time point, with the number of events in parentheses

Intensive Care Medicine Experimental 2025,* 13(1)*:001258

Introduction: Continuous renal replacement therapy (CRRT) with regional citrate anticoagulation (RCA) has become a standard approach in intensive care units for managing acute kidney injury, reducing bleeding risks and extending filter lifespan. Normal kidneys filter approximately 180 L of plasma daily, purifying more than four times the total body water. The objective of CRRT should be to purify at least all body water with good tolerance, in the shortest possible time, and with the lowest effective dose to avoid dialytrauma and reduce therapy costs. Currently, various CRRT protocols are available in Spain, utilizing different modalities (diffusive and/or convective) and dose distributions depending on the machine used.
Objectives: To analyze and compare different CRRT protocols using citrate anticoagulation in terms of guideline adherence,1,2 dose distribution, purification time, and fluid consumption efficiency, with the aim of determining the most efficient protocol for clinical practice.
Methods: We conducted a theoretical mathematical analysis of three citrate-based CRRT protocols available in Spain: CVVH post-dilution (Aquarius™), CVVHDF with diluted citrate (Prismax™ and Prismaflex™), and CVVHDF with concentrated citrate (Multifiltrate™, Multifiltrate Pro™, and Omni™). The analysis was standardized for a 70 kg ideal body weight patient with 42 L of body water, 30% hematocrit, 100 ml/h fluid loss, and 0.99 mmol/l ionized calcium. We calculated renal dose, filtration fraction, body water purification time, and total fluid volume used for each protocol.
Results: The CVVH postdilution protocol achieved a renal dose of 29 ml/kg/h and postdilution dose of 26 ml/kg/h, with a filtration fraction of 34%. This protocol purified total body water in 21 h using 41 L of fluids. The CVVHDF with diluted citrate protocol delivered a higher renal dose (43 ml/kg/h) but a lower postdilution dose (9 ml/kg/h), with a filtration fraction of 29%. It required 29 h to purify body water using 84 L of fluids. The CVVHDF with concentrated citrate protocol had the highest renal dose (48 ml/kg/h) with a post-dilution dose of 16.5 ml/kg/h and a filtration fraction of 31%. It required 32 h for body water purification using 105 L of fluids.
Conclusions: The CVVH postdilution protocol is the only one that meets major guideline recommendations (20–25 ml/kg/h postdilution dose) while demonstrating greater efficiency by using less fluid volume and achieving faster purification of both middle and small molecules. Higher doses do not always equal higher efficacy and may lead

to dialytrauma and excessive loss of trace elements. When using citrate anticoagulation, the need for predilution should be reconsidered, as it reduces both convective and diffusive efficacy. Convection with postfilter replacement most closely resembles normal renal function and provides the most predictable therapy for clearance of all types of molecules with the highest efficiency.

PARAMETER	CVVH Post-dilution (Concentrated citrate)	CVVHDF (Diluted Citrate)	CVVHDF (Concentrated Citrate)
Renal Dose (ml/kg/h)	29	43	48
Post-dilution Dose (ml/kg/h)	26	9	16
Filtration Fraction (%)	34	29	31
Purification Time (hours)	21	29	32
Total Fluid Used (L)	41	84	105
Guideline Compliance	Yes	No	No

(abstract 001258) Summary of the three protocols.

Intensive Care Medicine Experimental 2025,* 13(1)*:001260

Introduction: Professionals working in Intensive Care Units (ICUs) are routinely exposed to high-stakes clinical decisions, emotional strain, and physical demands. These conditions place them at increased risk of chronic stress, which is closely associated with anxiety, depression, and somatic disorders. The Perceived Stress Scale (PSS) is a validated tool that helps identify individuals under psychological strain. Understanding stress levels in ICU staff is crucial not only for their well-being, but also for maintaining patient safety and quality of care.
Objectives: To assess perceived stress levels among ICU professionals and to explore associations with demographic and occupational variables, aiming to raise awareness and promote targeted interventions.
Methods: A cross-sectional, descriptive study was conducted between April and June 2024 in a tertiary hospital ICU in southern Spain. All healthcare professionals working in the unit were invited to complete the 14-item Perceived Stress Scale (PSS-14). The data were analyzed using Excel to calculate mean values and standard deviations.
Results: Out of 100 professionals invited, 71 responded (71.43%). The overall findings reveal a substantial prevalence of moderate to high stress levels:

- Doctors (n = 22): Mean age 43.5 ± 13.7 years; mean PSS 20.5 ± 8.7. Staff physicians scored higher (23.0 ± 9.0) than residents (20.5 ± 8.7). On-call physicians reported higher stress (23.3 ± 9.0) than those without shifts (22.0 ± 8.7).
- Nurses (n = 45): Predominantly female (77.8%), mean age 40.9 ± 6.8 years; mean PSS 20.3 ± 9.0. Night-shift workers showed higher stress (23.9 ± 5.5).
- Nursing assistants (n = 30): Mostly female (93.3%), mean age 52.1 ± 8.8 years; mean PSS 19.3 ± 7.6.

Stress intensity categories (PSS):

- Low stress (< 14): 12.7%
- Occasional stress (15–28): 55.7%
- Frequent stress (29–42): 28.2%
- Very high stress (> 43): 2.8%

Higher stress levels were observed in women across all groups. Additional factors associated with elevated stress included age under 55, fewer than five years of professional experience, and temporary contracts.
Conclusions: Our findings reveal a widespread yet often underestimated burden of stress among ICU professionals. Over half experience occasional stress, while nearly one in three report frequent stress. Female gender, younger age, lower seniority, and contract instability appear to be contributing factors. These results highlight the urgent need for structured mental health support and occupational well-being strategies in ICU settings. Addressing staff stress is not only an ethical imperative but a cornerstone of safe, sustainable intensive care.

Feasibility and safety of a fully automated closeed loop ventilation mode (INTELLIVENT-ASV) during the pandemic: a pilot study

S. Yildirim, S. Acarbay, O. Sunecli, C. Kirakli
Intensive care unit, Dr. Suat Seren Chest Diseases and Surgery Training Hospital, Izmir, Turkey
Correspondence: C. Kirakli
Intensive Care Medicine Experimental 2025,* 13(1)*:001261

Introduction: The COVID-19 pandemic led to widespread intensive care unit (ICU) admissions, with a significant number of patients requiring invasive mechanical ventilation (IMV) due to acute respiratory distress syndrome (ARDS) [1,2]. Ventilation strategies tailored to lung mechanics are critical to minimize ventilator-induced lung injury (VILI).
Objectives: This study aimed to evaluate the feasibility and safety of INTELLIVENT-ASV, a fully automated closed-loop ventilation mode, in COVID-19 ARDS patients, focusing on lung mechanics.
Methods: This pilot study was conducted at University of Health Sciences, İzmir School of Medicine, Dr. Suat Seren Chest Disease and Thoracic Surgery Training and Research Hospital between April 2021 and October 2021. A total of 20 adult COVID-19 ARDS patients were included, all of whom received IMV with INTELLIVENT-ASV. Key ventilatory parameters, including tidal volume, plateau pressure, transpulmonary pressure, and mechanical power, were monitored throughout the study. Descriptive and comparative statistical analyses were performed to assess the association between mechanical ventilation parameters and patient outcomes.
Results: The median age of the patients was 60 years, and 75% were male. INTELLIVENT-ASV successfully maintained lung-protective ventilation in 95% of patients, with tidal volumes within recommended limits (6–8 mL/kg IBW). The median plateau pressure exceeded 30 cmH_2O in 70% of patients; however, inspiratory transpulmonary pressures remained within safe limits in most cases (Fig. 1). The 28-day survival rate was 65%. Survivors had significantly lower driving pressures

(median 14 vs. 17 cmH_2O, $p = 0.047$), transpulmonary driving pressures (median 11 vs. 13 cmH_2O, $p = 0.039$) and, transpulmonary mechanical power (15 vs. 22, J/min, $p = 0.02$) Transpulmonary mechanical power normalized to compliance was also significantly lower in survivors (median 0.57 vs. 0.89, $p = 0.01$).
Conclusions: INTELLIVENT-ASV appears to be a safe and feasible closed-loop ventilation mode for managing COVID-19 ARDS patients. It successfully maintained lung-protective ventilation and adapted to individual lung mechanics. Larger multicenter studies are needed to further evaluate its impact on clinical outcomes and its potential as a standard ventilation mode in ARDS management.

Introduction: Describe the characteristics and clinical evolution of patients with refractory cardiogenic shock requiring VA-ECMO support admitted to the ICU of a tertiary care hospital over a 10-year period.
Methods: A descriptive, retrospective analysis was conducted of all patients admitted to a 10-bed intensive care unit specialized in acute cardiac conditions, cardiac surgery, and heart transplantation who required VA-ECMO support from December 2019 over a 10-year period. Demographic data, clinical information, ECMO-related parameters including maintenance and weaning, and survival data at ICU discharge, 3 months, 6 months, and 1 year were extracted from the clinical records. Descriptive statistical analysis was performed using absolute frequencies for categorical variables, while continuous variables were summarized using means and standard deviations (SD).
Results: During the study period, a total of 90 VA-ECMO devices were implanted. The mean patient age was 57.52 years (± 13.52), with 74.74% being male (67/90). The main indications were postcardiotomy (50%, 45/90), ischemic heart disease (13.48%, 13/90), advanced heart failure (11.24%, 10/90), and post-heart transplantation (2.25%, 2/90). Cannulation modality was central in 10.23% (11/90) and peripheral in 89.77% (79/90). The mean SAVE score was -6.67. The average duration of ECMO support was 6.5 days. Venting strategies were used in 73.3% of cases, with the most commonly used being BCIAo (65%). The major complications included acute kidney injury (87%, 78/90), bleeding (50%, 45/90), lower limb ischemia (27%, 24/90), and infection (22%, 20/90). Overall ICU survival was 33.33% (30/90), with survival at 3 months also 33.33%, at 6 months 18.9% (17/90), and at 1 year 17.77% (16/90). Additional variables are detailed in Table 1.
Conclusions: Postcardiotomy shock was the most frequent indication, for over half of the cases. Most patients were male with a mean age of around 57 years, had an average ICU stay of approximately one week, and frequently developed acute kidney injury and infections as major complications. This dataset may provide valuable insights for generating new hypotheses and implementing quality improvement initiatives.

Correspondence: J.L. Romero Luján
Intensive Care Medicine Experimental 2025,* 13(1)*:001265

Introduction: Describe the experience of the University Hospital of Gran Canaria Dr. Negrín (HUGCDN) as the regional reference center for heart transplantation (HT) in the Canary Islands during its 5 first years.
Methods: A descriptive and prospective study analyzed the outcomes of all heart transplanted patients over the past 5 years. Markers are compared with national index for 2023 (NI). Categorical variables are expressed as frequencies and percentages, and continuous variables as means (± SD) or medians (IQR).
Results: From December 4, 2019, to December 31, 2024, a total of 98 patients were transplanted, exceeding 10 transplants per million population (pmp) per year—above the national average of 7.1 pmp in 2024. The mean age of recipients was 55.22 years (range: 16–71) compared to the NI of 49.5 years. The median waiting time on the transplant list was 28 days (range: 0–380) versus the NI of 84 days. In our HT program, only 3% of donors came from outside the Canary Islands (NI = 43%). Emergency level 0 transplants accounted for 8.16% (NI = 45%). Since the initiation of the controlled donation after circulatory death (cDCD) program, this donor type has contributed to 28% of our HTs (NI = 11.7%), making us the third leading hospital in Spain for this type of transplant per pmp. The mean total ischemia time was 153.9 ± 47.5 min. The average stay in the Intensive Care Unit was 12.8 ± 22.6 days (median: 6.5 days). One-year post-transplant survival was 95.7% (NI = 83%).
Conclusions: 1. Over the past 5 years, patients living in the Canary Islands have had a higher chance of undergoing heart transplantation than the national average, positioning our region as the third best in the country. 2. Our recipients are older than the national average. 3. We are the region with the lowest percentage of hearts received from other regions, confirming the high degree of self-sufficiency of the Canary Islands' heart transplant program. 4. Patients transplanted at HUGCDN have had the shortest waiting times in the country. 5. One-year survival following heart transplantation at HUGCDN is higher than the survival rate reported in the most recent national registry of heart transplants in Spain.

Intensive Care Medicine Experimental 2025,* 13(1)*:001267

Introduction: Recovery from acute kidney injury (AKI) is an essential determinant of prognosis for critically ill patients with AKI. Whilst recent research focused on AKI recovery based on the changes of absolute serum creatinine (SCr) values and corresponding AKI stages, there is limited understanding of the role of SCr trajectories and daily fluctuations of this biomarker for predicting survival outcomes.
Objectives: Do different phenotypes of renal recovery from AKI exist and if so, how do they differ in their recovery patterns and survival outcomes?
Methods: We included patients from a large, publicly available intensive care database from the electronic health record of the Beth Israel Deaconess Medical Center (MIMIC-IV, United States of America). Our study included 1394 critically ill surgical patients with moderate AKI (stage 2), as defined by KDIGO criteria. We included critically ill patients treated in the ICU and requiring vasopressors and/or mechanical ventilation. Further inclusion criteria were: No need for renal replacement therapy at the time of study enrolment, prior or within 24 h of AKI stage 2 diagnosis, estimated glomerular filtration rate > 20 ml/min/1.73 m^2, ICU length-of-stay of > 7 consecutive days and at least six days of SCr samples available. The primary outcome was renal recovery (resolvement of AKI or improvement to stage 1 AKI) or renal non-recovery (defined as persistence of moderate or severe AKI, death, or requirement of renal replacement therapy). When RRT was started during the observational period, serum creatinine values were interpolated from the last available SCr value for as long as RRT was used.
We analysed the patterns of SCr trajectories within the first 7 days after diagnosis of moderate AKI. To detect recovery patterns, we employed hierarchical clustering, specifically a correlation-based approach.

Euclidean distance methods were used to determine the nearest cluster mean for each data point. We calculated the distance of each trajectory to the averages of both clusters and assigned the sample to the cluster with the smaller distance.
Results: The clustering plot visualises the average trajectory within each cluster. Two clusters were identified: One cluster of patients with early daily improvement of SCr values (blue cluster), and another cluster of patients with an early further daily increase of SCr before improvement of SCr could be observed (red cluster). Daily SCr changes up until day 3 to day 4 were the most important for survival. Kaplan–Meier Estimators within each cluster suggest differences in survival until day 100.
Conclusions: Two different trajectories of daily changes in SCr during the early phase (first 7 days) of moderate AKI are associated with different survival outcomes. A phenotype of early decrease of SCr is associated with better survival outcomes until 100 days after AKI, compared to a phenotype with an initial increase in SCr. This association stays relevant even when both groups move towards similar creatinine values after more than 3 days, suggesting that that the early trajectory of SCr change within the first three days of moderate AKI is most relevant for outcomes. This is in line with the recent AKI literature on the concept of transient versus persistent AKI and improves prognostication for patients with moderate AKI.

Trajectories of serum creatinine over the identified clusters show one cluster with an early increase and one cluster with an early decrease in serum creatinine.

Kaplan–Meier curve of the two identified clusters shows a meaningful difference in the long-term survival.

Postcardiac arrest care guidelines: review of practice in a UK Tertiary University Adult ICU

M. G. Kaya, A. Conway Morris, R. Mahroof
Department of Intensive Care Medicine, Cambridge University Hospitals NHS Foundation Trust, Cambridge, United Kingdom
Correspondence: M.G. Kaya
Intensive Care Medicine Experimental 2025,* 13(1):*001268

Introduction: Cardiac arrest (CA) is a life-threatening event with a high mortality. Out-of-hospital cardiac arrests (OOHCA) have a global annual incidence of ~ 40–100 per 100,000 population1 with a 16.4% survival to hospital discharge, at best [1]. Protocol-led, evidence-based management by ICU teams is an integral process in reducing secondary injury and/or subsequent CAs.
Objectives: We evaluated adherence to the ICU guidelines in postcardiac arrest care and identify areas that require improvement to enhance patient outcomes.
Methods: LREC approval was waived. Contemporaneous electronic health records (EHR) were retrospectively analysed for patients admitted to a 32 bed UK University tertiary centre adult ICU over 2 years from Jan 2023. Only patients fulfilling clinical criteria for cardiocirculatory arrest with ROSC, requiring mechanical ventilation and ICU support were included.
Results: 77 patients were identified in total (59.7% male). The median age was 61 (IQR 46–74). The median ICU stay was 4 days (IQR 1–7). Of these 60% of patients had had an OOHCA. The commonest causes were thrombosis and hypoxia, affecting 39% of all patients. The ICU mortality was 67.5% with a 6-month mortality of 70.1%. As expected, patients with an initial nonshockable rhythm (71.4% of the cohort) had significantly worse subgroup outcomes (mortality rate of 83.6%, $p < 0.005$).
Pre ICU care was nearly satisfactory for ECGs (88%) and blood tests (96%). However, performance was suboptimal for computed tomography (CT) head (63.6%) and CT pulmonary angiogram (CTPA) scans (48%); and amylase levels when indicated (57%).
1 in 10 patients (10%) had a massive PE (mPE) with a subgroup mortality of 87.5%, despite lysis ($p = 0.218$). Documentation of direct laryngoscopy grade, RASS and glucose targets were disappointing, with adherence of 21%, 25% and 56%, respectively. Initial temperature control was done well, with active warming done where indicated in 82.4% of the patients and pyrexia addressed in 94%. However, management of persistent pyrexia requires improvement, as only 64% of these patients received prompt secondary temperature control measures such as active cooling. Antiepileptic drug choice/use were 100% when indicated. Other parameters are as shown in Fig. A and B.
Conclusions: Several areas require improvement. Documentation of the initial cardiac rhythm is not included in the current Trust guideline, but it should be in our view—for identifying causes for CA and directing further investigations. Given the high mortality with mPE a low threshold for CTPA may be valid. Improved documentation of specific

neuroprotective targets also need addressing. Given EHR use, guidance will be updated to create proformas to help improve communication and clinical management.

Double low-dose abdominopelvic CT for acute appendicitis: early exploratory analysis on image quality and diagnostic performance

S. Y. Park, H. J. Kim
Emergency Medicine, The Catholic University of Korea, Seoul St. Mary's Hospital, Seocho-gu, Republic of Korea
Correspondence: S.Y. Park

Intensive Care Medicine Experimental 2025,* 13(1)*:001270

Introduction: Modern CT technology has enabled lower tube voltages (kVp; kilovoltage peak) while maintaining diagnostic image quality, offering opportunities to reduce radiation dose. Automated kVp selection tailors tube voltage to patient body habitus,while automated tube current modulation and iterative reconstruction algorithms mitigate the associated increase in image noise [1, 2]. These advancements have facilitated a shift from conventional 120–140 kVp settings to lower tube voltages of 80–100 kVp in routine CT imaging.
A key additional benefit of low-kVp imaging is the enhancediodine attenuation, as the lower mean photon energy approximates the K-edge of iodine at 33.2 keV. This physical property supports simultaneous reduction of both radiation and iodinated contrast media (CM) doses [3] without compromising diagnostic contrast enhancement.
Herein, we present an early exploratory analysis from an ongoing prospective single-arm study (NCT****) evaluating a tailored DLCT protocol in young adult patients with suspected acute appendicitis This interim analysis compared image quality and diagnostic performance for acute appendicitis and alternative diagnoses between DLCTs and historical SLCTs performed immediately prior to study initiation.
Objectives: To evaluate the feasibility of a standardized double low-dose CT (DLCT) protocol that simultaneously reduces both iodine contrast media (CM) dose and tube voltage, and to compare its image quality and diagnostic performance with a single low-dose CT (SLCT) protocol using fixed iodine doseand reduced tube voltage, representative of institutional low-radiation dose imaging practice in suspected acute appendicitis.
Methods: In this exploratory analysis of a prospective single-arm study, 49 participants aged 18–44 years presenting to the emergency department (ED) with suspected acute appendicitis underwent DLCT using automated kVp selection and a kVp- and weight-adjusted CM dosing protocol. This protocol targeted a 10% iodine dose reduction for every 10 kVp decrease from a reference standard of 0.521 gI/kg at 120 kVp.A historical control group of 53 patients with the same inclusion criteria, who had undergone SLCT using a fixed CM dose and low-kVp protocol (80–100 kVp) prior to study initiation, was retrospectively included. Quantitative (signal-to-noise ratio [SNR] and contrast-to-noise ratio [CNR]) and qualitative (subjective image quality and appendiceal visibility) assessments were compared. Diagnostic performance was evaluated using positive predictive value (PPV) for acute appendicitis and alternative diagnoses, based on surgical findings, clinical follow-up, or an Alvarado score ≥ 7.
Results: DLCT significantly reduced iodine dose (0.383 $\pm$ 0.049 gI/kg vs. 0.589 $\pm$ 0.085 gI/kg; $P < 0.001$) while maintaining comparable image noise and appendiceal visibility. Although SNR and CNR were lower in the DLCTgroup, diagnostic performance including PPVs for acute appendicitis (63.6% vs. 72.7%) and alternative diagnoses (100% vs. 86.7%) did not significantly differ between groups.
Conclusions: An iodine dose-reducing DLCT protocol tailored to tube voltage and body weight is feasible in the ED setting and offers substantial CM dose saving without compromising diagnostic performance for acute appendicitis or alternative diagnoses.

Intensive Care Medicine Experimental 2025,* 13(1)*:001272

Introduction: Sepsis, the leading cause of death in intensive care units, represents a major public health challenge. Its pathophysiology involves intricate mechanisms associating an exacerbated systemic inflammatory response and profound immunosuppressive mechanisms, primarily driven by the differentiation of immunosuppressive cell subpopulations. Among these, we recently described the induction of plasma cells (rPC) with immunoregulatory functions on T cell activation through increased PD-L1 expression and IL-10 production.
Inflammasomes are supramolecular complexes that act as sensors of cellular stress, controlling the secretion of inflammatory cytokines (IL-1β and IL-18) and pyroptosis, a form of pro-inflammatory cell death. Inflammasome pathways are rapidly activated after sepsis and are associated with an increased risk of death. In patients with gain-of-function mutations in inflammasome-related genes, excessive inflammasome activation contributes to the differentiation of immunosuppressive myeloid cells.
Objectives: In this project, we hypothesize that excessive inflammasome activation plays a central role in inducing rPC during sepsis.
Methods: Using a murine model of sepsis (cecal ligation and puncture (CLP)) that replicates the immune alterations observed in patients and genetically deficient mice for specific components of inflammasome pathway or administration of IL-1β and IL-18 inhibitors, we will identify the molecular and cellular mechanisms linking canonical and/or non-canonical inflammasome pathways to the emergence of rPCS.
Results: We observed that Caspase1/11-double deficient mice and ASC-/- CLP mice exhibited a decreased induction of rPC after sepsis compared to their wild-type (WT) littermate as well as reduced PD-L1 expression and IL-10 production by these cells. No difference was observed in NLRP3-/- mice after sepsis compared with WT littermate.
These results were reproduced in CLP mice treated with inflammasome final products inhibitors (IL1-receptor antagonist and anti-IL18) injected together before surgery and until sacrifice.
Conclusions: Taken together, these data demonstrated a role for inflammasome pathway activation in the expansion and immunoregulatory functions of rPC after sepsis. Beside NLRP3, the involvement of other inflammasome pathways (AIM2, NLRC4, NLRP1, pyrin) remains to be determined. These results reveal potential therapeutic targets to prevent sepsis-induced immune alterations.

A quality improvement project to reduce unnecessary blood loss whilst sampling from arterial catheters in Aberdeen Royal Infirmary Intensive Care Unit

E. Kerr, A. Jagger, A. Lapukhova, D. Middleton, A. Dutia
Critical Care, NHS Grampian, Aberdeen, United Kingdom
Correspondence: A. Jagger
Intensive Care Medicine Experimental 2025,* 13(1)*:001274

Introduction: Care of critically ill patients involves frequent blood sampling to inform clinical decision making, often via an indwelling arterial line. When sampling from this set up, a volume of blood is discarded before sample collection. Repeated accessing of this system can lead to significant volumes of blood being lost over an ICU admission, contributing to iatrogenic anaemia.
Objectives: This quality improvement project aimed to quantify the amount of blood lost due to sampling and reduce this through interventions that minimise the blood volumes discarded and rationalise sampling frequency.
Methods: Over a 2-month period in 2022, nurses were observed obtaining samples from arterial lines and the volume of blood sampled was recorded. Retrospective analysis of 39 patients over the same period was performed to determine the median number of samples taken during ICU admission and used to estimate the total volume of blood lost to sampling.
Changes enacted:
1. Suggest a sampling frequency on ward round notes for laboratory tests and arterial blood gases (ABG).
2. Short length manometer tubing for line set up to reduce discarded volume.
3. Education on blood sampling practices.
Following these changes, sampling observations were repeated in February 2025 and retrospective analysis of 28 patients was performed. Outcome measures included the use of short manometer tubing, compliance with suggested frequency of blood tests and total volume of blood lost to sampling.
Results: At baseline, short manometer tubing was used in 5% of arterial line set ups, increasing to 55% post intervention. The volume of blood discarded had increased in both short and long tubing set ups, by 1.1 and 0.6 ml, respectively.
Compliance with suggested frequency of laboratory tests was good with a median of 4 more tests performed per admission as compared to the suggested number. However, a median of 2.7 times more ABG were performed than specified as needed over a patient's admission.
There was an overall reduction in the median number of ABG taken per day, from 4.66 to 3.5, with greater reduction in level 3 patients than level 2. In level 3 patients, the median number of daily laboratory tests also decreased, from 3.01 to 2.80. This led to a 13% reduction in median blood volume lost to sampling daily.
In both cycles, increasing volume of blood lost to sampling correlated with requirement for red cell transfusion.
Conclusions: Our interventions led to a reduction in blood lost to sampling during a level 3 admission to ICU, through reduction in both laboratory tests and ABG. However, more ABG are being tested than the number suggested to be needed clinically. Although the use of short manometer tubing increased, the volume of blood discarded also increased, highlighting challenges with making lasting changes to practice. Further engagement with stakeholders is planned to address this, alongside review of the arterial line set up to minimise the required discard volume.

Intensive Care Medicine Experimental 2025,* 13(1)*:001275

Introduction: The icteric index (II) is a reagent-free parameter routinely measured by many modern clinical chemistry analyzers. It reflects the degree of bilirubin interference in plasma samples based on absorbance at specific wavelengths and is often automatically reported as part of hemolysis, icterus, and lipemia (HIL) indices (1). Given its availability and zero reagent cost, the II may offer a valuable surrogate for total plasma bilirubin (TBIL) in critically ill patients. This study aimed to assess the relationship between the II and TBIL in ICU patients to assess if II could serve as a proxy for bilirubin monitoring.
Objectives: To evaluate the correlation between total plasma bilirubin levels and the II in a large cohort of critically ill patients.
Methods: This retrospective study included ICU patients admitted between November 2017 and December 2023. For each patient, daily TBIL values and the corresponding II were collected. The TBIL and II were measured with a Roche Cobas 8000 or PRO clinical chemistry analyzer in lithium-heparin anticoagulated plasma samples. Only paired measurements from the same sample were analyzed. Our tertiary ICU serves a mixed medical–surgical population, including patients with acute liver failure and those undergoing liver transplantation. Correlation and agreement between II and TBIL were assessed using linear regression.
Results: A total of 65,805 paired II and TBIL values were collected from 13,702 patients with a mean (± SD) age of 61 ± 15 years and 63% males. With linear regression analysis, a strong relation was observed between the II and TBIL, with a Pearson's correlation coefficient yielding an R^2 value of 0.99 ($P < 0.001$). This correlation was particularly strong in samples with TBIL concentrations above 100 µmol/L. Below this threshold, a much greater degree of variability was observed in the relationship between II and TBIL.
Conclusions: In ICU patients with total bilirubin levels elevated above 100 µmol/L (5.85 mg/dL), the II demonstrated excellent correlation with total plasma bilirubin. In this range, the II can be considered a reliable and reagent-free surrogate marker for detecting significant hyperbilirubinemia. However, at lower bilirubin concentrations, only moderate agreement was noted, suggesting that direct measurement of TBIL remains preferable in patients with mild bilirubinemia.

Intensive Care Medicine Experimental 2025,* 13(1)*:001276

Introduction: According to a recently published pilot study, using a comprehensive redesign of the ICU rooms could help reduce the incidence of delirium and influence circadian melatonin rhythms [1]. In critically ill patients, sleep architecture is significantly disrupted, leading to circadian disruption, fragmented sleep, and the loss of a physiological diurnal cycle [2, 3].
Objectives: To evaluate the impact of a multicomponent room design that includes dynamic lighting therapy on daytime polysomnography in critically ill, mechanically ventilated patients.
Methods: Two double ICU rooms underwent significant architectural changes, including interventions for noise reduction and dynamic light therapy [4, 5]. Polysomnography (PSG) was performed for a maximum of three 24-h periods. The recordings were manually scored by a sleep specialist, blinded to the study, using conventional sleep staging and following the American Academy of Sleep Medicine (AASM) criteria. The depth of sedation was evaluated every eight hours using the Richmond Agitation Sedation Scale (RASS). PSG data collected from 06:00 AM to 10:00 PM were included in this analysis.
Results: In this study sample, the total sleep time accounted for a significant portion of the day for both patients in standard rooms and those in modified rooms (81.67% for standard rooms vs. 63.09% for modified rooms). However, patients in modified rooms showed significantly less total sleep time ($p = 0.03$). The percentage of light sleep (N1; 7.2% for standard rooms vs. 10.0% for modified rooms) and intermediate sleep (N2) were similar between the groups. The proportion of time spent in deep sleep (N3) was significantly higher in standard rooms (46.7% for standard vs. 25.8% for modified; $p = 0.001$; see Fig. 1). REM sleep was nearly absent in both groups with less than 1% each. Patients in modified rooms experienced significantly fewer sleep stage transitions per hour than those in the standard rooms (10.6 for modified vs. 15.0 for standard; $p = 0.035$). Although not statistically significant ($p = 0.06$), there was a trend toward an increased Arousal Index (AI) in the standard rooms, with an average of 49.2 arousals per hour compared to 32.2 in the modified rooms. Sedation levels, measured using the RASS, were comparable between both groups, with a median score of −2 (modified rooms: IQR −3 to 0; standard rooms: IQR −4 to −1; see Fig. 2).
Conclusions: This preliminary analysis suggests that a multicomponent room redesign that includes dynamic lighting therapy may help reduce daytime sleep in mechanically ventilated patients while also influencing the distribution of sleep stages by reducing deep sleep.

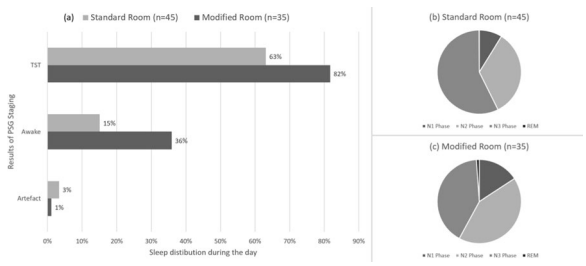

Fig 1 (abstract 001276) a Distribution of sleep from conventional polysomnography sleep staging between 6 a.m. and 10 p.m for patients in standard ($n = 45$) and modified ($n = 35$) rooms [%]. TST, total sleep time. **b** + **c** Distribution of sleep stages from conventional polysomnography as percentages of total sleep time (TST) for each group; N1, N2, and N3 Phases comprise non-rapid eye movement (NREM) sleep; REM, rapid eye movement sleep

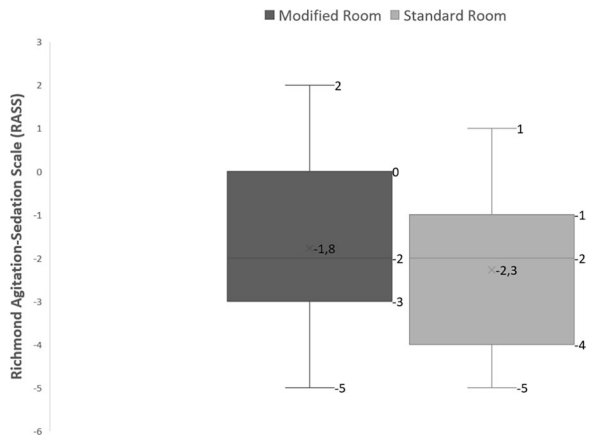

Fig 2 (abstract 001276) Distribution of sedation levels, measured using the Richmond Agitation Sedation Scale (RASS), for patients in standard ($n = 45$) and modified ($n = 35$) rooms. The means are marked with an "x," and the median is indicated by a horizontal line. Investigate the effect and mechanism of glymphatic system on sepsis associated encephalopathy based on MRI VFA-SPGR sequence

Y. Xue, L. Mi, Q. Wang, Y. Yang, Y. Long
Department of intensive care unit, Peking Union Medical College Hospital, Beijing, China
Correspondence: Y. Xue
Intensive Care Medicine Experimental 2025,* 13(1)*:001277

Introduction: Sepsis-associated encephalopathy (SAE) is a severe complication of sepsis, and elucidating its pathogenesis is critical for prevention and treatment. The glymphatic system (GS), a novel pathway for cerebral metabolic waste clearance, is crucial for brain homeostasis, lipid transport, and immune surveillance. Alterations in cerebrospinal fluid flux serve as a pathophysiological basis for acute and chronic cognitive impairments in various diseases. Previous studies indicate that sepsis is associated with amplified inflammatory cascades. During sepsis, the brain injury biomarker S100β protein accumulates in the parenchyma, activating astrocytes and microglia to release pro-inflammatory cytokines and reactive oxygen species. These mediators exacerbate mitochondrial damage through downstream signaling pathways involving ERK1/2, p38/nuclear factor kappa B (NF-κB), and JNK, thereby aggravating SAE-related cognitive deficits. A. Plog demonstrated that suppressing glymphatic transport in traumatic brain injury mice via four distinct methods reduced cerebral waste clearance efficiency, with serum levels of S100β becoming nearly undetectable, confirming that this biomarker is primarily cleared from brain parenchyma to blood via the glymphatic system. This suggests that intact glymphatic function may prevent cerebral accumulation of inflammatory mediators, mitigate neurotoxin-induced proptosis, and potentially halt SAE progression.
Objectives: Demonstrate the impairment of glymphatic efficiency during sepsis constitutes a pivotal mechanism underlying SAE pathogenesis.
Methods: The mode of SAE was induced by cecal ligation and puncture (CLP) in 12-week-old C57BL/6 J mice ($N = 8$). Control group was done sham surgery ($N = 5$). Twenty-four hours later, the mice underwent MRI for characterization of GS transport. The mice were anesthetized with isoflurane and dexmedetomidine and received CSF injection of Gd-DOTAREM (1:20; 0.5 ml/min, 10 min). All MRI was done on a 9.4 T MRI instrument (Fig. 1). Fifty min after administration of Gd-DOTAREM, T1 maps were acquired at a spatial resolution of 100 mm. The volume of T1 voxels = 400-1600 ms (representative of DOTAREM-solute tissue levels and GS transport) where extracted from whole brain and nasal conchae masks from each mouse and compared across groups(Fig. 2).
Results: T1 maps acquired 50 min after Gd-DOTA CSF administration demonstrates significantly reduced glymphatic transport efficiency across multiple brain regions in CLP septic mice compared to sham-operated controls (brainstem $p < 0.01$; hippocampus $p < 0.01$; hypothalamus $p < 0.001$; thalamus $p < 0.05$; olfactory bulb $p < 0.001$)(Fig. 3,4), suggesting that impaired glymphatic function plays a critical role in SAE pathogenesis. Meanwhile, we found in CLP group there was significant intra-group heterogeneity in glymphatic influx/efflux efficiency, mirroring clinical heterogeneity where some septic patients develop SAE while others retain cognitive integrity. These findings imply that maintaining effective cerebral metabolic waste clearance may represent a novel therapeutic strategy for SAE prevention and treatment.
Conclusions: In CLP mice group, GS transport of Gd-DOTA from the CSF compartment into brain parenchyma decreased as compared to sham control group. It indicates the impairment of GS transport efficiency during sepsis as a pivotal modulator in SAE progression.

Intensive Care Medicine Experimental 2025,* 13(1)*:001279

Introduction: Survivors of critical illness experience a range of long-term health problems, negatively affecting health-related quality of life [1]. Coordination of care across the critical care recovery continuum is essential to improving patient outcomes reflected in national guidelines [2–5]. Although survey data suggest that there remains wide variation in service configuration within the UK [4], this does not provide a complete picture of actual care provision. The granular information captured in electronic health records (EHRs) provides an opportunity for greater understanding of rehabilitation provision using data-driven methods, facilitating benchmarking against standards and information on resource allocation.
Objectives: We aimed to understand the delivery of rehabilitation during the inpatient phase of post-ICU recovery across three acute hospitals in Scotland with a funded regional rehabilitation service. We explored whether data-driven methods could be used to understand the frequency and type of rehabilitation contacts provided by the multidisciplinary team (MDT), factors associated with MDT healthcare contact frequency, and whether there are distinct patterns/clusters of MDT contact identifiable within the dataset.
Methods: We conducted a cohort study of adult critical care survivors in NHS Lothian in South-East Scotland, admitted between 01/03/2019 and 30/03/2021, using linked hospital and national EHRs. The primary outcome was number of MDT contacts between critical care and hospital discharge, with multivariable negative binomial regression used to analyse the association between this and demographic, medical history and admission factors. K-means clustering was used to group patients with similar care pathways, using daily contacts with each MDT member as input features.
Results: In 3272 admissions, 87.6% of patients saw at least one MDT service, with a majority seeing intensive therapy recovery service

(67.5%) or physiotherapy (62.9%). In regression analysis, MDT contact frequency was associated with increased patient age (adjusted incidence rate ratio (adjIRR) 1.13 (1.10–1.17), $p < 0.001$) and conditions, such as intracranial haemorrhage (adjIRR 2.40 (1.82–3.17), $p < 0.001$ and gastrointestinal perforation or obstruction (adjIRR 1.87 (1.39–2.53), $p < 0.001$) (Fig. 1). In clustering analysis, eight clusters were identified, with distinct profiles of MDT involvement (Fig. 2) linked to patient characteristics and treatment factors.

Conclusions: Leveraging EHR data, we observed wide inter-patient variation in frequency and type of post-ICU rehabilitation contacts. Older age and specific conditions were associated with greater MDT contact frequency, and eight distinct clusters of rehabilitation provision were identified. Using a novel, data-driven approach, we were able to quantify rehabilitation contacts for all patients in the cohort, providing the foundations for a system to efficiently monitor one key aspect of post-ICU recovery service provision.

Intensive Care Medicine Experimental 2025,* 13(1)*:001280

Introduction: Vasopressin (VP) is recommended as a second-line vasopressor in septic shock (SS) when norepinephrine (NE) exceeds 0.25 mcg/kg/min, according to international guidelines [1–3]. However, real-world adherence to this recommendation remains inconsistent. We assessed protocol adherence to VP initiation and its association with clinical outcomes in critically ill patients with SS.
Methods: We conducted a retrospective observational study in a tertiary hospital ICU (Jan–Dec 2023). Adult patients with SS, defined by Sepsis-3 criteria [4], who received NE > 0.25 mcg/kg/min were included. Protocol adherence was defined as VP administration under this indication.
Baseline characteristics, comorbidities, complications, and mortality were compared between patients who received VP and those who did not. Categorical variables were analyzed using chi-square or Fisher's exact test, and continuous variables with the Mann–Whitney *U* test.
A multivariable binary logistic regression model was used to identify independent predictors of ICU mortality, including VP use, hydrocortisone, age, APACHE II, lactate, and mechanical ventilation.
A separate model explored predictors of arrhythmias, including VP use, dobutamine, age, APACHE II, and lactate, to isolate treatment effects while adjusting for clinical severity.
The study was approved by the Clinical Research Ethics Committee of Hospital Universitari Vall d'Hebron (EOM(AG)014/2024(6245)).
Results: Ninety patients met inclusion criteria (median age 63 [IQR 56–72], APACHE II 26 [21–32]); 52 (57.8%) received VP and 38 (42.2%) did not, despite exceeding the NE threshold.
VP recipients were younger (63 vs. 67, $p = 0.012$), with higher SOFA (12.0 vs. 9.0, $p = 0.004$), lactate (5.7 vs. 3.6 mmol/L, $p = 0.008$), and greater need for mechanical ventilation (94.2% vs. 63.2%, $p < 0.001$) and ECMO (9.6% vs. 0%, $p = 0.016$). CRRT and ventricular dysfunction were comparable (30.8% vs. 28.9%, $p = 0.85$; 17.3% vs. 5.3%, $p = 0.09$). Comorbidities were also similar: cardiopathy (19.2% vs. 23.7%), COPD (11.5% vs. 21.1%), cirrhosis (3.8% vs. 5.3%), chronic kidney disease (15.4% vs. 10.5%), and immunosuppression (23.1% vs. 15.8%; $p = 0.436$). Hydrocortisone was used in 57.7% vs. 42.1% ($p = 0.12$).
The most common infection sites were pulmonary (43.3%), abdominal (24.4%), and urinary (15.6%), with similar distribution between groups. Inflammatory biomarkers at baseline differed between groups. Median procalcitonin was 14.9 [IQR 5.0–83.8] ng/mL in VP patients and 4.4 [IQR 0.8–20.6] ng/mL in non-VP patients ($p = 0.0020$). C-reactive protein was 20.1 [IQR 7.4–29.4] mg/L in the VP group vs. 17.8 [IQR 7.8–26.4] mg/L in the non-VP group ($p = 0.4722$). IL-6 levels were 10,677.0 [IQR 833.3–106,425.0] pg/mL vs. 1,015.0 [IQR 311.9–7,807.5] in non-VP patients ($p = 0.0081$).
Dobutamine use (48.1% vs. 15.8%, $p = 0.002$), arrhythmias (38.5% vs. 13.2%, $p = 0.016$), and digital ischemia (21.2% vs. 2.6%, $p = 0.025$) were more common in the VP group, though no ischemic events led to amputation or death. Given the strong imbalance in ischemic events between groups (11 of 12 cases occurred in VP patients), a multivariable model could not reliably estimate the independent association of VP with ischemia due to near-complete separation. Therefore, results are reported descriptively.
Multivariable analysis of predictors of arrhythmias showed no independent association for VP (OR 0.22, 95% CI 0.04–1.33, $p = 0.098$) or dobutamine (OR 0.29, 95% CI 0.07–1.27, $p = 0.102$).
ICU mortality was 42% overall: 44.2% with VP vs. 39.5% without ($p = 0.43$). Adjusted analysis showed a non-significant trend toward lower mortality with VP (OR 0.37, 95% CI 0.10–1.38, $p = 0.14$); no other covariates were independently associated.
Conclusions: Adherence to VP initiation based on NE thresholds was limited. VP was more frequently used in patients with greater hemodynamic severity, but was not associated with improved survival. A nonsignificant trend toward lower mortality was observed after adjustment. VP and dobutamine were not independently associated with arrhythmias.
Further prospective studies are needed to clarify the complex interplay of contributing factors and better define which patients may benefit most from VP.

Variable	VP group	Non-VP group	p-value

T2Bacteria® magnetic resonance assay for early detection of bacteraemia in critical care: a pilot study

D. O'Driscoll[1], M. Lincoln[2], C. Brennan[3], A. Rueda Benito[3], A. Giraldez[1]
[1]Critical Care Medicine, Sligo University Hospital, Sligo, Ireland; [2]Critical Care Medicine, Sligo University Hospital, Sligo, Ireland, Ireland; [3]Clinical Microbiology, Sligo University Hospital, Sligo, Ireland
Correspondence: D. O'Driscoll
Intensive Care Medicine Experimental 2025,* 13(1)*:001281

Introduction: Challenges exist in diagnosing and treating bacteraemia in the critical care unit. Mimicry of sepsis by non-infective syndromes such as heart failure and inflammatory conditions, the insensitivity and prolonged time to results of blood cultures, and the confounding of signs of organ system dysfunction in sepsis by post-operative complications such as hypotension and haemorrhage are contributory.The T2Bacteria® Panel (T2 Biosystems) is a whole blood, non-culture test that identifies the most common "ESKAPE" bacteria (*Enterococcus faecium*, *Staphylococcus aureus*, *Klebsiella pneumoniae*, *Acinetobacter baumannii*, *Pseudomonas aeruginosa*, and *Escherichia coli*) within 3–5 h with a reported sensitivity of 90% and specificity of 98%.

These opportunistic organisms are leading causes of nosocomial infections in critical care and represent major therapeutic challenges.
Objectives: To compare paired testing T2Bacteria® Panel versus peripheral blood culture results in patients undergoing blood culture sampling admitted to critical care over a 4-month period in a model 3 hospital. To review antimicrobial changes guided by T2Bacteria® Panel results.
Methods: Institutional ethical approval was obtained. Patients were prospectively enrolled (13 November 2024–19 March 2025). All patients undergoing blood sampling for clinical suspicion of sepsis in the critical care unit had paired T2Bacteria® Panel and peripheral blood culture samples sent for analysis. Clinical and laboratory data were collected, anonymised and basic statistical analysis performed with Microsoft Excel.
Results: $n = 60$ patients admitted to critical care (both HDU and ICU level; model 3 hospital) undergoing paired sampling for sepsis screening were enrolled during the study period. $n = 79$ specimens sent to the laboratory for analysis.
$n = 2$ patients had negative T2Bacteria® Panel but had positive blood cultures with *Staphylococcus capitis* and *Staphylococcus epidermidis*, both clinically deemed contaminants and were excluded from analysis.
$n = 9$ (15%) patients had bacteraemia on peripheral blood culture or T2Bacteria® Panel (Table A). $n = 51$ patients were blood culture and T2Bacteria® Panel negative.
$n = 5$ patients had a positive T2Bacteria® Panel for *E. coli*, including one patient also with *K. pneumoniae*, which correlated to blood culture positivity in $n = 3$ patients. This resulted in antimicrobial changes each of the 5 cases.
$n = 4$ patients had positive blood cultures and negative T2Bacteria® Panels, with organisms not identifiable on the assay (including ESBL and fungal organisms). The antimicrobial changes in these instances were therefore not guided by the T2Bacteria® Panel.
Conclusions: In this single centre pilot study of critically ill patients, the T2Bacteria® Panel was concordant in detecting *E. coli* bacteraemia with a significantly shorter turn-around time as compared to conventional blood cultures. The results also impacted decisions on antibiotic therapy. The limitations of this study include the low prevalence of positive blood cultures and inability of T2Bacteria® panel to detect non-targeted pathogens. Future work aims to further investigate the utility of the T2Bacteria® Panel in a wider cohort of critically ill patients.

ICU diagnosis	T2Bacteria	Organism	Blood cultures (hours)	Organism	Antimicrobials
Septic shock	Positive	*E. coli*	Positive (8 hours)	*E. coli + P. mirabilis*	Co-amoxiclav -> Gentamicin + Pip/Taz
Septic shock	Positive	*E. coli + K. Pneumoniae*	Positive (12 hours)	*E. coli*	Meropenem -> Ceftriaxone
Septic shock	Positive	*E. coli*	Negative	/	Pip/Taz
Septic shock	Positive	*E. coli*	Positive (8 hours)	*E. coli*	Pip/Taz -> Meropenem
Anastomotic leak	Positive	*E. coli*	Negative	/	Pip/Taz/Gentamicin/Anidulafungin
Septic shock	Negative	/	Positive (9 hours)	*K. oxytoca*	Pip/Taz -> Meropenem
Urosepsis	Negative	/	Positive (45 hours)	*Candida Glabrata*	Anidulafungin
Post cardiac arrest	Negative	/	Positive (13 hours)	*Enterobacter kobei (ESBL)*	Meropenem
Respiratory failure	Negative	/	Positive (18 hours)	*S. epidermidis*	Flucloxacillin

ICU diagnosis and paired testing T2Bacteria® Panel versus peripheral blood culture results.

The effect of oral health on dysphagia level in acute stroke patients: a cross-sectional and correlational study

S. Gungor[1], I. Kose Tosunoz[2], E. Bulmus[3]
[1]Vocational School of Health Services, Kahramanmaraş Sütçü İmam University, Kahramanmaraş, Turkey; [2]Faculty of Health Sciences, Department of Nursing, Hatay Mustafa Kemal University, Hatay, Turkey; [3]Nurse Manager, Adana City Education and Research Hospital, Adana, Turkey

Intensive Care Medicine Experimental 2025,* 13(1)*:001283

Introduction: Dysphagia is a common complication after a stroke. Maintaining oral health is of vital importance in stroke patients.
Objectives: This study was conducted to determine the relationship between oral health and dysphagia at the time of admission of acute stroke patients.
Methods: This descriptive and correlational study was conducted in the Neurology and Stroke Center Intensive Care Unit of a training and research hospital in Southern Türkiye. The study sample consisted of 82 acute stroke patients. The data were collected within the first 24 h following the admission of the patients to the unit using the "Patient Information Form" the "Turkish Modified Mann Swallowing Assessment Test (TR-MMASA Test)" to determine the dysphagia level, and the "Oral Assessment Guide (OAG)" to assess oral health. Data were analyzed using an independent samples *t* test, one-way ANOVA, Mann–Whitney *U* test, and simple linear regression analysis.
Results: The mean age of the patients was 65.41 ± 12.94, 64.5% were male, and 68.3% were primary school graduates. Of the patients, 24.4% smoked, 13.4% consumed alcohol and 47.6% had a chronic disease. The mean OAG score of the patients was 7.52 ± 3.58 (min–max: 5–15) and the mean TR-MMASA Test score was 83.04 ± 24.68 (19–100). The oral health status of acute stroke patients at the admission to the unit explains 80% of the change in dysphagia levels.
Conclusions: As a result of the evaluations made within the first 24 h after the admission of acute stroke patients to the Neurology and Stroke Center ICU, a medium risk assessment level for oral health and a high risk for dysphagia. Oral health has been determined to have a strong effect on the risk of dysphagia.

Intensive Care Medicine Experimental 2025, **13(1)***:001285*

Introduction: Critical care outreach teams (CCOT) support ward staff and prevent patient deterioration across majority of Trusts. However, its impact on clinical outcomes remains inconclusive, necessitating an alternative evaluation, such as assessing the service quality (SQ) from staff perspectives.
Objectives: The aim of the study is to evaluate the quality of CCOT support from the perspective of the medical and nursing staff using SERVQUAL model as a framework.
Methods: A concurrent embedded mixed-methods design that utilised an online questionnaire with Likert-scale questions, comments and suggestions has been employed. The study was conducted from October 2024 to December 2024 across two sites of an NHS Trust, with purposive sampling of 300 staff (68 respondents, 22.6% response rate). The data were analysed using SPSS (quantitative) and content analysis (qualitative).
Results: Overall, CCOT provides quality service based on the ratings received. Both sites scored high for importance (mean: 4.51–4.78), patient safety enhancement (4.51–4.74), and likelihood of recommendation (4.59–4.81). Sutton staff rated CCOT significantly higher than Chelsea in importance, satisfaction, and clinical practice improvement ($p < 0.05$). Nurses reported greater satisfaction than doctors, particularly in feeling supported ($p = 0.037$). Qualitative themes highlighted strengths (responsiveness, expertise) and areas for improvement (communication training, night staffing, and education for ward teams).
Conclusions: CCOT is meeting the needs of the stakeholders and the organisation though perceptions varied by site and profession. Recommendations include cross-site collaboration, engaging better with doctors, more staff education and training, communication skills training, additional night staffing, and strive for continuous improvement. This study underscores the importance of assessing SQ to ensure that CCOT satisfies staff needs and organizational goals.

Five years of severe acute pancreatitis in ICU: a tertiary center perspective

M. J. Fernandes[1], J. Capingala[1], J. P. Santos[1], A. Sukhoviy[1], I. Palmares[1], A. C. Araújo[1], P. T. Freitas.
[1]Intensive Care Department, Hospital Prof. Dr. Fernando da Fonseca, Amadora, Portugal, Lisbon, Portugal, Portugal

Intensive Care Medicine Experimental 2025, **13(1)***:001287*

Introduction: Pancreatitis is an acute or chronic inflammatory condition of the pancreas that may lead to serious local and systemic complications. In its severe form, it can rapidly progress to multiorgan failure and death if not promptly recognized and managed. Given the unpredictable clinical course, early identification of severity markers and risk factors for poor prognosis is essential. Critically ill patients often require ICU support, reinforcing the need for reliable clinical scores and biochemical markers to predict complications and mortality at presentation. Early and accurate risk stratification is crucial to guide timely and effective intervention.
Objectives: To identify the clinical and demographic characteristics, the risk factors associated with the progression to severe forms and worse clinical outcomes in patients admitted to Intensive Care Unit with a diagnosis of acute pancreatitis over a 5-year period.
Methods: This retrospective, monocentric cohort study included all adult patients admitted to the Intensive Care Unit of Hospital Professor Doutor Fernando Fonseca with a first diagnosis of acute pancreatitis between January 2017 and December 2021. Collected data included clinical and demographic characteristics, severity scores (APACHE II), laboratory and imaging findings, therapeutic interventions, organ support requirements (e.g., mechanical ventilation, vasopressors, renal replacement therapy), ICU length of stay, progression to more severe forms and in-hospital mortality.
Results: A total of 51 patients were included (22 females, 29 males), with a mean age 65 (± 17.4). A total of 49 (96.1%) patients had other comorbidities at admission; from all the patients 15 had a history of alcohol abuse and 11 had a history of chronic pancreatitis. Mean APACHE II at admission was 21.5 (± 13). 23 patients presented with organ dysfunction at admission. Organ support was required at 40 patients. Antibiotics were used in 42 patients. Surgery was performed in 22 patients. Pancreatic necrosis at admission was present at 23 patients, and 10 other patients developed necrosis during ICU stay. The mean length of stay at ICU was 15.4 (± 27.3) days. The mortality rate was 60.8% (31 patients), 22 of them in the first 14 days of hospitalization.
Conclusions: Progression to severe pancreatitis and worse outcomes was associated with older age (> 65), lithiasic etiology, high APACHE II, pleural effusion (51%), and pancreatic necrosis (51.1%). Mortality was higher in patients with necrosis (69.6%) and those requiring organ support, especially vasopressors (100%) and mechanical ventilation (90.3%).
This study reinforces the prognostic value of early findings in acute pancreatitis and supports the development of standardized protocols for early assessment. It lays the groundwork for future research focused on risk stratification tools and targeted interventions to improve ICU outcomes.

Multi-omics analysis identifies S100a9hi monocyte/macrophages as pathogenic targets for sepsis-induced acute respiratory distress syndrome

R. Gong, Y. Shang
Department of Critical Care Medicine, Wuhan Union Hospital, Tongji Medical College, Huazhong University of Science and Technology, Wuhan, China
Correspondence: R. Gong
Intensive Care Medicine Experimental 2025,* 13(1):*001288

Introduction: Sepsis-induced acute respiratory distress syndrome (S-ARDS), a critical and life-threatening condition prevalent in septic patients, exhibits an aberrant immune response and high mortality rates. However, the underlying cellular and molecular changes associated with inflammation during S-ARDS development remain elusive.
Objectives: This study aims to elucidate the molecular mechanism through multi-omics analysis in S-ARDS and to explore potential immunotherapeutic targets.
Methods: A murine S-ARDS model was generated via cecal ligation and puncture (CLP) using S100A9-KO monocyte/macrophage-specific knockout (S100A9-CKO), and wild-type mice. Multi-omics analyses (bulk/single-cell RNA-seq, proteomics) identified S100A9 + monocyte/macrophage subpopulations. CCR2 antagonist or paquinimod interventions suppressed monocyte migration. In vitro co-culture assays with S100A8/A9-stimulated macrophages/neutrophils and LPS/nigericin-induced pyroptosis validated mechanisms. Lung injury and pyroptosis markers were assessed via histopathology, immunofluorescence and Western blotting. Serum proteomic analysis in S-ARDS patients revealed elevated S100A9 levels correlating with disease severity.
Results: Multi-omics analysis identified a pro-inflammatory S100A9 + monocyte/macrophage subpopulation (Mono1) in septic murine lungs, characterized by co-expression of CCR2 and enriched inflammatory markers. Genetic ablation of S100A9 (global or monocyte/macrophage-specific) significantly attenuated lung injury, reducing histopathology scores and edema. Pharmacological inhibition of S100A9 + cell migration (CCR2 antagonist) yielded comparable protection. Mechanistically, S100A9 triggered macrophage pyroptosis, propagating neutrophil pyroptosis in co-culture models. Clinically, serum S100A9 levels correlated with ARDS severity and mortality.
Conclusions: Our findings suggest the modulation of S100A9 + monocytes/macrophages and S100A9 as targets for immunotherapy in S-ARDS.

Highlights:
1. This study identifies S100A9 + monocytes/macrophages (Mono/Mac) as a key driver of septic ARDS, promoting lung injury via multi-omics sequencing.
2. S100A9 deficiency in Mono/Mac or suppression of the migration of S100A9 + Mono/Mac protects against lung injury and improves survival in sepsis mice, highlighting therapeutic potential.
3. Serum S100A9 levels correlated with the development of ARDS, suggesting diagnostic utility.
Collectively, targeting S100A9 + Mono/Mac and its downstream pathways may offer novel strategies for mitigating sepsis-induced ARDS.

Intensive Care Medicine Experimental 2025,* 13(1):*001289

Introduction: In the intensive care unit, endotracheal intubation is used to secure the airway [1]. Typically, intubation is performed orotracheally (OTI) with subsequent administration of sedation to ensure tolerance of the orotracheal tube. To avoid the adverse effects of sedation [2] nasotracheal intubation (NTI) might be advantageous [3] due to fewer sedatives, vasopressors, and a higher rate of spontaneous breathing [4].
Objectives: To compare NTI versus OTI on depth of sedation and rate of spontaneous breathing in a prospective randomized trial.
Methods: With ethics approval, this study was conducted at the Department of Intensive Care Medicine of the University Medical Center Hamburg-Eppendorf, Germany. Patients were randomized in a 1:1 ratio to NTI or OTI. Patients were eligible if they were at least 18 years old and required tracheal intubation for any reason. Patients with a length of ventilation < 48 h, indication for deep sedation, known risk factors for bleeding or contraindications to NTI were excluded. The primary outcome measure was depth of sedation assessed by the percentage of time with a Richmond–Agitation–Sedation Scale (RASS) of 0 or −1 for 10 days after intubation. Secondary endpoints were rate of assisted spontaneous breathing (ASB), and complications, i.e. sinusitis. Generalized linear mixed models (GLMM) and chi-squared tests were used for analyses, as applicable.
Results: From 05.03.2023 to 09.10.2024, we included 126 patients with 65 randomized to OTI and 61 to NTI (Table 1). The percentage of the time with RASS 0 to -1 (Fig. 1) did not differ significantly between the groups while average RASS was higher in the NTI group on days 1 and 4 (both $p = 0.04$).The rate of ASB (Fig. 2) did not differ significantly between the two groups. Sinusitis occurred in 3 cases in OTI and 6 in NTI (p = n.s.).

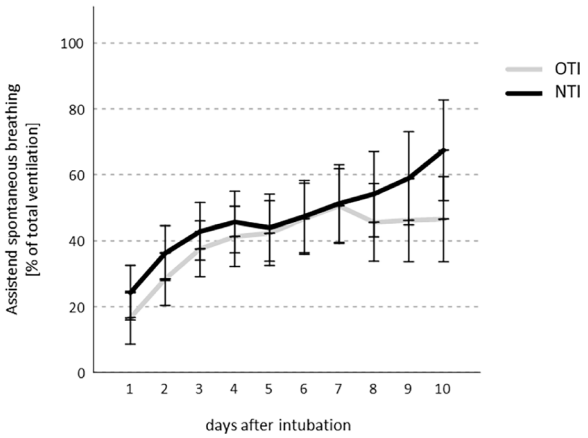

Table 1(abstract 001289) Outcome parameters

Parameter	Orotracheal intubation ($n = 65$)	Nasotrache-alintubation ($n = 61$)	*p* value
Length of ICU stay [d]	29.3 ± 24.6	24.5 ± 21.9	0.122
Length of hospital stay [d]	35.2 ± 28.5	30.8 ± 26.3	0.188
Extubated successfully on first attempt [n]	26 (40%)	28 (46%)	0.504
Tracheostomy [n]	23 (35%)	18 (30%)	0.482
Deceased [n]	19 (29%)	18 (30%)	0.973
Length of ventilation [d]			
Overall [d]	7.5 ± 5.1	7.0 ± 4.4	0.274
Before successful extubation [d]	5.8 ± 3.3	7.1 ± 4.5	0.117
Before any extubation attempt [d]	5.7 ± 3.6	6.2 ± 4.2	0.258
Before tracheostomy [d]	10.6 ± 5.5	7.0 ± 4.8	0.017

Conclusions: Patients in the NTI group may have a shallower depth of sedation while no significant differences on ASB and complications were found between the groups. Nasotracheal intubation may be a feasible alternative to OTI. Further studies are needed to explore the effects on sedation in a larger cohort and to elucidate the impact of NTI on other outcome parameters such as rate and timing of tracheostomy, or patient comfort.

RASS: Richmond–Agitation–Sedation Scale Measurements. OTI: orotracheal intubation group, NTI: nasotracheal intubation group. * p < 0.05.

Proportion of assisted spontaneous breathing.
OTI: orotracheal intubation group, NTI: nasotracheal intubation group.

Introduction: Critically ill patients admitted to the ICU often display hemostatic imbalance and are susceptible to bleeding. Bleeding complications worsen outcome, rendering a better understanding of risk factors pivotal to prevent bleeding. Identification of patients at risk for bleeding may also help in tailoring the use of anticoagulant medication.
Objectives: To identify risk factors for bleeding complications in critically ill who are at risk.
Methods: In this multicenter prospective cohort study, adult patients (≥ 18 years) who were admitted to the ICU of 8 European hospitals and who had a risk factor for developing diffuse intravascular coagulation (DIC) were included. The data collected from November 2017 to July 2023 was analyzed. The development of a fatal, major or minor bleeding was defined according to WHO criteria.
Patient characteristics, vital parameters and laboratory values were chosen as possible predictors based on clinical relevance, and were included into a prediction model of bleeding. A multivariable analysis using binary logistic regression was used with backward selection to identify associated risk predictors. The diagnostic performance of the model was evaluated by computing a receiver operator characteristics curve (ROC curve) based on the predicted probabilities.
Results: Of 842 patients included, 201 (23,9%) developed bleeding, of which six (3%) were fatal, 100 (49,7%) were major bleeding and 95 (47,3%) were minor. The most prevalent site of bleeding was the gastrointestinal tract. Low platelets (odds ratio 0.997 [0.995–0.999]), a low admission hemoglobin level (0.82 [0.72–0.93]) and a prolonged aPTT (1.04 [1.02–1.07]) showed a statistically significant relationship with the development of a bleeding complication. The ROC-curve showed a significant AUC of 0.75 [0.70–0.80]. Furthermore, patients with an obstetric complication (7.91 [1.51–41.39]) and critical illness due to a solid tumor (3.48 [1.12–10.88]) were more susceptible to hemorrhage compared to patients with septic coagulopathy.
Conclusions: Low platelets, a low hemoglobin level and a prolonged aPTT are risk factors for bleeding in the critically ill. A primary diagnosis of an obstetric complication or the presence of a solid tumor was also associated with an increased risk of bleeding. These variables can be used with moderate sensitivity for predicting bleeding complications in critically patients at risk for DIC.

Intensive Care Medicine Experimental 2025,* 13(1)*:001291

Introduction: Right ventricular (RV) dysfunction is a frequent perioperative complication after cardiac surgery under cardiopulmonary bypass (CPB). An underrecognized factor is the presence of lung collapse that increases pulmonary vascular resistance contributing to an increased afterload in an recovering ischemic RV.
Objectives: To study the effects of inhaled nitric oxide (iNO) alone or in combination with lung recruitment to mitigate the effects of lung collapse on RV function after cardiac surgery.
Methods: This was a prospective, single-center, randomized study conducted in patients after cardiac surgery. We included patients with preserved heart function, without pulmonary hypertension that underwent uncomplicated cardiac surgery. Patients were under passive mechanical ventilation ventilated with PEEP 5 cmH_2O and VT 6—8 ml/kg, with postoperative lung collapse: compliance ≤ 35 ml/cmH_2O, and dorsal electrical impedance tomography (EIT) distribution of ventilation < 40%, were randomized into one of three groups: Control**:** standard postoperative management; **iNO:** 60 min of 40 ppm iNO and RM-iNO: lung recruitment and postrecruitment PEEP 10 – 12 cmH2O + 60 min of 40 ppm iNO. Measures: gas exchange, lung mechanics, hemodynamic parameters, EIT relative distribution of ventilation-perfusion and RV function by transesophageal echocardiography. This measures were obtained at baseline and after 60 min.
Results: We included 17 patients in this preliminary analysis underwent different types of cardiac surgery, such as coronary (7) or valvular (10) procedures.The left ventricular ejection fraction was 65 ± 9%. The median age was 65 years (range 55–76), and the mean BMI was 30 ± 4. At baseline, EIT dorsal ventilation was 34 ± 4%
1. **Control group** gas exchange, lung mechanics, hemodynamics, and RV function remained unchange *(table)*
2. **INO group** we observed a significant redistribution of pulmonary perfusion towards the ventral regions of the lung (table), improving the V/Q ratio and reducing shunt, which led to improved oxygenation. TEE determined pulmonary artery systolic pressure decreased by 8% and stroke volume increased by 10%. Respecting RV function contractilty parameters slightly improved as did right ventricle ejection efficiency a parameter intimately related to ventricular vascular coupling
3. **MR-INO group** we observed significant improvements in lung mechanics, gas exchange, and hemodynamic parameters. Pulmonary perfusion was redistributed to the ventral regions (51% to 56%), with decreased lung collapse (increase in dorsal ventilation from 29 to 44%), leading to improved V/Q matching and ventricular–vascular coupling, and consequently, improvement in all parameters of RV function

Conclusions: The postoperative use of iNO decreases pulmonary artery pressure improving ventricular–vascular coupling, with the consequent improvement of RV function in patients under cardiac surgery. All this is enhanced by the combination with lung recruitment, also improving pulmonary mechanics and oxygenation.

***Intensive Care Medicine Experimental 2025,* 13(1)**:001292

Introduction: The perioperative period of liver transplantation (LT) poses a challenging and highly stressful situation in which the heart must maintain adequate blood flow to achieve optimal organ perfusion. Furthermore, achieving an optimal balance between preload optimization and prevention of fluid overload is essential to ensure adequate perfusion of both the graft and kidneys. Acute kidney injury (AKI) remains a major postoperative complication following liver transplantation and has multifactorial pathophysiology. Although biomarkers, such as cystatin C, BNP, and troponin, have been investigated, their comparative utility in this setting is still evolving. In addition, the E/e'ratio as a surrogate of left ventricular filling pressure has emerged as a noninvasive echocardiographic tool for monitoring preload and potential volume overload.
Objectives: This study aims to evaluate the relationship between preload status and biomarker trajectories for the prediction of postoperative renal dysfunction in liver transplant recipients.
Methods: This is a preliminary finding of an ongoing study on fluid management in the immediate postoperative period after liver transplantation. We analyzed nine liver transplant recipients for clinical, hemodynamic, and biochemical data collected 0, 24, and 72 h postoperatively. Associations were made between cystatin C, troponin, BNP, and volume parameters (fluid intake, balance, cumulative fluid) with reduced creatinine clearance (< 40 ml/min) at 24 h of LT. Acute kidney injury occurrence was explored using non-parametric tests (Mann–Whitney, Spearman), trajectory analysis, and logistic regression.
Results: Nine patients were included in the preliminary report: 3 (30%) were female, the mean age was 57 ± 6 years, and the MELD score was 13.0 (IQR: 11.0–17.0). Three patients 33% exhibited with reduced creatinine clearance (< 40 ml/min) at 24 h after LT. The troponin level gradually decreased. However, BNP levels exhibited a progressive increase and Cystatin C levels showed a significant increase.
Changes in the key biomarkers and fluid balance over time after the immediate postoperative period following liver transplantation are shown in Table 1.

Table 1	0 h(Median [IQR])	24 h(Median [IQR])	72 h(Median [IQR])	*p* value
Fluid Balance	2076 [1877–2695]	740 [87–2212]	−51 [−151 to 64]	0.072
Troponin	46.8 [25.0–91.6]	24.7 [22.4–72.0]	38.9 [11.6–45.2]	0.045
Pro-BNP	158 [66–213]	254 [230–423]	836 [567–2277]	0.004
Cystatin C	1.1 [1.0–1.3]	1.5 [1.2–1.7]	1.7 [1.2–2.1]	0.001
NGAL	259 [195–288]	194 [129–247]	N/A	0.164

Among the various clinical and biochemical variables analyzed, only baseline Cystatin C levels (measured 0 h post-liver transplantation) significantly predicted reduced creatinine clearance (< 40 ml/min). No significant associations were found between fluid balance and renal dysfunction, although marked interindividual variability was noted.
A statistically significant positive correlation was observed between the E/e' ratio and pro-BNP levels 24 h after liver transplantation (Spearman's $\rho = 0.73$, $p = 0.025$).
Conclusions: These preliminary findings suggest that, among the biochemical parameters evaluated, baseline cystatin C (measured at 0 h post-transplantation) was the only independent predictor of impaired renal function at 24 h post-liver transplantation. Dynamic changes in troponin and BNP were observed, indicating myocardial stress and progressive ventricular loading, respectively. Similarly, the E/e ratio was associated with elevated BNP levels, reinforcing the utility of both markers in evaluating preload and potential volume overload in the early postoperative period. However, neither factor was found to be significantly associated with renal dysfunction. Further data collection and a larger sample size are required to strengthen these preliminary findings and improve the robustness of statistical associations.

Individual trajectories of biomarkers and fluid balance over time.

Intensive Care Medicine Experimental 2025,* 13(1)*:001296

Introduction: The shock index could have a predictive value in the evolution of septic patients. We wanted to evaluate the different shock indices described in the literature and their predictive capacity in a cohort of septic patients in a Spanish tertiary hospital.
Objectives: To analyze the prognostic value of the different shock indices (SI) described in the literature in patients with septic shock.
Methods: An observational, prospective study in patients diagnosed with septic shock (according to SSC guidelines) who were admitted to the ICU of the HGUGM, between October and November 2024. Epidemiological, clinical, and analytical variables, as well as the need for organ support and clinical outcomes, were collected. The different shock indices: systolic (HR/SBP), diastolic (HR/DBP) and mean (HR/MBP), were calculated at the first hospital visit (Triage) and upon admission to the ICU.
Quantitative variables were expressed as mean with standard deviation or median with interquartile range, and qualitative variables were expressed as percentages. The possible association of shock index with the onset of organ failure and/or mortality was analyzed using simple logistic regression.
Results: A total of 51 patients were analyzed. Age: 58 ± 15 years. Of wich 61% were male. Charlson I. 2 ± 3. Infections origin: respiratory 35%, abdominal 20%, and urinary 20%. Primary bacteremia 14%. Microbiological isolation: *E. coli* 26%, *Klebsiella spp* 16%, *S. pneumoniae* 12%. Admission severity: APACHE II 18 (IQR 13–23), SOFA 7 (IQR 4–13), lactate 3.7 ± 3.4 mmol/l. IS triage: systolic 1.31 ± 0.51, diastolic 2.18 ± 0.68 and modified 1.71 ± 0.67; on admission to ICU: systolic 1.17 ± 0.44, diastolic 2.92 ± 0.68 and modified 1.66 ± 0.79. Severe shock (NA > 0.5 µg/kg/min) was present in 25.5%, AKI in 71% and moderate/severe cardiac dysfunction in 16%. 53% required IMV, duration 6 days (IQR 2–12). ICU stay 4 days (IQR 3–12), with a 20% mortality rate.
In the univariate analysis, none of the shock indices analyzed were associated with organ failure and/or mortality (Table 1).
On the contrary, other variables related to prognosis, APACHE II (OR 1.12; 95% CI 1.02–1.23), SOFA (OR 1.39; 95% CI 1.14–1.71) and lactate (OR 1.77; 95% CI 1.17–2.68), were significantly associated with an increase in mortality.
Conclusions: In our experience, none of the shock indices analyzed were associated with the development of organ failure or mortality in patients with septic shock admitted to the ICU.

Table 1 (abstract 001296) Association of shock indices with organ failure and mortality

		Severe shock (NA > 0,5 γ) OR (CI95%)	AKI OR (CI95%)	Dysfunction VI OR (CI95%)	Mortality OR (CI95%)

Analysis of mortality after discharge from the intensive care unit

A. Candela Fernandez, E. Bermejo López, C. Frías Gatell, P. Garcia-Olivares, A. San José Sebrango, J. C. Sotillo Díaz, R. Ruiz Cacho
Intensive care unit, H.G.U Gregorio Marañón, Madrid, Spain
Correspondence: R. Ruiz Cacho
Intensive Care Medicine Experimental 2025,* 13(1)*:001298

Introduction: Owing to advances in medicine, more and more patients with significant comorbidities are being admitted to intensive care units. That said, we wanted to analyse the profile of the patients who are admitted and survive in the ICU of the HGU Gregorio Marañón, Madrid.
Objectives: Analysis of hidden mortality after discharge from intensive care medicine in a highly complex hospital.
Methods: Observational, prospective, single-centre study, between December 2023 and June 2024, of follow-up of patients after discharge from the intensive care unit.
Results: 391 patients were included, 61% male. Mean age 60 ± 16. Hospital stay after ICU less than 3 days 14%, 4–7 days 25%, 8–21 days 59% and more than 21 days 2%.
The reason for admission: respiratory failure 42.5%, neurological deterioration 28.6%, shock 23%, metabolic disorder 5.4%. Categorised as septic 25.6%, respiratory 23%, neurological 18.4%, metabolic disorder 6.6%, digestive 5.9%, oncological 5.4%, haematological 4.3%.
Classified by functional status as patient independent in performing activities of daily living (ADLs)79%, patient partially dependent for ADLs 18.2%, patient dependent in ADLs 2.8%. Other relevant aspects were delirium 32%, DAUCI 30.9%, need for MV 83.1% divided into NIV 58% and IMV 42%, ALS 61.1%.
Problems at ICU discharge: 1 problem: 4.9%, 2: 29.9%, 3: 41.7%, 4: 18.9%, 5 or more: 4.6%. According to limitation at discharge they were classified as without LET 87.7%, with restrictions 5.1%, LET 7.2%. Days of hospitalisation after ICU were less than 7 days 39%, between 8 and 21 days 59%, more than 22 days 2%.
Mortality at discharge was 9%. On admission, patients with shock had a mortality of 16.9%, by oncological categorisation 40%, haematological 23.3%, septic 12.2% and according to functional status PDABVD or DABVD over 20%.
Mortality by problems at ICU discharge was 1 problem: 0%, 2: 1.7%, 3: 11.8%, 4: 12.3%, 5 or more: 29.4%. Mortality for the most significant problems was ICUAD 13.3%, neurological deterioration 14.3%, respiratory failure 8.6%, renal failure 11.3%. Mortality according to limitation by readmission was 5.3% and 57.1% in non-readmission patients.
Among the re-admittable patients, VAD, VMI, DAUCI, ARF, ARF and discharge problems were associated with mortality. Social problems were not associated with higher mortality.
7.2% of patients at discharge had criteria for non-readmission.

Multivariate analysis was performed including discharge problems [OR 2.0 CI 95% (1.33–2.99) p 0.001] and previous functional status [OR 4.2 CI 95% (2.0–9.1) p 0.000], with an AUC for this model of 0.82.
Conclusions: Our population stands out for its high mortality at discharge from the intensive care unit, with a high percentage of patients with limited therapeutic effort. They are also characterised by a risk profile of poor outcome, with a predominance of oncohaematological patients. Our predictive model includes dependency status and number of problems at discharge with a high predictive capacity.

An ethnographic study of teamwork in intensive care units in the United Kingdom: findings from FEARLESS ICU
A. Xyrichis, B. Wenning, S. Costello
Nursing, Midwifery, & Palliative Care, King's College London, London, United Kingdom
Correspondence: B. Wenning
Intensive Care Medicine Experimental 2025,* 13(1)*:001301

Introduction: Teamwork amongst healthcare professionals remains a crucial component of not only staff wellbeing and retention, but also patient safety and satisfaction. Despite this importance, teamwork may be strained, with negative implications for both staff and patients. The most recent National Health Service (NHS) Staff Survey in the UK indicates that perceptions of teamwork are declining, with variations amongst different professions.
These teamworking practices have becoming increasingly challenged since the COVID-19 pandemic. This post-pandemic landscape adds pressure to teams, notably those in intensive care units (ICUs), where new demands for flexible, ad hoc teams and cross-boundary working frustrate ways of working together. These demands have negative consequences, manifesting as added stress, higher turnover rates and increased patient safety concerns. These effects hamper both clinical and system resilience and continue to impact on the teamwork in ICUs.
Objectives: The objectives of Fostering teamwork for resilient staff and safe care in ICU (FEARLESS ICU) are to.
1. Investigate the changing nature of teamwork in ICUs post-pandemic
2. Identify facilitators and barriers to effective teamworking practices

Methods: This study consists of a rapid ethnography carried out across eight different ICUs in the United Kingdom. ICUs were purposively selected based on geography, size, speciality and NHS Staff Survey teamwork scores. Ethnographic fieldwork consisted of non-participant observations, shadowing of staff and one-on-one semi-structured interviews. Fieldnotes were kept digitally, and all interviews were recorded and transcribed. Analysis consisted of standard ethnographic principles of thematic coding, categorisation and abstraction. This approach provided an in-depth opportunity to observe how different health professionals interacted with one another and to explore factors influencing collaborative work.
Results: Initial findings underscore the additional challenges in the post-pandemic landscape. Healthcare staff discussed the added pressure of being redeployed to different ICUs in their hospital due to staff and skill shortages at short notice. This had direct implications on their teamworking practices, both with the established team and the new team. This extended to changes in organisational processes since the pandemic which further challenged teamworking practices. Furthermore, separate physical spaces within ICUs may hinder interprofessional communication. Observations revealed different communication styles between professions. Various intersectional demographic characteristics may have also contributed to observed dynamics. Facilitators to teamworking practices included identifying opportunities to teach and adopting more inclusive leadership styles.
Conclusions: This ethnographic study provides an in-depth understanding of ICU team working dynamics, particularly in a post-pandemic landscape. Effective teamwork is consistently linked to lower staff burnout rates, higher staff retention, improved staff wellbeing, and better patient outcomes. This research is vital to ensure that overburdened healthcare systems continue to maximise the existing resources (i.e. staff members) to address current crises. Through this study, we identify factors facilitating and inhibiting effective teamwork and offer practical steps for those working and managing staff in ICU to take to realise the improved staff wellbeing and patient outcomes that effective teamwork fosters.

Introduction: The increasing survival of critically ill patients, due to advances in intensive care, has led to a growing population of ICU survivors with complex post-discharge needs. Many of these patients develop persistent complications encompassed under Post-Intensive-Care Syndrome—which include physical, cognitive, and mental health impairments. However, despite the pre-existing comorbidities and prolonged ICU stays, the trajectories of these patients and their outcomes remain understudied.
Objectives: To identify and describe a population of patients and their characteristics after ICU discharge.
Methods: Observational, prospective, single-center study over nine months in 2024, following ICU discharge. Collected variables included clinical, epidemiological, etiological data, comorbidities, organ support, complications, interventions, discharge problems, and outcomes. Descriptive analysis was performed.
Results: 476 patients included, 61% male, mean age 59 $\pm$ 16 years. Mean ICU stay was 10.34 $\pm$ 15.49 days; hospital stay, 23.64 $\pm$ 25.65 days.
Reasons for admission: respiratory failure (42.2%), neurological deterioration (27.9%), shock (23.1%), metabolic disorders (5.7%). By category: septic (24.6%), respiratory (22.5%), neurological (18.5%), oncohematological (10.5%).
Comorbidities: hypertension (47.6%), dyslipidemia (32.4%), diabetes (30.3%), obesity (26.7%), respiratory disease (37.6%), heart disease (24.8%), chronic kidney disease (15%). Solid tumors (22.1%), hematological disease (9.9%), liver disease (12.4%), psychiatric disorders (17%), alcohol use (21.8%), other substances (38.7%). Functionally independent (80.9%), dependent (2.7%).
Support: sedation (63.7%), invasive ventilation (35.5%), non-invasive ventilation (48.3%), tracheostomy (11.3%), vasoactive drugs (61.6%), renal replacement therapy (8.2%), neuromuscular blockade (29.6%).
Delirium in 30%, linked to longer ICU (19.45 vs. 6.50 days) and hospital stay (36.56 vs. 18.10) ($p < 0.000$), not mortality.
At discharge, 61.6% had $\geq$ 3 problems. Non-admissible 7.4%, limited admissibility 5%. Readmissions: 3.8%. ICU mortality: 17.8%; post-discharge mortality: 8.8%. 17.4% needed medium/long-term follow-up.
Conclusions: Patients were comorbid with prolonged stays, high incidence of delirium and PICS, elevated ICU and post-discharge mortality, and low readmission rates. Most had appropriate therapeutic limitation and many required continued care post-discharge**.**

Introduction: Cardiogenic shock is a challenging clinical entity that requires a multifaceted approach to treatment. Circulatory assist devices have been developed as a supportive option to help manage these patients, providing a greater chance of recovery from the underlying cause of shock.
Objectives: The objective of this meta-analysis is to compare the clinical outcomes of veno-arterial extracorporeal membrane oxygenation (ECMO-VA) with or without intra-aortic balloon pump (IABP) for the treatment of cardiogenic shock.
Methods: A systematic review and meta-analysis was conducted using articles from the Embase, PubMed, and Scopus databases. Observational studies comparing the use of IABP in patients with cardiogenic shock on ECMO were included. A random-effects model was employed, and a 95% confidence interval was defined for the analyses.
Results: A total of 199 studies was screened by two independent reviewers, with 16 included. The ECMO-VA + IABP group showed lower mortality (Odds ratio 0.77–0.63; 0.93). Meanwhile, the ECMO + IABP group had a higher rate of limb ischemia (Odds ratio 1.47–1.08; 2.01). Regarding major bleeding, need for renal replacement therapy, and infection, there was no statistically significant difference between the groups.
Conclusions: This meta-analysis showed a higher mortality in the ECMO group alone, despite similar rates of complication in both groups. However, interpretation is limited due to the inclusion of observational studies only. More research is needed on the topic, especially randomized control trials.

Introduction: Biotrauma is a potential mediator of distant organ failure (i.e. kidneys) by ventilator induced lung injuries (VILI), while cardiorespiratory interactions may alter regional and systemic hemodynamics. We aimed to evaluate the impact of experimental high tidal volume (VT) ventilation on renal perfusion, oxygenation and inflammation using renal coupled functional imaging.
Methods: After animal conditioning (general anesthesia, surgical tracheotomy, and pulmonary artery catheterization), swine weighting 30 ± 5 kg were randomized to protective ventilation (PV) in the prone position (PEEP [positive end-expiratory pressure] 5 cmH2O, VT 6–10 ml.kg-1), protective ventilation (same as prone group) in the supine position or high VT ventilation (HVT) in the supine position (PEEP 0 cmH_2O, VT set to reach an end-inspiratory transpulmonary pressure between 30 and 35 cmH2O), applied for 24 h. Animals underwent at H24 a renal dynamic positron-emission tomography (PET) with [15O]-H2O to quantify renal regional perfusion, a magnetic resonance imaging (MRI) with blood oxygenation level dependent (BOLD) sequence to evaluate renal tissue O2 content, and a renal dynamic PET with [11C](R)-PK11195 to quantify macrophage recruitment. All acquisitions were segmented to separate cortical and medullar regions. BOLD-MRI results were expressed as the ratio of cortical over medulla values, to account for inter-individual variability. Respiratory mechanics, hemodynamics and renal function were continuously monitored. The primary outcome was the regional renal standardized uptake value of [11C](R)-PK11195 at H24. PV-prone animals were the control group.
Results: 17 animals were enrolled (5 PV-prone, 6 PV-supine, 6 HVT-supine). At H24, VT, airway pressure at end-inspiratory and central venous pressure were significantly higher in the HVT-supine group, compared to PV prone, with no difference in PaO_2/FiO_2 ratio, $PaCO_2$, cardiac output and creatinine clearance (Fig. 1). Creatinine clearance was significantly higher in the PV-supine group, compared to PV-prone (Fig. 1-G). At H24, there was a non-significant trend in higher [11C](R)-PK11195 renal SUV in the HVT and PV-supine groups, compared to PV-prone (Fig. 2A). No significant difference existed in cortical or medullary perfusion between groups at H24, while there was a trend in lower cortical O_2 content in the HVT group, compared to PV-prone ($P = 0.06$, Fig. 2B and C).
Conclusions: After 24 h of application, high VT ventilation and protective ventilation in the supine position led to a nonsignificant increase in renal macrophage presence, as compared to prone protective ventilation, with varying effects on creatinine clearance. Also, high VT ventilation led to alterations in cortical O_2 content, as compared to the prone protective ventilation. The analysis of data is ongoing and these results are preliminary.

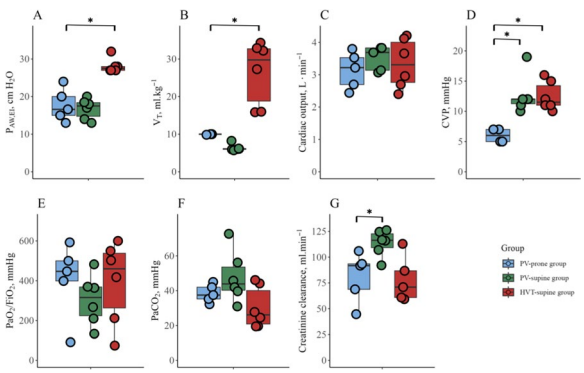

Fig. 1 (abstract 001305) Respiratory mechanics, hemodynamics and renal function at H24. The figure shows airway pressure at end-inspiratory (**A**), Tidal volume (**B**), cardiac output (**C**), central venous pressure (**D**), PaO_2/FiO2 ratio (**E**), arterial $PaCO_2$ (**F**) and creatinine clearance (**G**) at H24. Boxplots (PV-prone group in blue, PV-supine group in green and HVT-supine group in red) represent data by group and dots are each individual value ($n = 17$). Comparisons between the PV-supine and HVT-supine groups with the PV-prone group were performed using the Dunnett test, with the PV-prone group as the control. *$p < 0.05$ compared with PV-prone group. *CVP* central venous pressure, *HTV* high VT, central venous pressure. *PAW,EI* airway pressure at end-inspiratory, *PV* protective ventilation, *VT* Tidal volume

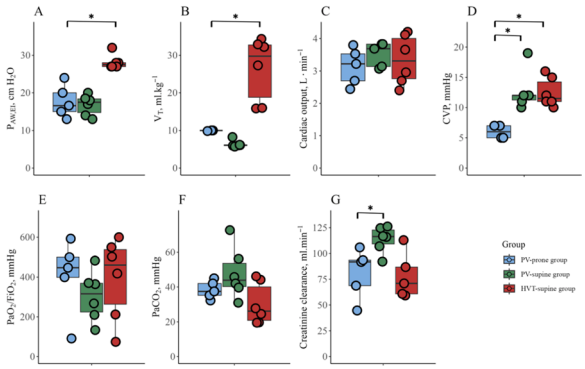

Fig. 2 (abstract 001305) Renal outcome at H24. The figure shows the standardized uptake value (SUV) of [11C](R)-PK11195 (**A**) and the regional kidney perfusion (in milliliters of blood per gram of tissue per minute) (**B**) in the cortex and the medulla and the R2*ratio between the medulla and the cortex (**C**) at H24. The R2* is the apparent relaxation rate measured in BOLD–MRI sequences and inversely proportional to oxygen levels. It is not a direct measure of regional oxygenation but rather reflects relative differences between regions. Hence, a [Medulla/Cortex]R2*ratio > 1 meant that the pO_2 was higher in the cortex as compared to the medulla, while an increase in the R2*ratio meant that there was an increase in cortex oxygenation compared to the medulla (or a decrease in medulla oxygenation compared to the cortex). Boxplots (PV-prone group in blue, PV-supine group in green and HVT-supine group in red) represent data by group and dots are each individual value (n = 17). For panels A and B, comparison of data between regions and groups were performed using mixed effects linear regression, with the animal number as a random effect. For panel C, comparisons between the PV-supine and HVT-supine groups with the PV-prone group were performed using the Dunnett test, with the PV-prone group as the control. *BOLD* blood oxygenation level dependent, *K1* regional blood perfusion, *HTV* high VT, *MRI* magnetic resonance imaging, *SUV* standardized uptake value, *VT* Tidal volume

Intensive Care Medicine Experimental 2025,* 13(1):*001306

Introduction: The diversity of infection sources, pathogen profiles, and resistance patterns all play a role in optimal antibiotic selection1,2. A strategic approach, guided by clinical evidence and microbiological data, is essential to improve patient outcomes and restrain antimicrobial resistance3,4.
Objectives: To analyze risk factors for IAI by pathogens resistant to piperacillin–tazobactam (pip/taz) and those associated with sensitivity to non-pseudomonal cephalosporin plus metronidazole (NP Cef + Met).
Methods: Retrospective cohort study of patients with IAIs receiving empiric antibiotic therapy admitted to the ICU of a secondary care hospital between April 1, 2021, and December 31, 2023.
Results: There were 73 patients included in the study: 44 (60%) were sensitive to NP Cef + Met and 20 (27%) were resistant to pip/tazo. General characteristics of patients included and description of risk factors associated with resistance to pip/tazo are shown in Table 1. After adjustment to sex, diabetes, immunosuppression, prior hospitalization (90 days), prior antibiotic therapy (90 days), surgery in the last month, hospital-acquired infection, hospital length of stay prior to ICU admission, focus of infection, the final model retains as independent variables number of hospital days prior to ICU admission and prior antibiotic therapy with an adjusted OR (95% CI) of 1.505 (1.165–1.944) per day and 4.718 (1.203–18.506), respectively. The same risk factors were studied to predict sensitivity to NP Cef + Met and only residence in a long-term care facility was found to be associated with a crude OR of 1.704 ($p = 0.028$).

Table 1 (abstract 001306) Characteristics and description of risk factors associated with resistance to pip/taz

Risk factor	Total	Resistant to pip/tazo	OR	*p* value
Age, mean ± SD	67 ± 15	70 ± 17	1.007	0.671
Male sex, n (%)	37 (51)	14 (38)	2.522	0.087
Hospital-acquired infection, n (%)	26 (36)	11 (42)	2.713	0.061
Hospitalization in the last 90 days, n (%)	28 (38)	12 (43)	3.000	**0.040**
ATB in the last 90 days, n (%)	20 (27)	11 (55)	5.256	**0.004**
Diabetes, n (%)	26 (36)	4 (15)	0.321	0.068
Immunosuppression, n (%)	15 (21)	7 (47)	2.750	0.093
Surgery in the last month, n (%)	14 (19)	7 (50)	3.214	0.058
Days previously to ICU admission, median (IQR)	0 (0–2)	2 (0–10)	1.455	**0.001**
Focus of infection, n (%)	45 (62)	10 (22)	1.000	0.091
Hepato-bilio-pancreatic	5 (7)	3 (60)	5.250	0.270
Gastro-entero-colic	23 (32)	8 (35)	1.867	
Peritonitis due to perforation				
Days until source control, median (IQR)	2 (1–7)	1 (1–10)	1.026	0.269
Low risk IAI, n (%)	7 (10)	2 (10)	0.989	0.990

Risk factor	Total	Resistant to pip/tazo	OR	*p* value
Septic shock, n (%)	59 (81)	15 (75)	0.582	0.398
SOFA, mean ± SD)	8 ± 4	8 ± 5	0.984	0.811
SAPS II, mean ± SD	44 ± 19	47 ± 23	1.012	0.373
APACHE II, mean ± SD	18 ± 9	20 ± 11	1.042	0.174

APACHE Acute Physiology And Chronic Health Evaluation, *ATB* Antibiotic, *IAI* Intra-abdominal Infection, *IQR* inter-quartile range, *OD* Odds Ratio, *SAPS* Simplified Acute Physiology Score, *SOFA* Sequential Organ Failure Assessmentm *SD* standard deviation

Conclusions: Sensitivity to NP Cef + Met was low, with no clear predictors. In contrast, resistance to pip/tazo was also low but it was independently associated with number of hospital days prior to ICU admission and prior antibiotic therapy. Pip/tazo seems to be a good empirical proposal, but in patients with risk factors doctors should be alert to the need of alternative antibiotic schemes particularly in patients who fail to respond promptly after focus control.

Intensive Care Medicine Experimental 2025,* 13(1):*001307

Introduction: Pain is a common concern for intensive care unit (ICU) patients, particularly during procedures like turning. Effective sedation and analgesia are essential for managing pain and preventing adverse outcomes in critically ill, noncommunicative patients. Despite established protocols, not much is known about how sex influences pain perception and the administration of analgesics and sedatives. Understanding these disparities is crucial for improving patient care and ensuring equitable treatment in ICU settings.
Objectives: This study explores sex-based differences in pain, analgesia, sedation, and their associations during turning procedures in non-communicative, critically ill patients.
Methods: A prospective cohort of adult ICU patients with stays exceeding 48 h was observed. Pain was assessed using the critical care pain observation tool (CPOT) before, during, and 20 min after routine turning procedures, conducted twice daily across five consecutive days. Analgesic and sedative use was documented within the hour prior to each assessment.
Results: A total of 123 patients (79 men, 44 women) were included, with mean ages of 55.3 (SD = 17.6) and 61.3 (SD = 18) years for men and women, respectively ($p = 0.074$). CPOT scores did not differ significantly between sexes ($p > 0.05$). Pain (CPOT > 2) was observed in 67.1% of men and 56.8% of women ($p = 0.257$), with more men reporting pain on Day 1 (41.9% vs. 19%; $p = 0.012$). CPOT > 2 scores decreased over time in men from Day 1 to Day 5 (OR = 0.75; 95% CI 0.65–0.85; $p < 0.001$), and in women from Day 2 to Day 5 (OR = 0.71; 95% CI 0.54–0.92; $p = 0.011$). While overall analgesic and sedative use showed no sex-related differences, men received higher doses of remifentanil ($p < 0.05$). In women, no significant association was found between medication use and pain, but in men, dexmedetomidine administration reduced the likelihood of experiencing pain (OR = 0.33; 95% CI 0.19–0.57; $p < 0.001$).
Conclusions: The findings suggest that sex may influence pain, analgesia, and sedation in critically ill patients. These results highlight the need for sex-sensitive management strategies in the ICU, including updated protocols, continuous staff education, and further research to enhance critical care outcomes.

Echocardiographic control during ClotPro-guided individualised thrombolytic therapy: results of a feasibility, randomised, interventional study

M. Berczi[1], D. Skultéti[1], A. Párkányi[1], E. Bíró[1], J. D. Stubnya[2], H. D. Szász[2], Z. Imre[2], G. Szombath[3], A. Fehér[4], Z. Iványi[5], J. Gál[6], J. Fazakas[1], A. Kállai[1]

Intensive Care Medicine Experimental 2025,* 13(1):*001308

Introduction: Pulmonary embolism (PE) is the 3rd leading cause of cardiovascular mortality. According to the current ESC guidelines, systemic thrombolysis (ST) is reserved for those at high risk. However, persistent haemodynamic instability or unresolved right ventricular (RV) dysfunction occurs despite ST. The use of fixed, high-dose alteplase (tPA) regimens has been increasingly questioned in recent literature. Echocardiography is endorsed by the European Society of Intensive Care Medicine as a critical bedside tool for identifying RV dysfunction.
However, no clear guidance exists on which echocardiographic parameters should be monitored to guide prolonged thrombolytic therapy in critically ill patients.
Objectives: This study aimed to develop a safer and more effective therapeutic approach using prolonged, third-generation ClotPro viscoelastic test-guided systemic thrombolysis, combined with echocardiographic monitoring, to enable individualised treatment of patients with pulmonary embolism (ethics license: 65187-5/2021/EÜIG; clinical trial registration: NCT06667882).

Methods: This prospective, randomised, interventional study included patients aged ≥ 18 years diagnosed with PE between December 2021 and October 2023, and who provided informed consent. Exclusion criteria included lack of consent, absolute contraindications to thrombolytic therapy, and pregnancy. Patients were randomised into two groups:
ClotPro-guided (CPG) group: Coagulation was monitored hourly using viscoelastic testing (VET) with the ClotPro system before and during thrombolysis. The dose of tPA was adjusted based on VET results. Bedside transthoracic echocardiography (TTE) was performed every two hours to assess RV function. Thrombolysis was discontinued once echocardiographic signs of RV strain—specifically, the presence of a D-sign—had resolved.
Control (C) group: VETs were performed at the same intervals, but results did not influence clinical decisions. Echocardiography was performed only before and after thrombolysis, and not used for real-time monitoring.
Results: Of the 33 patients initially screened, 11 were excluded (1 due to head injury, 2 with active bleeding, 2 without consent, and 6 with low early mortality risk). One patient in the C group was excluded due to early termination of thrombolysis after 50 mg tPA because of severe chest pain. One CPG patient was later excluded after arterial occlusion caused by angiosarcoma was diagnosed. Ultimately, 20 patients were included in the final analysis:

- **ClotPro-guided group (CPG):** 13 patients (4 females, 9 males; mean age: 55.76 ± 13.34 years)
- **Control group (C):** 7 patients (3 females, 4 males; mean age: 66.0 ± 9.02 years)

Initial results related to the ClotPro-guided thrombolysis protocol were presented at the 2023 ESICM LIVES Congress. This analysis focuses on the echocardiographic monitoring component of therapy.
For assessment of the effectiveness of the ST, the following echocardiographic parameters were evaluated and expressed as the percentage of patients achieving normalisation by the end of therapy: RV diameter: CPG 23% vs. C 16%; RV/LV ratio: CPG 66% vs. C 50%; TAPSE: CPG 84% vs. C 66%; Stroke volume index (SVI): CPG 90% vs. C 60%; Eccentricity index: CPG 69% vs. C 40%.
Conclusions: During ClotPro-guided prolonged thrombolysis for pulmonary embolism, effective revascularisation was observed in nearly all cases, in contrast to lower early phase clinical effectiveness seen with conventional thrombolysis. Owing to the limited sample size, detailed statistical analysis was not feasible. A multicenter, controlled interventional trial is planned to validate these preliminary findings.

Intensive Care Medicine Experimental 2025,* 13(1)*:001310

Introduction: Non-traumatic subarachnoid haemorrhage (SAH) is a significant global health issue. It is recognized that SAH affects not only brain tissue but also contributes to non-neurologic complications. The aim of this study was to assess whether there is a correlation between early organ dysfunction and intensive care unit (ICU) mortality or functional outcomes in SAH patients.
Methods: A retrospective analysis was conducted on data from all SAH patients admitted to the ICU at Hôpital Universitaire de Bruxelles (Belgium) over a 10-year period, from January 2012 to December 2022. The Sequential Organ Failure Assessment (SOFA) score, used to assess organ dysfunction, was recorded daily during the first five days after ICU admission. Neurological outcomes were evaluated at three months using the Glasgow Outcome Score (GOS), with an unfavourable outcome defined as a GOS score of 1–3.
Results: A total of 387 patients were admitted over the study period, with a mean age of 54.6 (± 13.1) years and 62% of them being females. On admission, the median World Federation of Neurological Surgeons (WFNS) score was 3 (1–5); and Fisher score was 4 (3–4). A total of 125 (32.3%) patients died in the ICU, and 189 (48.8%) had an unfavourable outcome at 3 months. The median total SOFA score on admission was 3 (1–7). There was a statistically significant difference, higher SOFA score was associated with higher mortality, unfavourable neurological outcome at 3 months (all of them $p < 0.001$). This difference persisted over the first five days.
The respiratory and cardiovascular SOFA subscores increased over time in non-survivors and those with unfavourable neurological outcomes, compared to others. Cardiovascular SOFA differed over time based on the WFNS grade ($p < 0.001$), while respiratory SOFA subscores showed differences starting on day 3 ($p < 0.05$).
In a multivariate model adjusted for age, DCI, ICHT, re-bleeding and Fisher scores, a higher cardiovascular SOFA subscore was independently associated with unfavourable neurological outcome (β -3.97, OR 0.02, 95% CI 0.02–0.02, $p < 0.001$). No correlation was found

between the cardiovascular SOFA subscore and mortality, or the respiratory SOFA subscore with either mortality or neurological outcome. The haematologic SOFA subscore was significantly associated with higher values in individuals who experienced unfavourable outcomes, with statistical significance observed on days 1 and 5. Although a higher renal SOFA subscore was associated with increased mortality and unfavourable outcomes, the difference was not statistically significant.

Conclusions: In this cohort of SAH patients, respiratory and cardiovascular dysfunction worsened over time in nonsurvivors and those with unfavorable outcomes as compared to others. These results highlight the importance of monitoring cardiovascular and respiratory function in critically ill patients.

Sequential organ failure assessment (SOFA), favorable outcome (FO), Unfavourable outcome (UO)

Intensive Care Medicine Experimental 2025,* 13(1)*:001311

Introduction: Intensive care unit (ICU) acquired weakness and reduced functional outcomes are well-recognised sequalae of a prolonged critical care admission. Extensive research supports early rehabilitation, but its impact on patients with acute liver failure (ALF) and chronic liver disease (CLD) remains unclear. ALF patients frequently present in a pro inflammatory state and multiorgan failure, whereas CLD patients are prone to sarcopenia secondary to malnutrition, protein catabolism, and reduced physical activity.

Methods: An observational cohort study (July–October 2024) was conducted in a specialist Liver Intensive Care Unit to explore the rehabilitation trajectory and functional outcomes of patients admitted for ALF and decompensated CLD patients with ICU stay $\geq$ 5 days.

Muscle strength, functional outcomes and indirect measures of muscle mass were assessed at the initiation of rehabilitation, ICU discharge, and hospital discharge. Measurements included hand grip strength (using a Jamar Plus digital hand dynamometer), the Medical Research Council (MRC) sum score, ICU Mobility Scale (ICUMS), and muscle mass (measured via mid-upper arm circumference). Patient demographics, frailty scores, rehabilitation frequency, ICU and hospital length of stay (LOS) were also collected.

The results were analysed using descriptive statistics (median (range)).

Results: 38 patients were analysed (ALF: 18, CLD: 20). ALF patients were predominantly female (72%), younger (37 vs 48 years) and less frail (frailty score 2 vs 3) at admission as compared to those with CLD.

Rehabilitation commenced at a similar time frame for both groups of patients following admission (10 days ALF Vs 9 days CLD).

ICU and hospital length of stay (LOS) was shorter for ALF than CLD (19 vs. 23 days and 30 vs. 48 days, respectively). Despite lower functional scores and muscle strength at ICU discharge, ALF patients reached comparable levels of function to CLD patients by hospital discharge. Indirect muscle mass showed a slight decline in ALF patients but improved in CLD patients. Although more rehabilitation sessions were planned for CLD patients (150 vs. 109), fewer were delivered proportionally (64% vs. 76%), largely due to medical instability.

Mortality was significantly higher in the CLD group (50% vs. 5.5%).

Conclusions: Patients admitted to ICU with ALF and decompensated CLD achieve similar measures of muscle strength and physical outcomes at hospital discharge. However, patients with ALF have both shorter ICU and hospital LOS and a lower in hospital mortality than those with CLD.

Patients with CLD had more rehabilitation sessions planned during their hospital admission, but delivered less frequently, primarily due to medical issues.

Owing to the high mortality in the CLD group, these results should be interpreted with caution and greater patient numbers needed to draw further conclusions.

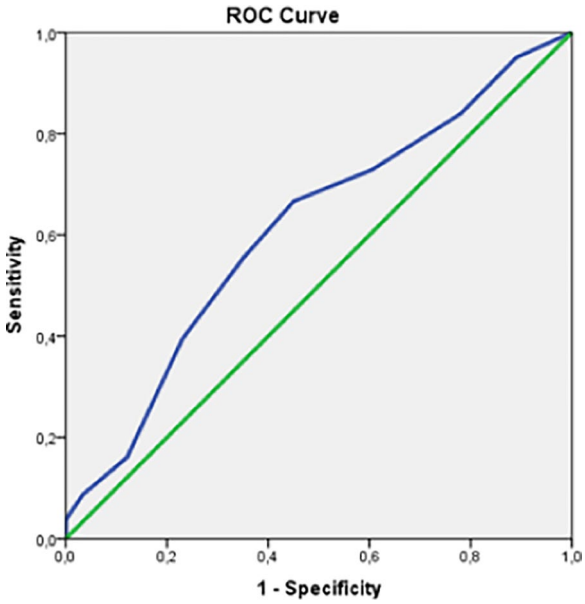
Intensive Care Medicine Experimental 2025,* 13(1):*001312

Introduction: The H2FPEF score is a clinical tool designed to aid in the diagnosis of HFpEF [1,2]. The H2FPEF score, incorporates key clinical parameters, such as age, body mass index, hypertension, diabetes, atrial fibrillation, and elevated filling pressures to stratify patients with suspected HFpEF. In addition, the H2FPEF score has been shown to have a relationship with rehospitalization rates and prognosis in patients with HFPEF. Since diastolic dysfunction is frequently seen in intensive care patients and its early diagnosis and management are important, simple and effective tools such as the H2FPEF scoring system may be potentially valuable.

Objectives: The study aimed to investigate the diagnostic value of the H2FPEF score in intensive care patients with heart failure.



Methods: This retrospective study included 195 intensive care patients, and heart failure was diagnosed by examining the echocardiography records of the patients. Echocardiography of the patients was performed during their stable periods.

Results: Fifty-three percent of the patients were males and 47% were females, and their average age was 71 ± 14 and APACHE II scores were 18 ± 7. Seventeen patients were diagnosed with HFrEF, 25 patients with HFmrEF, 120 patients with HFpEF and 86 patients with right heart failure. According to the statistical analysis results, there was no significant difference between the H2FPEF scores of patients with and without HrEF, HFmrEF, and HFpEF, and the H2FPEF scores of patients with right heart failure were significantly higher than those without(Table). In ROC curve analysis, the sensitivity of an H2FPEF score above 2.5 in predicting right heart failure was 75%, and the specificity was 40% (Figure).

Conclusions: The study results suggest that the H2FPEF score may predict right heart failure in intensive care patients. This may be because the score includes pulmonary artery pressure, or that one of the most common causes of right heart failure is problems with the left heart. Further studies are needed on this subject.

Table (abstract 001312) ...

H2FPEF Score	present	absent	p
HFrEF	4+ 2.5	3.6+1.6	.550
HFmrEF	4.5±2.1	3.8±2.4	.182
HFpEF	4.1±2.4	3.7±2.3	.295
Right Heart Failure	4.4±2.4	3.5±2.3	.008

ROC curve for H2FPEF score and Right Heart Failure

AUC:0.612, 95% CI (0.527–0.697), *p*: 0.011. H2FPEF score > 2.5, sensitivity:73%, specificity:%40. H2FPEF score > 3.5, sensitivity:67%, specificity:%55.

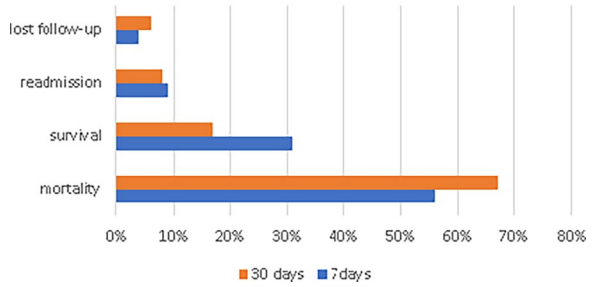
Intensive Care Medicine Experimental 2025,* 13(1)*:001313

Introduction: Discharge or leave against medical advice (LAMA) from critical care units has always been a serious concern in global health care scenario. There are various factors affecting this decision and need to be evaluated. Through limited studies, we assume that severity of disease and prognosis along with financial constraints are the major impactors in decision making1,2 "Financial toxicity" 3 is the current term coined for the adverse the economic stress faced by patients or relatives during ICU treatment. This burden is shared worldwide and becomes a huge liability on healthcare scenario especially in resource limited set-up. Despite free health insurance by government penetration of insured individuals remains below 40%. This study carried out in tertiary NABH accredited hospital in semi-urban region is majorly aimed at determining the outcomes of critically ill patients leaving against medical advice, factors involved and implications.
Methods: This is a prospective observational cohort study, carried out in Sevasadan Hospital, during January 2023 to December 2024. The Institutional Ethical Committee approval was duly obtained. Inclusion criteria: all patients above 18 years admitted to critical care unit. Decision for LAMA or request initiated by family or patient. Exclusion criteria: treatment under palliative care for terminal illness. Missing contacts, documents for follow-up. The baseline demographics, socioeconomic background along with SOFA scoring on admission and day of LAMA, length of stay were noted. On discharge, the reason for LAMA was recorded and counselling was offered. The follow-up data at 7-day and 30-day noted survival, re-hospitalization and barriers to care. Statistical analysis was done using SPSS software. Categorical variables presented as frequencies and percentages.
Results: Data were collected from 1087 cases, off them 143 cases were excluded. 14.7% went LAMA against total normal discharges. The avg age 52.3 years, males to females % 61:39. The socioeconomic status recorded 13% from middle-higher income, low income 45%,32% very low income group. 66% came from interiors while 34% were from district places. Admissions through Emergency 615; Trans-in 245; OPD 84 were recorded. 73% were medical cases while 27% were surgical. 41% had history of prior admission within a week elsewhere. SOFA on admission was 5 ± 0.6 and on day of LAMA 10 ± 0.4. ICULOS was 6 ± 0.8. 56% mortality, survivors 31%, 9% readmission either at same or other hospital and 4% lost to follow-up recorded at 7 days. At 30-day figures changed to 67% mortality, 17% survival, 8% readmission and 6% were lost to follow-up. The analysis of discharge counselling revealed 46% LAMA were due to financial constraints. Other reasons were poor prognosis 19%, refusal for escalating treatment/demand for DNR 15%, 14% to other hospital and 6% to home. ICU LOS in patients availing LAMA for finances was 8 ± 0.7 and SOFA scoring on LAMA was 11 ± 0.5. diagnosis wise category recorded were ARDS 18%, CVA 13%, neurosurgery 11%, ALD 9%, IHD 10%, sepsis/MODS 21%, CKD/AKI 7%, trauma 6%, others 5%.
Conclusions: A significantly high mortality at 30-day is noted in LAMA patients, readmissions increasing morbidity. Financial constraints remain the most important reason for LAMA, with direct co-relation to length of stay, age and prognosis of the patient. Elderly, poor prognosis, longer stay from rural background were the key factors. Prior inpatient days exhausting funds impacted outcome. Refusal to escalate the treatment was noted in 14% of LAMA patients marking the rising need for clear guidelines on end of life care.

Fig 1:**outcome of LAMA**



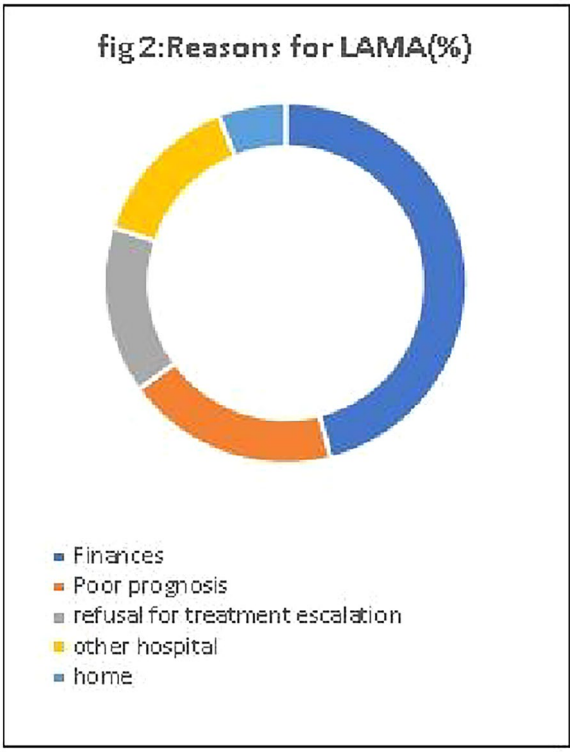


Chart depicting outcome of LAMA at 7th day, 30th day.

Reasons for LAMA.

Predicting colonization with multidrug-resistant microorganisms upon intensive care unit admission: time to update the risk profile?

D. Pérez-Torres, I. Canas-Pérez, E. Diez-Urdiales, P. A. Merino-García, J. Sánchez-Ballesteros, J. Á. Berezo-García, L. M. Tamayo-Lomas
Servicio de Medicina Intensiva, Hospital Universitario Río Hortega, Valladolid, Spain

Intensive Care Medicine Experimental 2025,* 13(1)*:001314

Introduction: Early identification of patients at risk of colonization with multidrug-resistant organisms (MDROs) upon admission to the Intensive Care Unit (ICU) is essential for implementing effective infection control measures and for selecting the most appropriate antibiotic strategy, particularly when admission is due to severe infection or sepsis.
The risk factor checklist proposed by the Spanish ICU "Zero Resistance" project [1] is designed to identify such patients. However, recent studies suggest that it may fail to detect up to one in three colonized individuals [2].
Objectives: To evaluate the prevalence of MDRO colonization at ICU admission, assess the predictive performance of the zero resistance checklist, and identify additional risk factors to improve early detection strategies.
Methods: We conducted a retrospective, observational, single-center case–control study in the ICU of a University Hospital in Spain, between 2021 and 2023. Surveillance cultures (nasal, oropharyngeal and rectal swabs, and tracheal aspirate in ventilated patients) were obtained at ICU admission from all patients expected to stay > 48 h, targeting identification of methicillin-resistant *Staphylococcus aureus* (MRSA), ESBL-producing *Enterobacterales*, carbapenem-resistant *Enterobacterales*, MDR *Pseudomonas aeruginosa*, carbapenem-resistant *Acinetobacter baumannii* (CRAB), *Stenotrophomonas maltophilia* and vancomycin-resistant *Enterococci* (VRE). Exclusion criteria: age < 18, ICU stay < 48 h, or missing surveillance cultures. Cases were defined as patients with at least one positive surveillance culture; controls had all negative cultures.
The results are presented as mean, median or percentages. Chi-square, Student's *t* or Mann–Whitney *U* tests were used as appropriate. Variables associated with colonization in the bivariate analysis were used to build a predictive model through logistic regression.
Results: Of the 3,465 patients, 2,134 met inclusion criteria; 332 (15.6%) were colonized with MDROs at ICU admission. Compared with controls, cases were older (64.9 vs. 61.5 years, $p < 0.001$), had longer pre-ICU hospital stays (4.6 vs. 2.4 days, $p = 0.033$), higher APACHE II (20.2 vs. 17.4, $p < 0.001$), and Charlson index (2.1 vs. 1.4, $p < 0.001$). Hypertension (52.7% vs. 42.8%, $p < 0.001$), diabetes with organ damage (7.5% vs. 3.9%, $p = 0.003$), peripheral vascular disease (9.9% vs. 3.2%, $p < 0.001$), and proton pump inhibitor use (56.3% vs. 41.1%, $p < 0.001$) were also more frequent.
Colonization rates increased over time ($p < 0.001$): 11.7% (2021), 14.2% (2022), 19% (2023). The main isolation sites were rectal swabs (44.9%) and respiratory samples (42.5%). Predominant organisms: ESBL-*E. coli* (31.9%), MRSA (16.9%) and *S. maltophilia* (16.9%). The most frequently identified risk factors according to the zero resistance checklist were prior hospitalization ≥ 5 days (44.6%), chronic comorbidities associated with a high risk of MDRO colonization (cystic fibrosis, bronchiectasis, chronic ulcers,…) (18.4%), known MDR carrier status (13.6%), and institutionalization (9.9%). The overall predictive performance of the Zero Resistance tool was moderate (AUC ROC 0.66, sensitivity 14%, specificity 98%). Notably, 41.6% of the cases had no identifiable risk factors.
In logistic regression, independent predictors of MDRO colonization at ICU admission were immunosuppression (OR 1.56, 95% CI 1.15–2.11, $p < 0.01$), proton pump inhibitor use (OR 1.55, 95% CI 1.2–2, $p < 0.01$), APACHE II (per point) (OR 1.03, 95% CI 1.02–1.05, $p < 0.01$), and admission from surgical ward (OR 1.61, 95% CI 1.05–2.47, $p = 0.03$).

Conclusions: MDRO colonization at ICU admission affected 15.6% of patients and showed a rising trend over time. The zero resistance checklist demonstrated high specificity but low sensitivity, failing to identify over 40% of colonized patients. Logistic regression revealed additional predictors that may enhance risk stratification. These findings suggest the need to revise current screening tools to better guide early preventive and therapeutic decisions.

Intensive Care Medicine Experimental 2025,* 13(1)*:001315

Introduction: Monocyte distribution width (MDW) is an in vitro diagnostic parameter that reflects a change in the volume of circulating monocytes in response to pro-inflammatory signals. This study analyzes the utility of MDW as a prognostic factor in the early period after liver transplantation (LT).
Methods: Retrospective, single-center cohort study including adult patients who underwent LT between January 2021 and October 2023. Patients were classified into two groups based on whether they presented persistently high MDW (defined as a MDW > 20.0 during the first 6 h after LT). Demographic and evolutionary variables were collected. The results are presented as median (IQR) or %, with differences analyzed using the Mann–Whitney *U* test or chi-square test, respectively. Kaplan–Meier curve was plotted to explore the influence of persistently high MDW on graft survival at 3 months, defined as absence of graft failure requiring re-transplantation or patient death during the first three months. A p value < 0.05 was considered statistically significant.
Results: We included 308 LT procedures. Baseline characteristics and clinical outcomes for persistently high MDW are shown in Table 1. A total of 52 patients (41%) presented values of MDW > 20.0 during the first 6 h of postoperative period. Persistently high MDW was significantly associated with alcohol etiology and MELD score as well as with worse clinical outcomes. There was a significant decrease in graft survival at 3 months in patients with MDW persistently high (Fig. 1).

Table 1 (abstract 001315) Cohort baseline characteristics and clinical outcomes

	Total ($n = 308$)	MDW persistently high ($n = 52$)	MDW persistently low ($n = 73$))	*p* value

Intensive Care Medicine Experimental 2025,* 13(1)*:001317

Introduction: Intermediate Care Units (IMCUs) were established to bridge the gap between general wards and intensive care units (ICU), providing an intermediate-level of care (1). Over time, IMCUs have evolved significantly in structure, organization, staffing, and care models (2). Therefore, understanding IMCU bed usage is essential for improving patient flow and outcomes.
Objectives: This study aims to compare clinical characteristics, resource utilization, and outcomes of patients admitted to IMCUs as step-up versus step-down admissions.
Methods: This retrospective cohort study was conducted in three open medical-surgical IMCUs (95 beds in total) of a private, tertiary care, hospital in São Paulo, Brazil. Patients (≥ 18 years) admitted to the IMCUs from the ICU were categorized as 'step-down' group and patients admitted from other sources (emergency room, operating room, hemodynamics department and wards) were classified as the 'step-up' group. Patients' demography, clinical characteristics, resource use, and main clinical outcomes were described and compared according to the admission source. The association between admission source and hospital mortality as well as transfer to the ICU were investigated using a multilevel logistic regression model incorporating the type of IMCU unit (neurological, cardiological or general unit) as random effect and patient-level characteristics as fixed effects. Similarly, we evaluated IMCU length of stay (LOS) using a negative binomial regression model. The results were presented as adjusted odds ratio (aOR) along with 95% confidence interval (95%CI). Two-tailed tests were used, and statistical significance was set at $p < 0.05$.
Results: A total of 51,026 IMCU admissions from 2012 to 2022 were analyzed. Out of those, 38,797 (76%) were 'step-up' and 12,229 (24%) were 'step-down' admissions. Step-down group had a higher median SAPS 3 on IMCU admission as compared to step-up (44 [37–52] vs. 42 [34–50]; $p < 0.001$). Step-down group had a higher hospital mortality (5.3% vs. 4.0%; $p < 0.001$) and higher hospital LOS (10 [6–19] vs. 5 [3–10] days; $p < 0.001$) as compared to step-up admissions (Table 1). Step-down group had higher risk of in-hospital death (aOR: 1.14; 95% CI 1.02–1.28; $p = 0.025$) (Fig. 1) and a higher risk of longer IMCU LOS (aOR: 1.25; 95% CI 1.22–1.27; $p < 0.001$) compared to step-up admissions. In contrast, step-down patients had significantly lower odds of being transferred to the ICU compared to those admitted as step-up (aOR: 0.86; 95% CI 0.79–0.93; $p < 0.001$).
Conclusions: We observed significant differences in IMCU patient characteristics, resource utilization and outcomes based on admission source, with step-down patients exhibiting a higher risk of in-hospital mortality and a longer IMCU LOS compared to step-up patients. These findings underscore the significance of admission source as an important factor influencing IMCU outcomes and emphasize the need for targeted strategies to manage the complex needs of step-down patients effectively.

Breathing with dignity: palliative extubation in the ICU: clinical practice, comfort measures, and survival outcomes

F. Sarmento[1], G. Magalhães[2], A. R. Rodrigues[3], D. Silva, A. Gaspar, J. M. Ribeiro

Introduction: Palliative extubation (PE), the withdrawal of invasive mechanical ventilation when treatment goals shift from life-prolonging interventions to comfort-focused care, is a key component of end-of-life (EOL) management and compassionate ICU care. Although high-quality evidence is limited, expert opinions continue to support its integration into end-of-life care in the ICU setting. However, implementation remains inconsistent due to clinical, ethical, and organizational challenges. In Portugal, there is minimal evidence on care transitions, structured communication, and early identification of palliative needs in ICU settings, especially palliative extubation.
Objectives: This study aims to examine the clinical and demographic profiles of patients undergoing palliative extubation in a Portuguese ICU, explore factors influencing decision-making and timing, and analyze post-extubation trajectories.
Methods: Retrospective, single-center study, including all patients who died in a general ICU in 2024. Data collected included age, sex, SAPS II, type of ventilatory support, palliative status at admission, family discussions, documentation of palliative care plans, medications prior to extubation, postextubation support, and survival time. Descriptive statistics, nonparametric tests (Mann–Whitney *U*), and multiple linear regression analysis were used.
Results: The study included 246 patients (60.6% male, mean age 67.6 ± 14.6 years) with high clinical severity (mean SAPS II 64.6 ± 18.4). Only 7.3% were identified as palliative at ICU admission, 92.7% of cases transitioned to palliative care during their stay, and documented transition in 89.0% of cases. Although 80.1% received invasive mechanical ventilation until death, PE occurred in just 13.8% ($n = 34$). Prior to extubation, patients had low oxygen requirements (mean FiO_2 0.28 ± 0.09), with 76.5% receiving symptom management, predominantly opioids (44.1%), followed by combination treatment with opioids and benzodiazepines (11.8%). Survival after PE averaged 9.2 ± 10.7 h, with no significant correlation to age, SAPS II or FiO2. Patients who underwent PE had significantly longer ICU stays ($p = 0.008$). Opioid use did not influence short-term survival ($p = 0.85$).
Conclusions: Although there's growing awareness of therapeutic limitations and end-of-life planning, PE is rarely practiced in the ICU, reflecting the influence of cultural, ethical, and institutional challenges. Our findings suggest that longer ICU stays may influence the decision to use PE. The variation in survival time and lack of association with clinical variables underscore the need for individualized planning and consistent symptom management. These findings highlight the need for improvement, including early patient identification, clear communication with families, documentation of transition plans and palliative interventions, and comfort-oriented care protocols, promoting multidisciplinary training for timely, compassionate care.

***Intensive Care Medicine Experimental 2025,* 13(1)**:001319

Introduction: Sepsis-induced paralysis of the innate immune system (immunoparalysis) can be defined by the occurrence of endotoxin tolerance (ET), i.e., reduced TNFα production upon a blood lipopolysaccharide (LPS) stimulus. Our previous work demonstrated that endotoxin tolerance predicts bacteremia in Emergency Department (ED) patients. Therefore, point-of-care devices to assess ET are urgently needed.
Objectives: To evaluate the feasibility and performance of Septiloop, a qualitative point-of-care (PoC) device designed to detect ET by profiling TNFα response after challenge with LPS.
Methods: A total of 146 bacteremia-positive ED patients were screened using Septiloop, which provides a binary classification of ET based on TNFα production following LPS stimulation: < 200 pg/mL indicates endotoxin tolerance, and ≥ 200 pg/mL indicates preserved immune response. The device provides results within 3 h and requires minimal laboratory infrastructure.
Results: The device generated valid results in 143 of 146 patients. Among those valid results, 133 patients (93%) were classified as endotoxin tolerant, while 10 patients (7%) had TNFα levels ≥ 200 pg/mL, indicating absence of ET. Device failure occurred in 3 cases (2%), mainly due to technical issues under investigation.
Conclusions: The Septiloop PoC device offers a rapid and practical method to assess innate immune function at the bedside in patients with suspected bacteremia. The high prevalence of endotoxin tolerance among bacteremia-positive patients highlights the potential clinical utility of this tool for early immune profiling and sepsis stratification. Further studies are warranted to assess its potential.

Intensive Care Medicine Experimental 2025,* 13(1)*:001320

Introduction: The velocity time integral (VTI) from the left ventricular outflow tract (LVOT) can be calculated as the systolic time multiplied by the mean beat velocity (VMEAN). Assuming constant LVOT diameter, change in the LVOT VTI is the change in stroke volume (SVΔ). Both systolic time and VMEAN can be measured in the common carotid artery, however, a recent framework for relating the LVOT VTI to the common carotid artery VTI states that correcting for the carotid artery flow fraction (CAFF) is imperative. One approach to accounting for the CAFF is by estimating velocity decay, akin to pulse contour analysis. Therefore, a corrected carotid artery VTI (VTICC) is generally approximated as: systolic time × VMEAN × velocity decay.
We tested two methods of estimating velocity decay for the VTICC, and we hypothesized that the area under the receiver-operator curve (AUROC) of the VTICC to detect a + 10% SVΔ would be better than that of uncorrected carotid VTI. We also hypothesized that the regression coefficient between the change in VTICC and SVΔ would be superior to change in the uncorrected carotid VTI and SVΔ. We tested this as a feasibility study from 18 postcoronary artery bypass grafted patients.
Objectives: 1. Determine the diagnostic accuracy of two novel VTICC equations to detect a 10% SVΔ in post-CABG patients.
2. Determine the regression coefficient between SVΔ and VTICCΔ
3. Compare these values to the corrected coronary artery flow time (ccFT) and uncorrected carotid VTI.
Methods: The Research Ethics Board of Health Sciences North approved the study. This is a feasibility study comprising 9 preload responsive and 9 preload unresponsive patients following coronary artery bypass grafting from a previously-published dataset. Exclusion criteria were history of severe carotid stenosis and contraindication to transesophageal echocardiography (TEE).
Anesthesia and ventilator settings were standardized as described in reference 1. The wearable Doppler patch (Flosonics Medical, Sudbury, ON, Canada) is a continuous-wave 4 MHz ultrasound placed over the carotid artery and calculates ccFT by Wodey's equation. LVOT velocity time integral (VTI) from TEE was measured by a cardiac anesthesiologist using a Phillips Epiq (Cambridge, MA, USA) 2.9 MHz probe in the trans-gastric window; the insonation angle was 0 degrees and sample window 4 mm.
Synchronized Doppler data from the carotid artery and TEE were recorded during a 60 s baseline and throughout an entire 90 s Trendelenburg maneuver following a coronary artery bypass grafting (CABG) with the chest open.
For each subject, baseline and intervention windows were chosen as the minimum and maximum value of 15 consecutive LVOT VTI cardiac cycles during the baseline and intervention periods, respectively. Synchronized carotid Doppler cardiac cycles from the same windows were chosen to compare. Four measures from the carotid artery were studied: the ccFT (1), uncorrected VTI (2), and VTICC-RI (3) and VTICC-MEANS (4) using resistive index (RI) and velocity means as decay factors (Figure). Comparisons were dichotomized into LVOTΔ (i.e., SVΔ, assuming constant LVOT diameter) of ≥ + 10% or < + 10%, Pearson's correlation was performed between LVOT VTIΔ and carotid Doppler measures.
Results: Patient characteristics can be found in reference 1. Data from 18 patients and preload challenges are included. Figure shows the receiver-operator characteristics and regressions for the 4 carotid Doppler measures.
Conclusions: The clinical relevance of our findings are as follows: 1. VTICC where pulse contour was assessed by mean systolic and diastolic velocities showed the highest diagnostic accuracy and regression coefficient comparable to the ccFT 2. The accuracy of uncorrected carotid VTI was comparable to ccFTΔ to detect SVΔ. 3. Carotid VTI pulse contour analysis lends itself to calibration such that SV trending might be possible.

Intensive Care Medicine Experimental 2025,* 13(1)*:001321

Introduction: The implementation of measures for reducing the use of broad-spectrum antibiotics is important to prevent the increase of high resistance rates to antimicrobials.
Objectives: To analyze the evolution of antibiotic consumption and characteristics of patients admitted to the Intensive Care Unit (ICU) in response to the increased consumption in the years 2022–2023 and after the implementation of corrective measures in 2024.
Methods: The data were obtained from the ENVIN registry of the ICU: demographics, reason and origin of admission, severity scores (APACHE II), percentage of patients receiving antibiotics in the ICU, duration of treatment and changes in empirical treatment. Data were analyzed from April to June 2022 to 2024, both years included.
Medications from the ATC J01 group were included, and consumption was calculated according to their established Defined Daily Dose (DDDs) and adjusted annually for every 100 stays.
Various measures were implemented during the year 2024: training sessions, daily communication of antimicrobial adjustment in clinical

sessions, a clinical pharmacologist joined the medical team and joint sessions were held with the microbiology service.

Results: The populations analyzed were 132, 120 and 139 admissions in the years 2022, 2023 and 2024, respectively. Demographic and severity variables were similar in the three periods. Admission for medical reasons predominated (2022: 59.09%; 2023: 60%; 2024: 62.6%), with a similar number of surgical admissions. Admission for acute coronary syndrome decreased progressively (28.79%; 25.83%; 21.6%). The percentage of admissions due to sepsis/septic shock was 25.7% in 2022, 28.3% in 2023 and 35.7% in 2024. There was no relevant variation in the origin of admissions with the most frequent being the emergency department. The percentage of severely immunosuppressed patients was 16.3% in 2022, 23.3% in 2023 and 25.9% in 2024 with respect to total admissions. The death rates were respectively 17.42%; 13.3%; 8.63%.

The evolution of total antibiotic consumption in DDDs/100 stays was 130.62 in 2022; 152.27 in 2023 and 147.69 in 2024. A 3% reduction was achieved between 2023 and 2024 after the implementation of these measures.

Regarding antibiotics, antibiotic utilization time was reduced from 2023 to 2024, after the intervention: Linezolid from 6.8 (SD 4.53) days to 6.09 (SD 3.5), Piperacillin tazobactam from 8.86 (SD 7) to 6.67 (SD 6.67), Amoxicillin clavulanate from 4, 79 (SD 2.36) days to 3.54 (SD 2.03), Vancomycin from 10 (SD 8.04) days to 9.45 (SD 15.4), ceftriaxone from 5.58 (SD 3.97) days to 5.04 (SD 3.67). In the case of meropenem there is an opposite and equivalent trend for imipenem.

Conclusions: The type of patient admitted to the ICU has changed, with an increase in immunosuppressed patients due to sepsis/septic shock. This explains the overall increase in antibiotics use. Measures for improved antibiotic use must be implemented and maintained for a better use of antibiotics, since it is foreseeable that the number of patients requiring them, and their complexity will continue to increase.

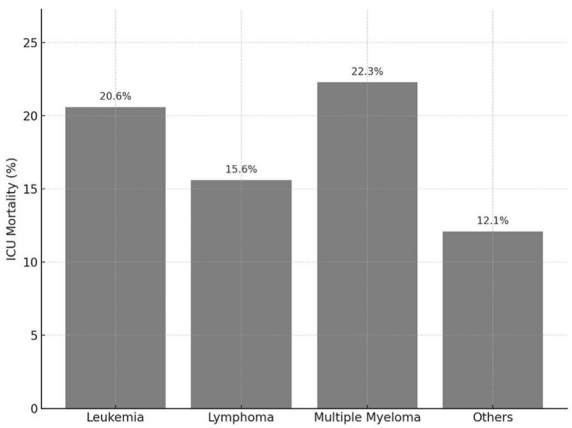
Intensive Care Medicine Experimental 2025,* 13(1)*:001324



Introduction: Patients with hematologic malignancies are increasingly admitted to intensive care units (ICUs), often requiring complex organ support and facing high mortality. Identifying early prognostic indicators is crucial for guiding care and resource allocation (1).

Methods: We conducted a retrospective cohort study with patients (≥ 18 years) with hematologic malignancies admitted to the ICU of a tertiary academic center from 2012 to 2019. Demographics, comorbidities, and ICU interventions—including respiratory, hemodynamic, and renal support—were recorded. Patients on palliative care were excluded. Independent predictors of ICU mortality were identified, using multivariable logistic regression. Adjusted odds ratios (aORs) and 95% confidence intervals (95% CIs) were reported. Statistical significance was defined as $p < 0.05$. Discriminative performance was assessed using the area under the receiver-operating characteristic curve (AUROC).

Results: A total of 692 patients were included (median age: 68 years; 62% male). ICU mortality was 18.6%. Patients with multiple myeloma had the highest ICU mortality rate (22.3%), followed by those with leukemia (20.6%), lymphoma (15.6%), and other malignancies (12.1%); however, differences were not statistically significant ($p = 0.210$) (Fig. 1). Within the first hour of ICU admission, noninvasive ventilation (31.0% vs. 12.6%) and vasopressor use (38.0% vs. 17.8%) were higher in nonsurvivals ($p < 0.001$). When compared with survivors, nonsurvivors had significantly higher rates of mechanical ventilation (47.0% vs. 23.1%), vasopressor use (63.8% vs. 28.5%), and renal replacement therapy during ICU stay (54.3% vs. 10.1%) (all $p < 0.001$) (Table 1). In multivariable analysis, a SAPS 3 score was an independent predictor of ICU mortality (OR 2.10; 95% CI 1.98–4.94; $p < 0.001$). The use of noninvasive ventilation (OR 1.36; 95% CI 1.03–3.42; $p = 0.043$) and vasopressors (OR 1.96; 95% CI 1.07–3.60; $p = 0.038$) at ICU admission also predicted ICU death. In addition, longer hospital length of stay prior to ICU admission was independently associated with mortality (OR 1.07; 95% CI 1.09–1.14; $p = 0.005$). The final model had an AUROC of 0.801.

Conclusions: Among critically ill patients with hematologic malignancies, early need for respiratory and circulatory support—particularly within the first hour of ICU admission—was independently associated with mortality. A longer hospital stay prior to ICU transfer was also linked to worse outcomes, potentially reflecting progressive clinical deterioration. These findings highlight the importance of timely escalation of care and may inform triage strategies for this high-risk population.

Intensive Care Medicine Experimental 2025,* 13(1)*:001325

Introduction: Diabetic ketoacidosis (DKA) is a serious complication of diabetes mellitus, particularly inchildren, which significantly increases the risk of morbidity and mortality.
Objectives: This study aims todetermine the incidence of DKA in pediatric patients and to analyze the clinical features andbiological outcomes during the management of DKA in an intensive care unit.
Methods: We conducted a retrospective study involving children under the age of 15 who wereadmitted for DKA in the pediatric intensive care unit at Mohammed VI University Hospital in Marrakech, Morocco, from January 2013 to December 2023. Inclusion criteria were based onstandardized diagnostic markers of DKA, including hyperglycemia, ketonuria or ketonemia,and acidosis. The severity of DKA was assessed through blood gas analysis, and renalfunction was evaluated using the KDIGO score. Epidemiological, clinical, paraclinical data,triggering factors, therapeutic management, and patient outcomes were collected andanalyzed.
Results: Over a 10-year period, 240 cases of DKA were identified among 8,222 admissions, representing 2.31% of total admissions. The average age of patients was 7.54 years, with a higher incidence observed in children over 10 years old. DKA was the initial presentation ofdiabetes in 67.81% of cases. The most common clinical signs included polyuria–polydipsiasyndrome, Kussmaul breathing, vomiting, and altered consciousness. Moderate acidosis wasobserved in 50.3% of cases, while severe acidosis was present in 23.4% of cases. Infectionswere the most frequent trigger for DKA, identified in 57.94% of cases. The majority of patients had a favorable outcome, with an average hospital stay of 2.4 days. However, 20.60% of cases experienced complications, and one death was recorded.
Conclusions: DKA remains a severe complication of pediatric diabetes, with significant risks of seriousconsequences. Increasing awareness among healthcare professionals, ensuring earlydiagnosis, and implementing comprehensive management are essential to improve clinicaloutcomes and reduce the incidence of complications.

Intensive Care Medicine Experimental 2025,* 13(1)*:001326

Introduction: Airway pressure release ventilation (APRV) is a special type of mechanical ventilation that has also been used in critically ill COVID-19 patients. The data from the literature regarding the effectiveness of APRV in this patient cohort are conflicting. A possible reason may be the presence of auto-PEEP in case of a pre-existing chronic respiratory disease, such as chronic obstructive pulmonary disease and asthma, which may limit the effectiveness of APRV.
Objectives: We aimed to investigate the possible effect of a chronic respiratory disease on the effectiveness of APRV.
Methods: This was a retrospective single-center study, that took place in the ICU of the General Military Hospital of Thessaloniki in Greece. Critically-ill patients who were older than 18 years, intubated due to COVID-19 and mechanically ventilated with APRV for > 1 day, were included in the study. Two groups were formed ("without history" and "with history"), which were compared in terms of a range of demographic and clinical parameters. All data were driven from patients' electronic files.
Results: Forty-five patients were included in the study, 23 in the group "without history" and 22 in the group "with history". Their mean age was 61 ± 12 years and 80% of them were men. There was no difference between the two groups in APACHE II score (15.13 ± 3.75 vs. 15.91 ± 3.57, $p = 0.48$), total ICU days (17.31 ± 8.39 vs. 20.6 ± 8.65, $p = 0.203$) and day of APRV initiation ($p = 0.190$). Contrary to the initial hypothesis, no difference was found between the two groups in blood gases as assessed by PaO2 ($p = 0.303$), PaCO2 ($p = 0.544$) and PaO2/FiO2 ratio ($p = 0.447$). As far as outcome is concerned, complications were observed in 39% and 45% of patients in the first and second group respectively ($p = 0.668$), while 86% of patients died in the first group and 65% in the second group ($p = 0.099$). Further statistical analysis showed that neither gender nor age exerted a significant role on the outcome measures ($p > 0.05$ for all variables).
Conclusions: It appears that the presence of a pre-existing chronic respiratory disease does not affect the efficacy of APRV in critically ill COVID-19 patients.

Exosome-based proteomics of patients with severe TBI: a pilot study

N. Romero Garcia[1], A. Ruiz Pacheco[1], B. Monleon[2], A. Gutierrez[1], S. Ubeda[1], R. Badenes[2]

Intensive Care Medicine Experimental 2025,* 13(1)*:001327

Introduction: Traumatic brain injury (TBI) has a high morbidity and mortality rate in intensive care units (ICUs). Recently, plasma biomarkers have been identified with the aim of predicting neurological prognosis and response to therapy (1). However, there is limited consensus on their usefulness due to heterogeneity and temporal variability (1). Extracellular vesicles (EVs) are stable carriers for biomolecule transport. The recent studies have highlighted the role of EVs as biomarkers in TBI, offering several advantages over soluble biomarkers, such as a longer half-life, greater resistance to degradation, and the ability to determine their tissue origin (2, 3).
Objectives: The objective of this pilot study was to compare the proteomic profile of EVs from TBI patients with that of control patients.
Methods: This observational case–control study included adult patients admitted to the ICU, with either: a) severe TBI, defined as a Glasgow Coma Scale (GCS) score < 9 upon admission (TBI group), or b) immediate postoperative status following cardiac surgery ($n = 11$ per group). Blood samples were collected upon admission and every 8 h for the first 48 h, then centrifuged at 3000 rpm to obtain plasma. EV extraction was performed by differential ultracentrifugation of plasma samples at 100,000G and 4 °C. Differential proteomic expression analysis was conducted using SWATH mass spectrometry.
Results: The proteomic profiles of TBI and control patients were clearly distinguishable at admission and at 24 h (Fig. 1). The search for individual proteins that differentiate both groups did not yield significant results, possibly due to sample size and multiple comparisons. Among the proteins close to reaching significance were some related to neuroinflammation, such as PTN or BGN, ganglioside accumulation such as HEXB, and natural killer-mediated immunity such as RASAL3. In the functional analysis, the proteomic profile of EVs from TBI patients vs. controls showed overexpression of biological processes related to:
1. Regulation of neuronal differentiation;
2. Axonal growth, and
3. Inflammatory response to antigens.

Conversely, the following processes were underexpressed:
1. Action potential of cardiac muscle cells;
2. Communication in the His–Purkinje bundle, and
3. Cardiac muscle cell adhesion.

Conclusions: The proteomic profile of plasma EVs allows differentiation of TBI patients and reflects pathophysiological processes consistent with their condition. This pilot study provides a foundation for research in the field of exosomal biomarkers in TBI and lays the groundwork for a future project correlating these biomarkers with parameters of neurological dysfunction.

Concordance between change in MAP and CO_2 as strategies to evaluate cerebral vascular reactivity by transcranial Doppler in patients under invasive mechanical ventilation

J. A. Morales-Ferrer[1], J. Garduño-López[2], M. A. Amezcua-Gutiérrez[3], J. C. Gasca-Aldama[2], F. G. Delgado-Mejía[1], F. J. Ramírez Almaraz[2], H. A. Velez Davila[2], F. P. Hernandez Bielma[2], F. Intensive Care Medicine Experimental 2025,* 13(1)*:001329

Introduction: Since the description of transcranial Doppler (TCD) in 1981 as an imaging technique that allows monitoring the cerebral blood flow velocity (CBF) of cerebral circulation (1), its use has spread in different fields of medicine (2) due to its benefits over other conventional imaging techniques. At the beginning of the nineteenth century, the relationship between the regulation of cerebral circulation with different stimuli was described, such as the variation of the partial pressure of carbon dioxide (CO2) and blood pressure (3). Although the use of DTC in conjunction with CO_2 variation and mean arterial pressure (MAP) as techniques to assess cerebral vascular reactivity has been widely described, different studies propose standardizing these tests to minimize the factors that may bias the information obtained. Currently the evidence between the correlation of these methods and their application in critically ill patients is uncertain.
Objectives: To evaluate the concordance between the change in MAP and CO2 as methods to evaluate cerebral vascular reactivity by TCD in patients under mechanical ventilation.
Methods: An experimental, cross-sectional, single-center study was carried out, where 3 measurements of the right and left middle cerebral artery velocity (MCA) values obtained by DTC were collected, the first measurement was made without any intervention, considering the baseline value, the second was performed after adjusting the dose of vasopressors in a controlled manner to raise the MAP by an average of 12 mmHg (7.3–14.3 mmHg). the third was obtained after adjusting the dose of vasopressors to return to the baseline value of the MAP and modifying the respiratory rate to obtain a change in arterial CO2 of 8.3 mmHg on average (7.3–9.1 mmHg) higher than the basal CO2. Statistical analysis was performed with Spearman's test between the MAP and CO2 switching groups to assess the correlation between these strategies.
Results: A total of 12 patients were included, all without comorbidities. In the measurements of the right and left MCA there is a very strong correlation; > 0.977 and > 0.933 respectively, between MAP and CO_2, all of which were statistically significant ($p < 0.001$).
Conclusions: The change of MAP and CO_2 as strategies to evaluate cerebral vascular reactivity in our study demonstrated a positive correlation between both tests, with high statistical value, in both the right and left MCA groups. However, a larger sample is needed to elucidate the role of cerebral vascular reactivity associated with other variables that may contribute to the success or failure of neurological monitoring.

Table 1 (abstract 001329) Correlation between basal and changing left middle cerebral artery (L-MCA) velocities of medical blood pressure (MAP) and carbon dioxide (CO_2)

		L – MCA basal	L – MCA MAP	L – MCA CO2
L – MCA basal	r_s	1.000	0.993	0.993
	p		< 0.001	< 0.001
L – MCA MAP	r_s	0.993	1.000	1.000
	p	< 0.001		
L – MCA CO2	r_s	0.993	1.000	1.000
	p	< 0.001	.	

Table 2 (abstract 001329) Correlation between basal and changing right middle cerebral artery (R-MCA) velocities of medical blood pressure (MAP) and carbon dioxide (CO_2)

		R – MCA basal	R – MCA MAP	R – MCA CO2
R – MCA basal	r_s	1.000	0.988	0.977
	p		< 0.001	< 0.001
R – MCA MAP	r_s	0.988	1.00	0.993
	p	< 0.001		< 0.001
R – MCA CO2	r_s	0.977	0.993	1.000
	p	< 0.001	< 0.001

Introduction: Hypocapnia is frequently observed in patients with acute brain injury (ABI) and has been associated with adverse effects, including cerebral vasoconstriction and reduced cerebral blood flow, which may worsen secondary ischemic damage. Despite its historical use for intracranial pressure control, its impact on mortality and neurological outcomes remains to be elucidated. To date, no meta-analyses have been conducted on the topic.
Objectives: The objective of our study was to analyze the association between hypocapnia and both mortality and poor neurological outcomes in apatients with acute brain injury.
Methods: We conducted a systematic review and meta-analysis of studies assessing the association between hypocapnia and both mortality and poor neurological outcomes in ABI patients, including patients with traumatic brain injury (TBI), postcardiac arrest (PCA), subarachnoid hemorrhage (SAH), ischemic stroke and intracranial hemorrhage. Only human studies that defined hypocapnia based on partial pressure of carbon dioxide (pCO_2) were included. Random-effects models (DerSimonian and Laird) were used to calculate pooled odds ratios (ORs).
Results: For mortality, 17 studies encompassing 80,959 patients were analyzed, including the following subgroups: 9 studies on traumatic brain injury (TBI), 1 on subarachnoid hemorrhage (SAH), 5 on postcardiac arrest (PCA), and 2 on general ABI. For poor neurological outcomes, 10 studies with a total of 3,183 patients were included. Hypocapnia was significantly associated with increased mortality in ABI patients, with a pooled OR of 1.6135 [1.0813; 2.4075]. Moderate heterogeneity was observed across studies, likely due to differences in hypocapnia definitions, injury severity, and ventilation strategies. For poor neurological outcomes, the pooled OR was 1.7576 [0.8482; 3.6420], indicating a trend toward worse functional prognosis, though the confidence interval crossed unity, suggesting a lack of statistical significance.
Conclusions: These findings suggest that hypocapnia may contribute to increased mortality in ABI patients and could negatively impact neurological recovery. The detrimental effects may stem from reduced cerebral perfusion, exacerbating secondary ischemic injury. While hypocapnia has been used for intracranial pressure management,

its routine application should be reconsidered, particularly given the potential risks. Further research is necessary to establish safe pCO_2 thresholds and optimize ventilation strategies to balance intracranial pressure control with cerebral perfusion preservation.

Meta-analysis for mortality of hypocapnia versus no hypocapnia in adult patients with ABI.

Intensive Care Medicine Experimental 2025,* 13(1)*:001331

Introduction: Airway management is a critical aspect in polytraumatized patients 1. Patients' clinical condition, intubation setting, and chosen drugs 2 can have impact on clinically relevant outcomes. However, no recommendations are currently available on this topic. The aim of this study was to describe the characteristics of polytraumatized patients requiring emergent endotracheal intubation, evaluate the drugs used for the procedure and compare patients intubated in the prehospital setting, with those intubated once arrived in the hospital.
Methods: This was a single-center, prospective observational study performed from February 2023 to October 2024 at ASST Niguarda Hospital. Trauma patients aged > 14 years, intubated either in the prehospital setting (Prehospital Group) or at admission to the shock room (Intrahospital Group), were enrolled. Demographics, clinical data, drugs used for intubation and clinical outcomes were recorded. Pre- and Intrahospital groups were compared.
Results: A total of 73 patients were enrolled. Fifty-six (77%) patients were intubated in the prehospital setting and were characterized by more severe trauma, a higher incidence of head injury, and a lower level of consciousness than those intubated in the shock room. Differently, the 17 (23%) patients intubated in the shock room experienced a higher incidence of trauma involving the abdomen together with a second district and arrived at the hospital with only minor consciousness impairment (**Table 1**). No difference in preintubation blood pressure nor in the choice of induction drugs was found. Lastly, the prehospital group was admitted to the ICU more frequently ($p = 0.04$) and had a higher mortality as compared to the Intrahospital Group ($p = 0.009$).
Conclusions: Our analysis revealed that prehospital intubation was mainly driven by the severity of trauma and a reduced consciousness level. However, regardless of the patient's condition and the intubation settings, no clinically relevant differences were found regarding the choice of induction drugs and their dose.

Introduction: Throughout the pandemic, the emergence of SARS-CoV-2 variants has posed interrogatives regarding their impact on the presentation and severity of complications in critically ill patients. An increase in multiorgan failure (MOF), thrombotic events and secondary infections has been observed.
Objectives: The objective of this study is to analyze the frequency and severity of these complications in patients with COVID-19 admitted to the ICU, in relation to the identified viral variant.
Methods: Observational, retrospective study in a second level ICU from March 2020 to December 2021. Demographic, clinical, and complication data (infectious, thrombotic, and development of MOF) were collected for each COVID-19 variant and its relationship with vaccination status. Quantitative variables are described with mean and standard deviation or with median and interquartile range, while categorical variables were analyzed using the chi-squared and Fisher's exact tests.
Results: From a total sample of 345 patients, we included 156 patients in whom each variant had been analyzed. The median age was 58.8 years, and 63% were male. Five variants were identified: Wild type ($n = 103$), B.1.1.7 ($n = 32$), Delta ($n = 18$), Gamma ($n = 1$), and South African ($n = 2$). Data from the Gamma and South African variants are limited due to the small sample size and may not be relevant. The main findings are detailed in Table 1.
The type and number of infectious and thrombotic complications and the development of MOF, whose results are detailed in Table 2, were collected.
A statistically significant association was observed between the development of bacteremia in the wild-type variant compared to the rest of the variants ($p = 0.02$). No association was observed between the COVID variant type and the number of ventilator-associated pneumonia (VAP), ventilator-associated tracheobronchitis (VAT), and urinary tract infection (UTI).
No statistically significant differences were observed regarding the number of thrombotic complications.
A statistically significant association was observed between the development of MOF and the wild variant ($p = 0.002$), with no relationship with the rest of the variants. There was no association between the development of MOF and vaccination status ($p = 0.680$), which could be limited by the sample size of vaccinated patients.
Conclusions: In our sample, the wild type of variant showed a greater association with the development of MOF and with the presentation of bacteremias as compared to Delta and B.1.1.7. These findings highlight the importance of considering the viral variant in the risk assessment of complications in critically ill patients with COVID-19.

Intensive Care Medicine Experimental 2025,* 13(1)*:001333

Introduction: Acute brain dysfunction (ABD, i.e. delirium and coma) is associated with significantly increased morbidity incritically ill patients, its high heterogeneity posing a challenge for prevention and treatment. Although machine learning is promising for subgroup identification, this approach has not yet been applied to COVID-19, despite the its remarkableprevalence of ABD.
Objectives: The aim of our study was to identify distinct endotypes among critically ill patients with COVID-19 and evaluate their association with clinical outcomes.
Methods: We retrospectively analyzed an internationalmulticentre database (COVID-D study) of critically ill adult patients with

COVID-19 and acute brain dysfunction; clinical features at the day of admission were included as input variables. We applied unsupervised machine learning to discover subphenotypes of ABD patients. Hierarchical clustering was performed with a bootstrap-based robustness assessment after dimensionality reduction. Clusters were analyzed for differences in neurological outcomes, mechanical ventilation and survival.
Results: For 13 PCs, 1,631 patients were divided into four robust endotypes with distinct clinical outcomes. Although endotype 1 ("moderate disease") included less severe patients with non-invasive ventilation, lighter sedation and the shortest duration of ABD, endotypes 2–4 represented more severe patients and differed in the choice of sedatives, anti-delirium measures and mechanical ventilation type, resulting in differences in delirium subtypes and duration, as well as persistent coma. Interestingly, no differences in survival were found.
Conclusions: Machine-learning-based endotypes highlight the heterogeneity of ABD in COVID-19 and offer insight into preventive strategies, such as family contact or choice of sedatives.

Radar chart of endotype characteristics in COVID-D patients with acute brain dysfunction. (A) Input variables (B) Outcomes.

Intensive Care Medicine Experimental 2025,* 13(1)*:001334

Introduction: Cardiopulmonary bypass (CPB) produces systemic inflammation that has been implicated in the pathophysiology of cardiac surgery-associated acute kidney injury (CSA-AKI). Our previous work demonstrated that extracorporeal blood purification (EBP) attenuates perioperative TNFα release. However, the clinical relevance of this modulation remains unclear.
Objectives: To analyze the relationship of TNFα changes with CSA-AKI, particularly in vulnerable subphenotypes, and to explore the relevance of immunoparalysis defined by endotoxin tolerance (ET) in this context.
Methods: A secondary analysis of the SIRAKI02 randomized clinical trial (n = 343), which evaluated EBP during cardiac surgery, was conducted. We analyzed the association between TNFα increase from baseline (T0) to end of surgery (T1) and the development of CSA-AKI, defined by KDIGO criteria. Comparative subgroup analyses were performed in patients with diabetes, hypertension, chronic kidney disease (CKD) or reduced left ventricular ejection fraction (LVEF < 40%). In addition, in a subgroup of 40 patients (20 per group), ET was assessed ex vivo by measuring TNFα production after lipopolysaccharide (LPS) stimulation of whole blood samples collected at T0, T1, 3 h(T2) and 24 h(T3) after surgery.
Results: A TNFα increase (T0 vs T1) over a certain threshold, associated with higher CSA-AKI risk. Patients in the EBP group had lower increases in TNFα when compared with standard care group. This effect of EBP was stronger in high-risk subphenotypes (i.e., diabetes, CKD, and low LVEF). In the ET substudy, TNFα production after LPS stimulation was significantly reduced at T1 compared to T0, indicating strong immunoparalysis, with no differences between EBP and standard care groups. Of note, this effect was partially reversed at 3 h and was completely inverted at 24 h postoperatively.
Conclusions: TNFα increase during surgery is associated with risk of CSA-AKI. EBP appears to mitigate this risk, at least in part, by modulating TNFα dynamics specially in high-risk subphenotypes. These results support the role of immune modulation during cardiac surgery in preventing AKI. The absence of differences in ET between intervention and standard care groups excludes any effect of EBP on the occurrence of ET.

Intensive Care Medicine Experimental 2025,* 13(1)*:001335

Introduction: Nosocomial infection is a major global public health problem at several levels: for the patient and the community as well as for health budgets.
Objectives: The objective of our study was to study the epidemiological profile of nosocomial infections in our department with analysis of the most incriminated microorganisms and their resistance profile as well as the morbidity and mortality linked to nosocomial infections.
Methods: This descriptive prospective work is carried out by analyzing the files of 303 patients who have been hospitalized for 48 h or more in the pediatric intensive care unit of the Mohammed VI university hospital center in Marrakech between July 2021 and February 2022. Criteria of infection used were those of the Centers for Disease Control (CDC).
Results: We identified 86 episodes of nosocomial infections in 58 patients, an incidence of 28.38%. The incidence density was 8.3 per 1000 days of hospitalization. The most affected age group was that varying between 28 days and 2 years. Esophageal atresia was the most common pathology in patients with nosocomial infection. Bacteremia was the predominant localization of nosocomial infection with an incidence of 14.85%. Pneumopathies with an incidence of 10.5% and they all occurred in intubated and ventilated children. Other sites of infection were: catheter-related infections (1.65%), urinary tract infections (1.32%) and surgical site or skin swab infections (in burn patients) (6.27%). The different incidence densities relating to the use of invasive procedures were relatively low. Thus, theincidence density of bacteremia was 5.7 per 1000 days of central venous catheterization, 7.5 per 1000 days of artificial ventilation and 4.7 per 1000 days of urinary catheterization. BGNs were the most isolated microorganisms in our series with a predominance of enterobacteriaceae (58.7%) represented by *Klebsiella pneumoniae* and *Enterobacter cloacae*, then non-fermentative BGNs (41.3%) represented by *Acinetobacter cloacae* and *Pseudomonas aeruginosa*. The probabilistic treatment of nosocomial infection was the combination Pipera-Tazo + an aminoglycoside for

post-op patients and Imipenem + Amikacin for the others with a therapeutic adjustment in 16% of our patients after microbiological identification and antibiogram. The evolution was marked by the occurrence of death in 54% of infected patients.

Conclusions: The incidence rates and incidence density of nosocomial infections calculated in our study are relatively lower than those found in studies from developing countries. However, they remain quite high compared to the results reported by studies carried out in developed countries. In addition, it appears in the light of our results that the resistance of germs to antibiotics is worrying and therefore the prevention of infections makes it possible to improve the prognosis and reduce morbidity and mortality.

Intensive Care Medicine Experimental 2025,* 13(1)*:001336

Introduction: Invasive candidiasis (IC) represents a growing concern in intensive care units (ICUs) due to their rising incidence, diagnostic challenges, and significant impact on patient outcomes. Critically ill patients are particularly vulnerable to these infections but timely recognition and management of IC are essential to reduce morbimortality.
Objectives: To characterize the epidemiology of IC in critically ill patients and identify factors of poor prognosis.
Methods: Retrospective, single-center, observational cohort study of critically ill patients with at least one episode of IC during their admission to the Intensive Care Department of a University Hospital between 2018 and 2023. SPSS was used for statistical analysis.
Results: 214 patients (1.17% of all ICU admissions) were included, mostly male (56.5%) with median age of 66y and 25.2% of them without co-morbidities. On admission, median SAPS II and SOFA scores were 52 (IQR 36.75–66) and 7 (IQR 4–10) respectively. The presence of a central venous catheter (66.4%) and previous use of antibiotics (70.1%) were the main risk factors for IC. Most episodes were ICU-acquired (40.7%) followed by hospital (36%) and community (23.4%) acquired. The most frequent source of IC was intra-abdominal infection (68.5%) followed by primary fungemia (20.7%). Septic shock was present in 43.9% of the cases and median C-reactive protein serum levels and leukocytes were 205.5 mg/l and 11200/µl, on diagnosis. Candida albicans (61.7%) was the most frequent yeast isolated followed by C. glabrata (14.5%) and C. parapsilosis (7.5%). Blood cultures were positive in 41.6% of the cases. Antifungal susceptibility testing was done in 18.7% of the isolates and resistance to azoles and echinocandins was documented in 20% and 12.5% of them, respectively. Antifungal (AF) therapy was started in 85.5% of the patients, mostly empiric (95.6%). Echinocandins was the most AF prescribed (66.1%). Median duration of AF therapy was 14 days (IQR 7–21) and it was changed in 20.3% of the patients. Median ICU and hospital length of stay were 15 and 38 days, respectively. ICU mortality was 38.3% and hospital mortality was 47.2%.
In logistic regression analysis, age (OR 1.043), SAPS II (OR 1.034), immunosuppression (OR 5.250), site of acquisition (Hospital—OR 3.714; ICU—OR 5.678), total parenteral nutrition (OR 0.286) and, compared to echinocandins, azoles use (OR 0.405) were independently associated with ICU mortality. Age (OR 1.044), SAPS II (OR 1.025), immunosuppression (OR 4.177), ICU acquisition (OR 3.629) and, compared to echinocandins, azoles use (OR 0.370) were independently associated with hospital mortality.
Conclusions: IC in critically ill patients is associated with prolonged length of stay and high mortality, in both ICU and hospital. Independent risk factors for mortality included age, SAPS II, immunosuppression and ICU acquisition. Azoles use and parenteral nutrition were protective.

Intra-abdominal candidiasis in the ICU: Is it time to challenge the antifungal dogma?

S. Teixeira[1], A. Pinho[1], S. Monteiro[2], J. Vilaça[1], J. M. Pereira[1], J. A. Paiva[1]
1Intensive Care Department, ULS São João, Porto, Portugal; 2Intensive Care Department, ULS Matosinhos, Matosinhos, Portugal
Correspondence: S. Teixeira
Intensive Care Medicine Experimental 2025,* 13(1)*:001339

Introduction: Intra-abdominal candidiasis (IAC) is a challenging and potentially life-threatening infection that frequently affects critically ill patients, especially when diagnosis and appropriate antifungal (AF) therapy are delayed. Although echinocandins are usually considered first-line therapy, there are several PK/PD concerns, namely regarding penetration and dosing.
Objectives: To characterize the epidemiology of IAC in critically ill patients and compare the effectiveness of empiric first-line use of echinocandins and azoles in this population.
Methods: Retrospective, single-center, observational cohort study of critically ill patients with IAC in the Intensive Care Department of a University Hospital between 2018 and 2023. SPSS was used for statistical analysis.
Results: During this period, 124 microbiological documented IAC were included, 49.2% males with median age of 67y. No comorbidity was present in 30.6% of them. Median SAPS II and SOFA scores on admission were 52 (IQR 37–67.75) and 7 (IQR 3–9), respectively. Most of the episodes were hospital-acquired (41.1%) followed by ICU-acquired (34.7%) and septic shock was documented in 47.6% of all IAC. Median ICU length of stay (LOS) and hospital LOS were 15 and 35.5 days. ICU mortality was 33.6% and hospital mortality was 43.8%. Candida albicans (65.3%) was the most frequent yeast isolated followed by C. glabrata (14.5%) and C. tropicalis (7.3%). Fungemia was documented in 15.3% of the episodes.
An echinocandin was used in 71% of all IAC and an azole in the remaining 29%. Median duration of AF therapy was 14 days (IQR 7.75–23.25) and it was changed in 17.8% of the cases.
In logistic regression analysis, the only variable independently associated with echinocandins use was previous use of antibiotics (OR 0.030). There was also a trend to higher use of this class of AF in patients under renal replacement therapy (OR 0.124; 95%CI 0.015–1.017).
Among all IAC, the variables independently associated with ICU mortality were age (OR 1.055), immunosuppression (OR 9.905), ICU-acquired IAC (OR 7.407). Age (OR 1.048), immunosuppression (5.589), hospital-acquired (OR 4.362) and ICU-acquired IAC (OR 8.559) were independently associated with hospital mortality.
In logistic regression analysis, empiric first-line use of an azole was independently associated with lower ICU (OR 0.189) and hospital (OR 0.196) mortality compared with echinocandins, but a significantly longer hospital LOS (40 vs. 32 days; $p = 0.041$).
Conclusions: IAC is associated with a significant ICU and hospital mortality and prolonged LOS, in both ICU and hospital. Age, immunosuppression and nosocomial acquisition of IAC were independent risk factors for mortality. Previous use of antibiotics was independently associated with empiric use of an echinocandin. Although its use is associated with a longer hospital LOS, empiric first-line use of an azole was independently associated with lower ICU and hospital mortality in this population.

Beyond the arrest: assessing survival with SOFA and SAPS II scores in OHCA patients

D. Inácio Cazeiro[1], J. Mendes Cravo[1], D. Ferreira[1], M. Miguez Vilela[1], C. Robalo[2], F. J. Pinto[1], D. Silva[3], J. M. Ribeiro[3]
[1]Department of Cardiology, CAML, CCUL@RISE, Faculdade de Medicina, Hospital de Santa Maria (ULSSM), Lisboa, Portugal; [2]Faculdade de Medicina, Universidade de Lisboa, Lisboa, Portugal; [3]Serviço de Medicina Intensiva, Hospital de Santa Maria, Lisboa, Portugal
Correspondence: D. Inácio Cazeiro
Intensive Care Medicine Experimental 2025,* 13(1)*:001342

Introduction: Out-of-hospital cardiac arrest (OHCA) is a global health concern with millions of cases yearly. Survival depends on factors like witnessed events, timely cardiopulmonary resuscitation, and initial shockable rhythms. Despite typically being admitted to intensive care units (ICUs), validated scores for post-admission survival prediction are lacking. Widely used ICU tools such as the Sequential Organ Failure

Assessment (SOFA) and the Simplified Acute Physiology Score II (SAPS II) to forecast clinical outcomes lack validation for predicting overall mortality in OHCA patients.
Methods: Retrospective, observational, single-center study conducted on patients admitted to a polyvalent ICU unit of a tertiary hospital following OHCA between 2017 and 2019. SOFA and SAPS II scores calculated in the first 24 h of admission were divided into tertile groups to determine whether a correlation between these scores and time to death could be identified. Kaplan–Meier survival analysis was performed.
Results: The study included 79 OHCA patients, with 32.9% being female. 84,8% of the cardiac arrests were witnessed, and 39.2% occurred at home. Sixty patients (75,9%) died during follow-up (FUP). Mean FUP time for surviving patients was 3,9 years. All patients had SOFA and SAPS II scores calculated within the first 24 h post-arrest.
SAPS II score first tertile was 50 and second tertile was 68. Patients with SAPS II score from 51 to 68 had a greater risk of mortality (HR: 3.17; 95% CI 1.28–7.86, $p = 0.013$) relative to patients under or equal to 50 and patients with SAPS II score greater than 68 had around 4,6 times the risk of mortality when compared to patients under 51 (HR: 4.64;95% CI 1.90–11.32, $p < 0.001$).
SOFA score within the first tertile was under or equal to 7. The second tertile was 10.
Patients within the second tertile (SOFA score from 8 to 10) had a greater risk of mortality relative to patients with a SOFA score under or equal 7 (HR: 2,19, 95% CI 1,06–4,52, $p = 0,03$) and patients with SOFA score greater than 10 had 2,5 times the risk (HR: 2,54, 95% CI 1,24–5,22, $p = 0,01$) of mortality when compared to patients within the first tertile (under or equal to 7). There was not a statistically significant difference in the risk of mortality in patients with SOFA score from 8 to 10 and patients with SOFA score greater than 10.
Conclusions: SOFA and SAPS II scores calculated within the first 24 h can be applied to estimate mortality risk in OHCA patients admitted to an ICU.

Cumulative survival in OHCA patients, according to SAPS II (left) and SOFA (right) risk scores.

Intensive Care Medicine Experimental 2025,* 13(1)*:001343

Introduction: The correction of metabolic acidosis is a key goal during continuous venovenous hemodiafiltration (CVVHDF) in critically ill patients (1). However, acid–base disturbances may result from distinct underlying mechanisms, such as hyperlactatemia or accumulation of unmeasured anions (UMAs)—which may influence treatment response and outcome (2). We hypothesized that the evolution of acid–base phenotypes during CVVHDF is heterogeneous and associated with ICU mortality.
Methods: In this retrospective study of 200 ICU patients on CVVHDF, we classified acid–base phenotypes at initiation (day 1) and after 72 h (day 3) based on lactate, standard base excess (SBE), strong ion difference (SIDa), and its inorganic component (SIDa-inorg). Three phenotypes were defined: (1) hyperlactatemic acidosis (lactate > 2.5 mmol/L), (2) unmeasured anion acidosis (SIDa-inorg > 3 mmol/L with normal lactate), and (3) dilutional/hypochloremic acidosis (SIDa > 38 mmol/L, lactate ≤ 2.5, and SIDa-inorg ≤ 3). Phenotype trajectories were categorized as: improvement (shift to a less severe phenotype), stability (same phenotype), or deterioration (shift to a more severe phenotype, particularly toward lactate or UMA-driven acidosis). ICU mortality was compared across trajectory groups.
Results: At baseline, 38% of patients had hyperlactatemic acidosis, 34% UMA-driven acidosis, and 28% a dilutional pattern. After 72 h of CVVHDF, 32% of patients improved their phenotype, 46% remained unchanged, and 22% deteriorated—mostly transitioning from dilutional to UMA or lactate-driven profiles. ICU mortality was 28% among improvers, 58% among stable patients, and 74% among those who deteriorated (Fig. 1). Patients with phenotype deterioration had persistently low SBE, elevated SIDa-inorg, and rising lactate. In multivariable analysis, phenotype deterioration was independently associated with ICU mortality (OR 3.1; 95% CI 1.5–6.3; $P < 0.01$).
Conclusions: The trajectory of acid–base phenotypes during CVVHDF is highly variable and strongly associated with outcome. Deterioration to more severe forms of acidosis, marked by increased lactate or accumulation of unmeasured anions, identifies patients at the highest risk of death despite renal support. Monitoring phenotype evolution provides a novel and clinically relevant framework to guide prognostication and metabolic management in critically ill patients.

Phenotype Trajectories D1 D3 with Estimated Mortality Reference = Dilutional | ORs: Hyperlactatemic = 5.67 (95% CI 2.47–13.02), UMA = 3.45 (95% CI 1.63–7.29).

Introduction: During continuous renal replacement therapy (CRRT), large volumes of fluids and electrolytes are exchanged between the machine and the patient (1). It is conceivable that the effects on plasma electrolytes and acid–base variables depend upon the employed dialysis fluid bags and the chosen dialytic modality, i.e., hemofiltration (CVVH) and/or hemodialysis (CVVHD) (2, 3). The aim of this study was to describe the trends in plasma electrolytes and acid–base equilibrium in critically ill patients undergoing CVVH or CVVHD.
Methods: Critically ill patients treated with CRRT (PrismaMax and Baxter) were enrolled. Regional anticoagulation was performed using diluted citrate [Regiocit, Baxter, and theoretical strong ion difference (SID) = 54 mmol/L]. Biphozyl (Baxter and theoretical SID = 23 mmol/L) was employed as dialysate during CVVHD treatment, while phoxilium (Baxter and theoretical SID = 30 mmol/L) or Multibic K2 (Fresenius, theoretical SID = 33 mmol/L) was used as replacement solutions in post-dilution during CVVH. Blood gas analysis was performed at 0, 24, 48, and 72 h (RAPIDPoint 500 Blood Gas System, Siemens). Electrolytes, Standard Base Excess (SBE), and the SID were analyzed (4).
Results: Twenty-seven patients were treated using CVVH and 11 with CVVHD. Demographics is reported in Table 1. After 72 h of treatment, both techniques led to a similar sodium concentration (135 ± 3 vs. 135 ± 3 mmol/L, $p = 0.76$), while chloride concentration was significantly higher in CVVHD (98 ± 2 vs. 103 ± 2 mmol/L, $p = 0.003$), leading to a lower SID in this CRRT modality (42 ± 3 vs. 36 ± 4 mEq/L, $p = 0.002$) (Fig. 1). Similarly, SBE was markedly lower in patients treated with CVVHD after 72 h (5 ± 4 vs. -2 ± 3 mmol/L, $p < 0.001$).

Table 1 Data are shown as mean and standard deviation or frequency (percentage).

	Overall (*N* = 38)	CVVH (*N* = 27)	CVVHD (*N* = 11)	*p* value
Age, year	64 ± 13	62 ± 15	68 ± 10	0.25
Gender male, *n* (%)	28 (74)	22 (82)	6 (55)	0.10
Weight, kg	87 ± 17	90 ± 15	82 ± 18	0.20

Conclusions: The choice of different dialytic fluid bags and modalities has a relevant impact on the electrolyte and acid–base equilibrium of critically ill patients. Understanding the implications of different CRRT approaches on acid–base equilibrium might help in the differential diagnosis of new onset metabolic disorders in critically ill patients.

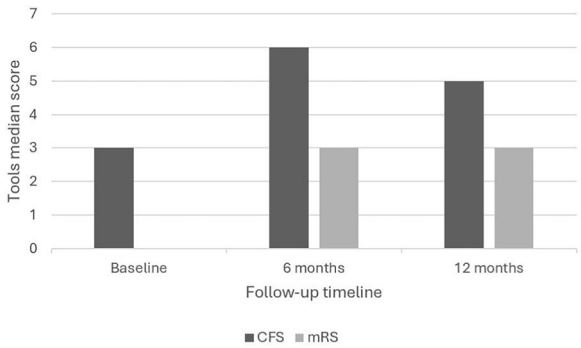
Intensive Care Medicine Experimental 2025,* 13(1)*:001345

Introduction: Intraventricular thrombolysis is an adjunct therapeutic option for patients with external ventricular drainage (EVD) in the context of intraventricular haemorrhage, aiming to reduce the obstructive component of hydrocephalus1,3. This strategy may reduce morbidity associated with EVD use by shortening the duration of its application2. Although controversial, it may be associated with reduced mortality and improved long-term functional outcomes.1
Objectives: The purpose of this study is to review our experience with intraventricular thrombolysis as an adjunctive therapy in obstructive hydrocephalus and evaluate its safety and its impact in mortality and long-term disability for survivors.
Methods: A 5-year retrospective study was conducted using records of all patients who received intraventricular alteplase between the periods of January 2020 and March 2025 at the Intensive Care Unit of the Local Health Unit of São João. Missing data were obtained through direct contact with the patient and/or family. In addition to demographic data, information regarding severity of disease, fibrinolytic administration, hemorrhagic and infectious complications, mortality, and functional status at 6 and 12 months was collected.
Results: During the evaluated period, a total of 34 patients underwent intraventricular thrombolysis (Table 1). The number of intrathecal alteplase administrations was determined according to clinical and imaging evolution, with a three-dose regimen being the most prevalent (41%). Time from hospital admission to first administration was also variable, with a median of 14 h. In two patients (5.9%), the worsening of intracranial haemorrhage potentially associated with the fibrinolytic agent was identified. No systemic haemorrhagic events were observed. There were a total of 11 EVD-associated infections (32%), with an average of 24 days under EVD. In-hospital mortality was 35%, rising to 46% at 6-month post-discharge. The assessment of functional status and long-term morbidity was performed by comparing tools, such as the Clinical Frailty Scale (CFS) and Modified Rankin Scale (mRS). At 6-month post-discharge, survivors had a median CFS of 6 and mRS of 3, while at 12 months, the median CFS was 5 and mRS remained at 3. Comparing both scales with pre-hospitalization functionality, an average increase of 2.5 points on the CFS and 2.8 points on the mRS was observed (Table 2 and Graph 1).
Conclusions: This population of patients with intraventricular haemorrhage with obstructive hydrocephalus treated with intraventricular thrombolysis showed a slightly lower mortality rate than the one reported in the literature. However, the long-term neurological and functional impact is relevant, with around half of patients not able to return to independent lifestyles. A longer follow-up and better scales of patient's and/or family's perception of quality of life are needed.

Table 1 Demographic and baseline patient characteristics and treatment variables

	Intraventricular thrombolysis (n=34)
Patient Characteristics	
Age (years)	61 (14,9)
Women	52,9%
Baseline CFS (mean ± SD)	3,0 ± 1,0
Baseline mRS (median ± IQR)	0 ± 1,0
Patient Severity	
Total GCS (mean ± SD)	7,6 ± 2,9
Maximum ICP in first 24 hours (median ± IQR)	15 ± 19
ICH	85,3%
Primary IVH	2,9%
Subarachnoid haemorrhage	8,8%
Treatment variables	
Total number of doses (mean ± SD)	2,5 ± 1,2
Time to first dose, hours (median ± IQR)	14 ± 20,5
Local haemorrhagic events	2
Systemic haemorrhagic events	0
Ventriculitis associated with EVD (per 1,000 EVD days)	13,7
Days in ICU (mean ± SD)	34,6 ± 18,6
Days in hospital (median ± IQR)	63 ± 56
Hospital mortality	35,5%
6 months mortality	46,4%



Data shown are mean (SD) or median (IQR). CFS, Clinical Frailty Scale; EVD, External Ventricular Drainage; GCS, Glasgow Coma Scale; ICH, intracerebral haemorrhage; ICP, intracranial pressure; ICU, Intensive Care Unit; IQR, interquartile range; IVH, intraventricular haemorrhage; mRS, modified rankin scale; SD, standard deviation.

Table 2 Survivors functional status follow-up

	Survivors
6-month follow-up	
CFS (1-4)	23,1%
CFS (5-9)	76,9%
mRS (0-3)	53,9%
mRS (4-5)	46,1%
12-month follow-up	
CFS (1-4)	41,7%
CFS (5-9)	58,3%
mRS (0-3)	58,4%
mRS (4-5)	41,6%
CFS variation (mean ± SD)	+2,5 ± 1,9
mRS variation (mean ± SD)	+2,8 ± 1,6

CFS, Clinical Frailty Scale; mRS, modified rankin scale; SD, standard deviation. CFS and mRS variation is based on 12-month follow-up.

Introduction: Central nervous system diseases requiring ICU admission carry a high risk of complications and demand continuous neurological monitoring. Transcranial Doppler ultrasound is a noninvasive, bedside tool that enables the early detection of cerebral hemodynamic changes, supporting timely clinical decision-making. This study aims to evaluate the relationship between transcranial Doppler findings during ICU stay and functional status at discharge, to assess its potential as a prognostic tool in neurocritical care.
Objectives: To describe the association between transcranial Doppler ultrasound findings in neurocritical patients and their functional status at ICU discharge, assessed using the Rankin scale. In addition, to determine whether sedation duration is related to the progression and functional outcomes in patients with neurological conditions.
Methods: This was a prospective, descriptive, and longitudinal study with a 28-day follow-up. The Kruskal–Wallis test was used to assess the association between Doppler flow patterns, functional scores, and sedation time.

Results: In a cohort of 35 neurocritical ICU patients, transcranial Doppler measurements at discharge, particularly in the right middle cerebral artery (diastolic velocity 28.93 ± 12.07 cm/s, $p = 0.007$; pulsatility index 2.70 ± 8.26, $p = 0.011$; and resistance index 1.70 ± 5.67, $p = 0.037$), were significantly associated with poorer functional outcomes, as measured by the modified Rankin Scale. At discharge, 45.7% of patients had a Rankin score of 5, and 40% reached a Rankin score of 6 at 30-day follow-up. Discharge measurements demonstrated greater prognostic value than those obtained at admission or at 24 h. In addition, a significant correlation was identified between prolonged sedation duration and worse functional status at discharge ($p = 0.008$), although this association was not sustained at 30 days (Table III).

Conclusions: Cerebral flow impairment at ICU discharge is strongly associated with poor functional outcomes, particularly in cases with a Rankin score of 5 or 6. In addition, a longer duration of sedation correlates with worse functionality, indicating that more critically ill patients requiring prolonged sedation are at higher risk of poor outcomes.

Liberal vs. restrictive transfusion strategies in the neurocritical care patient with acute brain injury: a systematic review, meta-analysis, and trial sequential analysis

B. Forestell[1]; G. Mcdougall[2]; S. Sharma[3]; S. Skitch[1]
[1]Critical Medicine and Emergency Medicine, McMaster University, Hamilton, Canada; [2]Emergency Medicine, McMaster University, Hamilton, Canada; [3]Medicine and Surgery, Division of Critical Care and Neurosurgery, McMaster University, Hamilton, Canada

Intensive Care Medicine Experimental 2025,* 13(1)*:001347

Introduction: Anemia is common in the critically ill patient with acute brain injury. Cerebral ischemia is an important cause of secondary brain injury among patients who have suffered a primary neurologic insult. The development of cerebral ischemia is dependent on multiple factors, including brain tissue oxygenation. Higher hemoglobin levels increase the oxygen-carrying capacity and improve brain tissue

oxygenation though not necessarily in a dose-dependent manner, which could reduce cerebral ischemia. However, there are limited data to inform red blood cell transfusion thresholds for critically ill patients with acute brain injury.
Objectives: Given the uncertainty regarding the optimal red blood cell transfusion threshold for critically ill adult patients with traumatic brain injury (TBI), subarachnoid hemorrhage (SAH), and intra-cranial hemorrhage (ICH), we conducted a systematic review and meta-analysis to compare liberal transfusion strategy (LTS) vs. restrictive transfusion strategy (RTS) to summarize the relative benefits in the neurocritical care patient with acute brain injury.
Methods: We searched MEDLINE, PubMed, Embase, Cochrane Library, as well as unpublished sources, from inception to December 15, 2024. We included randomized controlled trials (RCTs) of critically ill patients with acute brain injury randomized to LTS compared with RTS. Reviewers screened abstracts, full texts, and extracted data independently and in duplicate. Data were pooled using a random-effects model, risk of bias assessed using the modified Cochrane Risk of Bias 2 tool, and certainty of evidence using the Grading Recommendations Assessment, Development, and Evaluation approach. Trial sequential analysis for the outcome of favourable neurologic outcome (FNO) was performed using a random-effects model with model variance-based heterogeneity correction. We pre-registered the protocol on PROSPERO (CRD42024627556).
Results: We included seven RCTs (n = 2648 patients). RTS threshold was between 7 and 8 g/dL, and LTS threshold was between 9 and 10 g/dL. Compared with RTS, LTS may increase the rate of FNO (relative risk [RR] 1.13; 95% CI 0.97–1.32; low certainty). However, LTS probably has no effect on mortality (RR 1.98; 95% CI 0.85–1.12; moderate certainty) as compared to RTS. LTS probably results in higher rates of transfusion (mean difference [MD] 2.34 units more; 95% CI 2.76–3.24; low certainty). LTS had no effect on most adverse events as compared to RTS.
Conclusions: For critically ill patients with acute brain injury and anemia, the use of LTS, compared with RTS, may lead to higher rates of FNO but probably with no effect on mortality or most adverse events.

Intensive Care Medicine Experimental 2025,* 13(1)*:001348

Introduction: Acute lung injury (ALI) involves inflammatory cytokines and chemokines, resulting in lung and multiple organ injuries. This study explored the mechanism of mitophagy and cGAS/STING pathway in oleic acid (OA)-induced ALI.
Methods: Mice and pulmonary microvascular endothelial cells were divided into four groups: control, ALI, FUNDC1-control, and FUNDC1-ALI. After 24 h of modeling, proceed with tissue collection. Lung tissues were stained using hematoxylin–eosin. Autophagosomes were observed by electron microscope, and mtDNA was detected by qPCR. Western blot was used to analyze the protein expression of pathways cGAS, STING, pTBK1, pIRF3, and pNF-κB. Serum IFN-β expression was detected by ELISA. Cellular morphological changes were observed using microscopy. LDH level, cGAS, and STING in endothelial cells were observed.
Results: Compared with control, ALI group pathological changes were significantly aggravated. Expressions of serum IFN-β, cGAS, STING, pTBK1, pIRF3, and pNF-κB in lung tissues of ALI mice were significantly higher than control. After OA, the morphology of lung microvascular endothelial cells changed and LDH expression increased. After FUNDC1 gene was knocked out to inhibit mitochondrial autophagy, autophagosomes were significantly reduced and mtDNA increased. Expressions of pathway proteins in lung tissues and cells of FUNDC1-ALI group were higher than those of wild-type ALI group. Serum IFN-β expression also increased.
Conclusions: Silencing FUNDC1 inhibits mitophagy. Subsequently, accumulated mtDNA activates cGAS/STING pathway, aggravating ALI pathological damage and inflammation, suggesting that mitophagy may provide protection in OA-induced ALI through cGAS/STING pathway. Silencing FUNDC1 inhibits mitophagy. Subsequently, accumulated mtDNA activates cGAS/STING pathway, aggravating ALI pathological damage and inflammation, suggesting that mitophagy may provide protection in OA-induced ALI through cGAS/STING pathway.

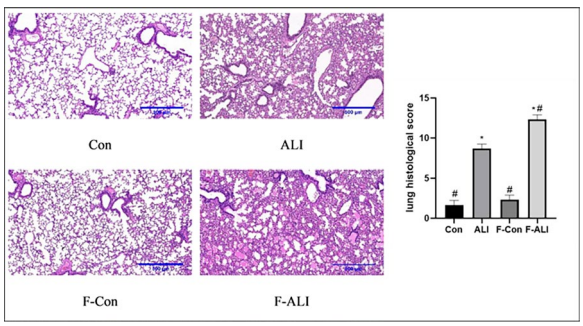

Figure 1 Histopathological assessment and quantitative evaluation of murine pulmonary tissue. After 24 h following tail vein injection of oleic acid, lung tissue was harvested and subjected to hematoxylin and eosin (H&E) staining. It was observed that the histopathological lung injury was more severe post-oleic acid administration. The group with FUNDC1 knockout exhibited more severe lung injury compared to the wild-type control group, with statistically significant differences in the histopathological scoring. The above figure presents representative images from each group. Con, control group; ALI, acute lung injury group; F-Con, the FUNDC1-control group; F-ALI, FUNDC1-acute lung injury group. * $p < 0.05$, compared with Con group; # $p < 0.05$, compared with ALI group.

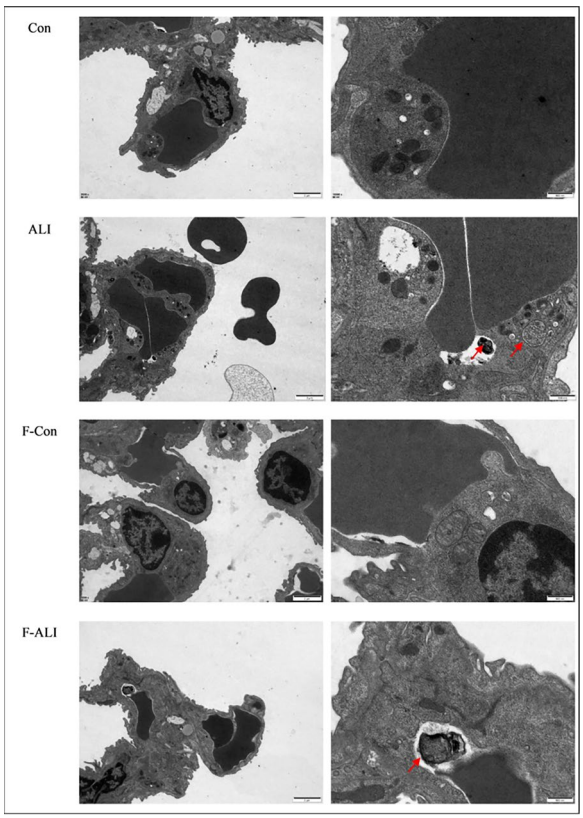

Figure 2 . Electron microscopic manifestations of mouse lung tissue. The picture shows the electron microscopic results of lung tissue of mice in Con group, ALI group, *F*-Con group, and *F*-ALI group. There were many autophagy bodies in the cytoplasm of endothelial cells (red arrow) in ALI group; autophagy bodies were seen in endothelial cells of *F*-ALI group, which were less than those of wild-type ALI group. No autophagy bodies were observed in the lung tissues of the normal groups of two kinds of mice. Con, control group; ALI, acute lung injury group; *F*-Con, the FUNDC1-control group; *F*-ALI, FUNDC1-acute lung injury group.

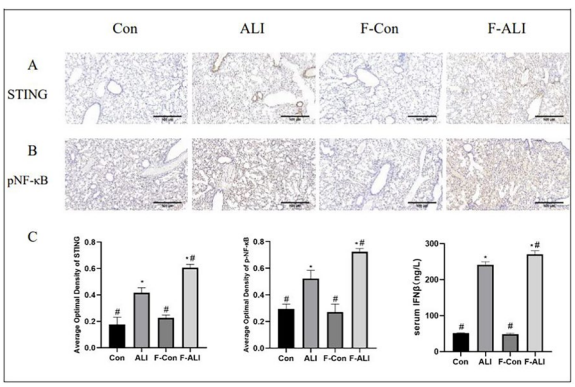

Figure 3 Immunohistochemical method was used to determine the expression of STING, pNF-κB protein in lung tissue, and serum IFN-β level in mice. Intensive Care Medicine Experimental 2025,* 13(1)*:001349

Introduction: Acute respiratory distress syndrome (ARDS) remains a significant medical challenge. Although most patients survive the acute phase, some ARDS survivors develop severe fibroproliferative responses. ARDS-induced pulmonary fibrosis (ARDS-PF) can persist after hospitalization, leading to decreased long-term quality of life and increased mortality. The role of neutrophils in this process is poorly understood.
Methods: This study is a single-center prospective investigation in which we collected bronchoalveolar lavage fluid (BALF) samples from 11 ARDS patients at the time of admission to the ICU. Patients were divided into non-pulmonary fibrosis (NPF, $N = 5$) and pulmonary fibrosis groups (PF, $N = 6$). BALF single-cell sequencing was used to explore early immune cell characteristics associated with ARDS-PF.
Results: We found that compared to the NPF group, C–X–C motif chemokine receptor 4 (CXCR4) neutrophils in the BALF of PF group were significantly increased. Within these CXCR4hi neutrophils, we detected upregulation of the ferroptosis metabolic pathway, involving key iron homeostasis regulatory genes, such as heme oxygenase 1 (HMOX1) and divalent metal transporter 1 (DMT1). This upregulation led to intracellular iron accumulation and disrupted iron metabolism, increasing the susceptibility of CXCR4hi neutrophils to ferroptosis. In addition, significant intercellular communication was observed between CXCR4hi neutrophils and macrophages. By releasing reactive oxygen species (ROS), CXCR4hi neutrophils can promote the transformation of macrophages into an anti-inflammatory and pro-repair phenotype characterized by CD163 and MRC1 expression, thereby promoting PF.
Conclusions: CXCR4hi neutrophils may play an important role in the early pathogenesis of ARDS-PF, promoting the progression of PF by facilitating the transformation of macrophages into a pro-repair phenotype.

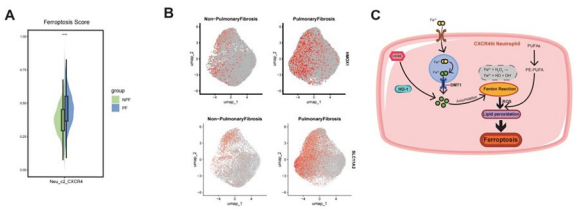

Figure 1 Subgroup of neutrophils with active ferroptosis was found in the PF group. **A** UMAP visualization of all single cells in BALF. **B** Changes in cell-type proportions between the PF and NPF groups. **C** Comparison of the neutrophil spectrum in BALF between the PF and NPF groups. **D** Comparison of changes in the proportions of neutrophil subpopulations between the PF and NPF groups. **E** Expression profiles of CXCR4 and CXCR2 in neutrophils. **F** Volcano plot of differentially expressed genes in eight neutrophil subpopulations. **G** Trajectory analysis roadmap of neutrophils. Introduction: Extracorporeal membrane oxygenation (ECMO) is a life-saving strategy for critically ill patients suffering from severe cardiac and respiratory failure caused by a potentially reversible condition [1, 2]. Analgesia is necessary to enhance patient tolerance and reduce stress responses in critically ill patients on ECMO support, and opioids are the first-line analgesics in clinical practice [3, 4]. However, traditional opioid analgesics, such as fentanyl and sufentanil, are heavily absorbed by the ECMO circuit due to their high protein-binding and lipophilicity, as demonstrated in ex vivo ECMO studies [5, 6]. Therefore, patients on ECMO support commonly receive higher doses of analgesics compare to patients with comparable disease severity who are not on ECMO support.

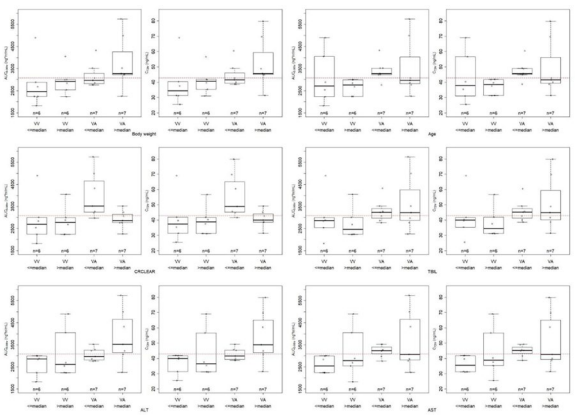
Hydromorphone is a potent analgesic synthesized from opiate drugs, with modifications made to groups at positions 6, 7, and 8 on the mother nucleus, adding a hydrogenated double bond and a keto group [7]. Its basic physicochemical properties are similar to those of morphine, but its potency is 5–10 times higher than that of morphine [8]. Hydromorphone is less lipophilic and protein-bound, which may limit its absorption in ECMO circuit [9]. These properties make hydromorphone a potentially superior option for ECMO patients compared to other analgesics. It has been reported that hydromorphone has good stability and a high drug recycling rate in polyvinyl chloride (PVC) infusion sets [10]. However, due to the large surface area of the ECMO circuit and the blood flowing through the membrane oxygenator, the stability of hydromorphone in ECMO remains uncertain. Currently, limited research on the pharmacokinetic (PK) changes of hydromorphone in ECMO.

A large variability in hydromorphone pharmacokinetics (PK) is anticipated in patients receiving ECMO support, due to the complex interplay between the extracorporeal circuit, the physicochemical properties of the drug, and critical illness-related physiological changes. This study aimed to characterize the PK of hydromorphone in critically ill patients undergoing veno-venous (V–V) and veno-arterial (V–A) ECMO using a population PK modeling approach. In addition, the study sought to explore the influence of clinically relevant covariates on hydromorphone PK.



Objectives: The pharmacological properties of hydromorphone, including lower lipophilicity and reduced protein binding, suggest that it may have less sequestration in the circuit with more predictable pharmacokinetics (PK) during extracorporeal membrane oxygenation (ECMO) compare to traditional analgesic. However, reports on its PK in ECMO patients are limited. This study aimed to develop a population PK model of hydromorphone in ECMO patients.
Methods: 12 veno–venous ECMO (V–V ECMO) patients and 14 veno–arterial ECMO (V–A ECMO) patients received hydromorphone infusion (0.03 mg · kg-1 · h-1) for 72 h. Blood samples were collected during infusion and after cessation of hydromorphone. Pharmacokinetics of hydromorphone was determined from arterial plasma concentrations. Using a non-linear mixed-effects, modeling approach analyzed the hydromorphone concentration vs. time data.
Results: A three-compartment model with first-order linear elimination in the central compartment best described hydromorphone PK in patients on ECMO. In V–V ECMO, estimates of a central compartment clearance and a central compartment volume of distribution were 0.955 L/min and 23.6 L, respectively, while in V–A ECMO, these values were lower (0.657 L/min and 16.3 L, respectively). Patients with high alanine aminotransferase and aspartate aminotransferase showed higher exposure in both V–V and V–A ECMO mode.
Conclusions: In our final model, increased volume of distribution and decreased values for clearance were reported compared with previous PK data from non-ECMO patients. Patients on V-A ECMO may have a lower demand for hydromorphone than those on V–V ECMO. Hepatic dysfunction was associated with increased drug exposure, highlighting the need for individualized dosing.

Diagnosis plot final hydromorphone model. Top-left panel: observed hydromorphone concentrations vs. individual predicted hydromorphone concentrations (IPRED). Top-right panel: observed hydromorphone concentrations vs. population predicted hydromorphone concentrations (PRED). Bottom-left panel: conditional weighted residuals (CWRES) vs. time. Bottom-right panel: conditional weighted residuals (CWRES) vs. population prediction. Points are the individual data. Black solid lines represent the line of unity (top panel) or line at zero (bottom penal). Green dashed lines represent the |CWRES|= 5. Red dashed lines represent the lowess smooth fit. The blue and pink represent the data from patients supported with V–V and V–A modes, respectively.

Prediction-corrected visual predictive check (pcVPC) of hydromorphone concentration–time profiles for V–V ECMO (A and C) and V–A ECMO (B and D). The final model parameter estimates and demographic information of subjects were utilized to simulate 1000 new virtual clinical trials. The observed concentrations are represented by points, with the solid line indicating the median observed value. The dashed lines represent the 2.5th and 97.5th percentiles of the observed values. The upper and lower shaded areas represent the 95% confidence interval (CI) spread of the 2.5th to 97.5th percentiles of predicted values, while the middle shaded areas represent the 95% CI spread of medium predicted values.

Impact of covariates of interest on hydromorphone steady-state exposure. Circles are the simulated hydromorphone exposure (AUC0-96h and C72hr) in individual subjects with 0.03 mg/kg/h based on post hoc pharmacokinetic parameters. The boxes represent the 25th to 75th percentiles (the interquartile range). The solid black horizontal line in the middle of each box represents the median. The bars extend to the most extreme data point which is no more than 1.5 × IQR from the box.

Introduction: Septic cardiomyopathy is a well-known consequence of sepsis and is associated with increased sepsis-related mortality. Several echocardiographic parameters have been studied in sepsis patients for early detection of septic cardiomyopathy; however, none of them could independently predict outcomes. Myocardial performance index (MPI), a tissue Doppler-derived global cardiac function index (assess both systolic and diastolic functions), has never been used for this purpose.
Objectives: This study was planned to investigate the predictive value of in MPI for 28-day ICU mortality in septic shock patients. The correlation of MPI with other laboratory parameters (Trop-I and NT-proBNP) and clinical outcomes (length of hospital and ICU stay, and duration of mechanical ventilation) was also investigated.
Methods: This prospective observational cohort study was conducted in 104 patients (> 18 years, septic shock as per Sepsis-3). All patients underwent transthoracic echocardiography at baseline and 24 h later. Tissue Doppler was used to calculate, isovolumetric contraction time (IVCT), isovolumetric relaxation time (IVRT), ejection time (ET), and MPI. Serum levels of NTproBNP and Trop-I were also measured at baseline and 24 h later. Patients were followed up for prognostic outcomes.
Results: The 28-day mortality in this study was 52.88% (55 non-survivors/49 survivors). Non-survivors demonstrated a significantly greater median change in MPI (0.13 [IQR: 0.11–0.18]) compared to survivors (0.05 [IQR: 0.03–0.08], $p < 0.0001$). There was a significant positive correlation ($r = 0.303$) between change in MPI and change in Trop I, and change in NTproBNP ($r = 0.528$). Changes in MPI and its components correlated with increased mortality, longer ICU stays, and duration of mechanical ventilation. (Fig. 1).
Conclusions: Among patients admitted to the intensive care unit with septic shock, a worsening of MPI within the initial 24 h following was associated with increased 28-day mortality. MPI values also corelate with change in Trop-I and NT-proBNP levels.

ROC Curve of Change in MPI for predicting mortality.

Introduction: The lungs are particularly vulnerable in sepsis, often developing sepsis-associated ARDS. Alveolar epithelial cell death plays

a pivotal role in ARDS pathogenesis by disrupting pulmonary fluid balance and causing alveolar edema, making its prevention a promising therapeutic strategy. Pyroptosis, a programmed cell death mechanism in ARDS, occurs when PRRs detect PAMPs/DAMPs, triggering inflammasome formation and caspase-1/4/5/11 activation. These caspases cleave GSDMD, generating GSDMD-NT fragments that form membrane pores—a hallmark of pyroptosis along with phosphatidylserine (PS) externalization.

Myoferlin (MYOF), a seven-C2-domain transmembrane protein, is crucial for membrane integrity maintenance due to its strong PS-binding capacity. While MYOF's role as an exosomal protein is established, its potential to mitigate GSDMD cleavage and PS externalization during alveolar epithelial pyroptosis in sepsis-associated ARDS remains unexplored. Using gene knockout, immunofluorescence, flow cytometry, and co-IP techniques, we investigated MYOF's protective mechanisms against pyroptosis in this context.

Objectives: The purpose of this study was to investigate the mechanism of myoferlin and alveolar epithelial cell pyroptosis on sepsis-associated ARDS.

Methods: This study employed CLP mouse models, clinical samples, and A549 cells to investigate MYOF's role in sepsis-induced lung injury. We first analyzed MYOF expression in septic mice and LPS-stimulated human alveolar epithelial cells. Using MYOF-knockdown and overexpression A549 lines, we assessed LPS-induced cell permeability, PS externalization, and pyroptosis via immunofluorescence, flow cytometry, and western blot. Protein interactions between MYOF and GSDMD were examined by co-IP and confocal imaging. We further explored MYOF regulation by measuring m6A modifications and validating METTL3–MYOF mRNA interactions through RNA pull-down assays. To evaluate therapeutic potential, we generated MYOF-overexpressing exosomes from transfected 293 T and NIH-3T3 cells. These exosomes were tested on LPS-treated A549 cells and CLP mice, with outcomes measured by flow cytometry, western blot, H&E staining, and lung injury scoring.

Results: The expression of MYOF protein was downregulated in the lungs of septic mice, as well as in human primary type II alveolar epithelial cells and A549 alveolar epithelial cells following LPS stimulation. Flow cytometry, immunofluorescence, and western blotting results demonstrated that, compared to the control group, MYOF-knockdown A549 cells exhibited increased cell permeability, elevated phosphatidylserine (PS) externalization, and enhanced pyroptosis levels under LPS stimulation. In contrast, MYOF-overexpressing alveolar epithelial cells showed reduced cell permeability, decreased PS externalization, and lower pyroptosis levels upon LPS stimulation compared to the control group. Co-immunoprecipitation and confocal immunofluorescence confirmed the interaction between MYOF and gasdermin D (GSDMD). RNA immunoprecipitation (RIP) and RNA pull-down assays revealed an interaction between METTL3 protein and MYOF mRNA. Flow cytometry and western blotting demonstrated that MYOF-overexpressing exosomes reduced PS externalization and pyroptosis levels in LPS-treated A549 cells.

Conclusions: LPS suppresses METTL3 expression in A549 alveolar epithelial cells, leading to a downregulation of m6A modification levels on MYOF mRNA, which impairs MYOF protein expression. This results in increased phosphatidylserine (PS) externalization and enhanced pyroptosis. MYOF-overexpressing exosomes mitigate the LPS-induced damage in A549 cells.

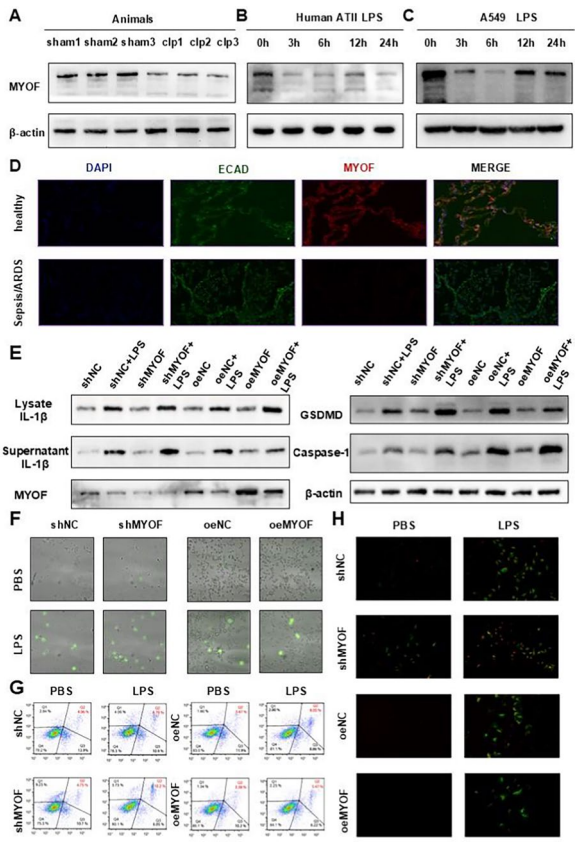

Figure 1 **A** Western blotting results demonstrated that the protein level of MYOF in the lung tissues of CLP group mice was downregulated compared to the sham group. **B** Western blotting results revealed that the protein level of MYOF in human primary type II alveolar epithelial cells was downregulated upon LPS stimulation. **C** Western blotting results indicated that the protein level of MYOF in the A549 alveolar epithelial cell line was downregulated following LPS stimulation. **D** Immunofluorescence analysis of clinical lung tissue samples showed that MYOF was downregulated in alveolar epithelial cells of sepsis patients. **E** Western blotting results showed that IL1B release in the supernatant of MYOF-knockdown A549 cells was increased compared to the control group upon LPS stimulation, while IL1B release was decreased in MYOF-overexpressing A549 cells compared to the control group. **F** SYTOX immunofluorescence results demonstrated that cell permeability was increased in MYOF-knockdown A549 cells compared to the control group upon LPS stimulation, whereas cell permeability was reduced in MYOF-overexpressing A549 cells compared to the control group. **G** Flow cytometry analysis of Annexin-V (FITC) and PI (PE) staining revealed that phosphatidylserine exposure on the cell membrane was increased in MYOF-knockdown A549 cells compared to the control group upon LPS stimulation, while it was decreased in MYOF-overexpressing A549 cells compared to the control group. **H** Immunofluorescence detection of Annexin-V (FITC) and PI (APC) staining showed that phosphatidylserine exposure on the cell membrane was increased in MYOF-knockdown A549 cells compared to the control group upon LPS stimulation, whereas it was decreased in MYOF-overexpressing A549 cells compared to the control group.

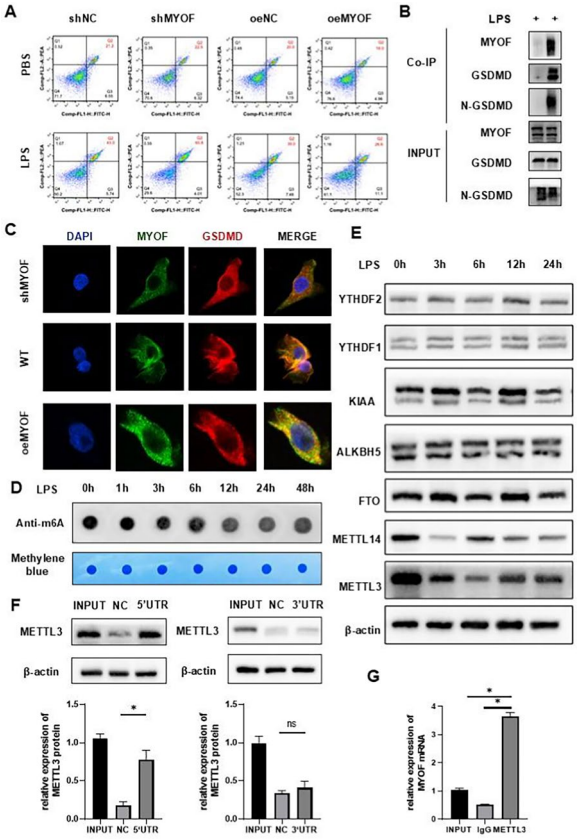

Figure 2 **A** Flow cytometry analysis of Annexin-V (caspase1) and PI (PE) staining demonstrated that pyroptosis levels were increased in MYOF-knockdown A549 cells compared to the control group upon LPS stimulation, while pyroptosis levels were decreased in MYOF-overexpressing A549 cells compared to the control group. **B** Co-immunoprecipitation results revealed that MYOF interacts with GSDMD and N-GSDMD in A549 cells upon LPS stimulation. **C** Confocal immunofluorescence results showed that MYOF co-localizes with GSDMD in A549 cells following LPS stimulation. **D** m6A dot blot assay results indicated that m6A modification was downregulated in A549 cells upon LPS stimulation. **E** Western blotting results demonstrated that METTL3 expression was reduced in A549 cells following LPS stimulation. **F** RNA pull-down assay results showed that MYOF 5'UTR mRNA could pull down METTL3 protein. **G** RNA immunoprecipitation (RIP) results revealed that METTL3 protein interacts with MYOF mRNA.

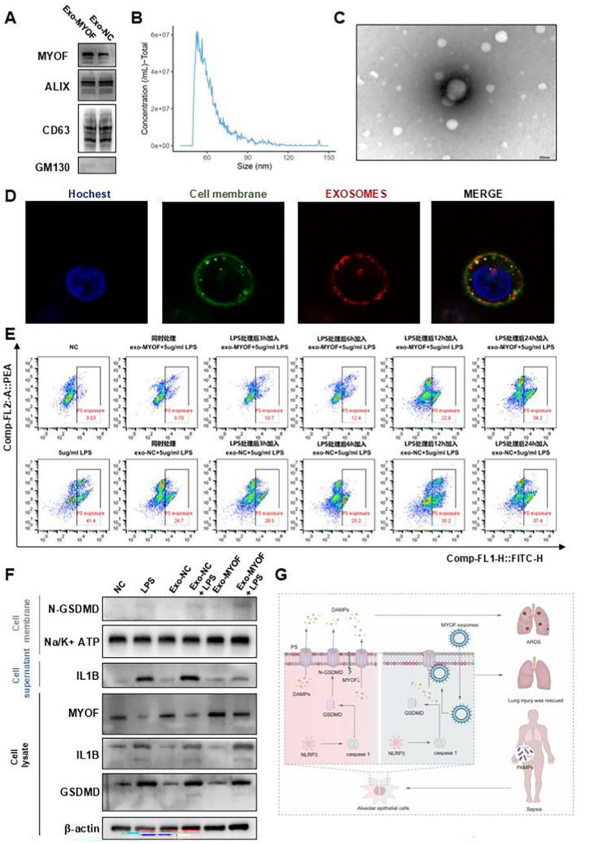

Figure 3 **A** Western blotting identification of MYOF-overexpressing exosomes. **B** Nanoparticle size characterization of MYOF-overexpressing exosomes. **C** Electron microscopy identification of MYOF-overexpressing exosomes. **D** Confocal immunofluorescence results demonstrated that MYOF-overexpressing exosomes were taken up by A549 cells and localized to the cell membrane upon LPS stimulation. **E** Flow cytometry analysis of Annexin-V (FITC) and PI (PE) staining revealed that phosphatidylserine exposure on the cell membrane was reduced in MYOF-overexpressing A549 cells compared to the control group upon LPS stimulation. **F** Western blotting results showed that IL1B release in the supernatant of A549 cells treated with MYOF-overexpressing exosomes was increased compared to the control group upon LPS stimulation. **G** Schematic diagram

Intensive Care Medicine Experimental 2025,* 13(1)*:001356

Introduction: Volatile anaesthetics have a direct vasodilatory effect on cerebral vasculature with increasing concentration, leading to increased cerebral blood flow and brain volume. An increase in cerebral blood volume will result in an increase in brain bulk and eventually makes surgical access difficult. This study aimed at comparing cerebral vasodilatory effects of isoflurane, sevoflurane, and desflurane in supratentorial lesions. Transcranial Doppler (TCD) provides an indirect measure of CBF by measuring blood flow velocity in middle cerebral artery, if the angle of insonation and vessel diameter remain constant. Although middle cerebral artery flow velocity (FVMCA) does not reflect absolute cerebral blood flow (CBF), change in MCA flow velocity is directly proportional to change in CBF. NIRS has been used to monitor regional cerebral oxygen saturation (rSO2), based on the assumption that the brain's oxygen content is positively related to cerebral blood flow.

Objectives: Primary objective
To compare change in mean blood flow velocity in middle cerebral artery (ΔFVMCA) from baseline to 1 MAC among the 3 inhalational agents.

Secondary objective
1. To compare Pulsatality Index at 1 MAC among the three inhalational agents.
2. To compare regional oxygen saturation (rSO2) at 1 MAC among the three inhalational agents.
3. To compare the effects 1 MAC of isoflurane, sevoflurane and desflurane on middle cerebral artery (MCA) flow velocities between the cerebral hemisphere with tumour and normal side.
Methods: In this prospective randomised study, 123 patients aged 18–60 years, with unilateral supratentorial lesion and ASA physical Grade 1 or 2, were selected and randomly divided into 3 groups of 41 patients each to receive isoflurane, sevoflurane or desflurane to achieve 1 MAC. Carotid artery Doppler was done the day before surgery to rule out presence of plaques/stenosis in the carotid artery. FVMCA, Pulsatility Index (PI) and rSO2 were measured bilaterally (tumour and normal side) at time intervals of pre-induction and 15 min after 1 MAC.
Results: On the normal side, all the three inhalational agents caused statistically significant increase in FVMCA and rSO2 (p value < 0.001). Increase in PI was statistically significant in desflurane ($p < 0.001$) and sevoflurane groups ($p = 0.031$), but trending toward significance in isoflurane group ($p = 0.057$). On the tumour side, all three inhalational agents caused statistically significant increase in FVMCA and rSO2 ($p < 0.001$). Increase in PI was statistically significant in isoflurane group ($p = 0.005$) and trending toward significance in sevoflurane group ($p = 0.09$).
While comparing the inhalational agents, desflurane caused significantly more increase in FVMCA and rSO2 than sevoflurane and isoflurane ($p < 0.001$) on the normal side. Increase in PI was trending toward significance while comparing desflurane and isoflurane ($p = 0.051$) on the normal side. Sevoflurane caused significantly more increase in FVMCA ($p < 0.001$) and rSO2 ($p = 0.042$) than isoflurane on normal side. On the tumour side, desflurane caused significantly more increase in FVMCA and rSO2 than isoflurane ($p < 0.001$). On comparing desflurane and sevoflurane on tumour side, increase in FVMCA was statistically significant ($p = 0.003$), while increase in rSO2 was trending toward significance ($p = 0.08$). On the tumour side, sevoflurane also caused significantly more increase in FVMCA ($p = 0.024$) and rSO2 ($p = 0.028$) than isoflurane.
Conclusions: All the three inhalational agents increase cerebral blood flow at 1 MAC on both tumour and normal sides. Desflurane causes maximum increase in cerebral blood flow, followed by sevoflurane and isoflurane. Thus, isoflurane may be the most suitable inhalational

agent in surgery for supratentorial lesions due to minimum cerebral haemodynamic effects as compared to sevoflurane and desflurane.

Comparison of MCA flow velocities on normal and tumor side.

Predictors and outcomes of failed extubation in neuro-intensive care unit

S. Kamath[1]; R. Prasath[1]; S. RP[2]
[1]Neuroanaesthesia and Neurocritical care, National Institute Of Mental Health & Neuro Sciences (NIMHANS), Bengaluru, India; [2]Neuroanaesthesia and Neurocritical care, National Institute Of Mental Health & Neuro Sciences, Bengaluru, India

Intensive Care Medicine Experimental 2025,* 13(1)*:001358

Introduction: Failed extubation in the neuro-intensive care unit (NICU) is likely and can affect outcomes. Currently, there is a paucity of data on failed extubation in the Indian NICUs, though India accounts for 1/5 of the world's population. Knowing the predictors will facilitate attempts to reduce failed extubation and the associated adverse outcomes.

Objectives: Our objectives were to assess the predictors and outcomes of failed extubation in one of the India's largest NICU.
Methods: This prospective observational study was conducted between March 2023 and November 2024 at our hospital's NICUs after ethics approval and registration with the Clinical Trials Registry–India. We included patients with neurological and neurosurgical illnesses of all etiologies admitted to the NICU. We excluded patients with pre-existing tracheostomy or absence of consent.
Results: We screened 1202 patients, of whom 523 were excluded from analysis, as they did not undergo extubation (direct tracheostomy, discharged with a tube in situ or death in NICU on the tube). The incidence of failed extubation was 24.9% (169/679) among the patients who underwent extubation**.** On univariate analysis, type of extubation, timing, the status of restraint, cough and gag reflex, secretion quantity, fluid balance, pre-extubation respiratory events, vasopressor and sedation use, APACHE2 score, ventilation duration, GCS, RASS, hemoglobin, and creatinine values were associated with failed extubation. On multivariate analysis, cardiac dysfunction in NICU ($p = 0.003$), positive fluid balance ($p < 0.001$), absent cough reflex ($p < 0.001$), increased purulence of secretion ($p < 0.001$), respiratory events in NICU ($p < 0.001$), higher APACHE 2 scores at NICU admission ($p = 0.037$), pre-extubation higher FiO2 requirement ($p = 0.017$), and pre-extubation lower haemoglobin ($p = 0.018$) were predictors of failed extubation. Failed extubation increased the rates of tracheostomy, pneumonia, neurological deficits, deaths, NICU, and hospital stay and lowered discharge GCS.
Conclusions: We observed a very high incidence of failed extubation in our NICU. Based on the significant predictors in this study, measures should be undertaken to minimize the occurrence of failed extubation and improve outcomes.

Characteristics of adult intensive care units and admissions in türkiye between 2018 and 2023: a nationwide cohort study

M. Yildirim[1]; B. Halacli[1]; E. Gemcioglu[2]; S. Baser[3]; EK. Kaya[1]; R. Bozkus[2]; N. Ata[4]; S. Birinci[5]; A. Topeli[1]

Intensive Care Medicine Experimental 2025,* 13(1)*:001359

Introduction: Despite the long history of intensive care units (ICUs) and intensive care medicine (ICM) being a recognized specialty for over 50 years, there is still a significant gap in large-scale epidemiological studies, especially from low- and middle-income countries (LMICs). This gap makes it difficult to fully understand and assess the global burden and trends of ICU admissions. Most of the available data come from high-income countries, even though LMICs are believed to bear the heaviest burden of critical illness (1.2). Türkiye, with one of

the highest ICU bed capacities globally, offers a unique opportunity to evaluate critical care utilization in a middle-income country.

Objectives: Despite the critical importance of understanding the burden of intensive care, the lack of comprehensive national epidemiological data and analyses on ICU admissions in Türkiye leaves its characteristics, outcomes, and largely unexplored. The aim of the study is to reveal characteristics of all ICUs and critically ill patients admitted to ICUs emphasizing on ICU mortality and readmission rates across the country with temporal trends over the past 6 years.

Methods: Data were retrospectively retrieved from the Turkish Ministry of Health National Electronic Database. Adult ICU admissions across all levels and types over 6 years were analyzed. Demographics, comorbidities, admission diagnoses, clinical interventions, and ICU outcomes were documented.

Results: A total of 3,362,539 ICU admissions were recorded. Among 22 ICU types, mixed ICUs accounted for the highest proportion of admissions (31.4%), followed by coronary (23.7%), anesthesiology (14.3%), medical (6.1%), and surgical (6.0%) ICUs. The proportion of mixed ICU beds decreased from 44% in 2018 to 25.1% in 2023. Most ICU beds were in state hospitals (50.8%), followed by private hospitals (34.8%). The number of ICU beds increased from 2019, with a notable rise in state hospitals after 2020. ICU admission per 100,000 population was 57.1, with regional differences. ICU mortality was 15.5%, and the median patient age was 65 years (IQR: 39–91). The leading admission diagnoses were respiratory failure (10.1%), cerebrovascular disease (7.1%), and acute kidney injury (5.2%). Hypertension (67.5%) and coronary artery disease (44.8%) were common comorbidities, particularly in non-survivors. The 7-day ICU readmission rate was 3.0%.

Conclusions: This study provides the first nationwide epidemiological analysis of ICU admissions and resource in Türkiye, shedding light on critical trends and disparities. Our findings highlight a significant increase in ICU admissions and bed capacity between 2018 and 2023, with a notable transition from mixed ICUs to specialized units. The predominance of state hospitals in ICU admissions underscores their essential role in critical care delivery. The male predominance in ICU admissions and higher mortality among men suggests potential biological and healthcare access-related differences, while the high burden of chronic diseases such as hypertension, coronary artery disease, and diabetes underscores the need for integrated chronic disease management strategies. The unexpectedly low reported sepsis prevalence points to potential coding inaccuracies or underdiagnosis, emphasizing the necessity of improving clinical documentation and epidemiological surveillance. In addition, the lower-than-expected ICU readmission rate raises important questions regarding discharge practices and post-ICU follow-up, warranting further research to ensure that patients receive appropriate continuity of care.

Intensive Care Medicine Experimental 2025,* 13(1):*001360

Introduction: Severe sepsis patients exhibit significant circadian rhythm disruption, with loss of diurnal patterns in serum melatonin and core rhythm genes [1]. In our LPS-induced macrophage tolerant model, NR1D1 expression was continuously upregulated with complete loss of rhythmic oscillation after 24–48 h. Based on our previous findings, we engineered biomimetic lipid nanoparticles for treating sepsis-induced immunosuppression through targeted regulation of macrophage circadian rhythm pathways [2].

Methods: Using single-cell sequencing from sepsis patients (GSE167363), we identified monocytes/macrophages as the most interconnected cell type. We established four murine groups (sham, mild CLP, moderate CLP, and moderate CLP with Imipenem) and monitored circadian rhythms via Comprehensive Lab Animal Monitoring System (CLAMS). Time-series RNA-seq revealed persistently upregulated NR1D1 under LPS stimulation, with siRNA knockdown effects verified by Lumicycle assay. Multi-omics analyses identified IGF2BP2 as a direct NR1D1 target. For in vivo applications, we synthesized CLOCK-Lipo using co-extrusion and DNA zipper-mediated membrane fusion.

Results: Cell interaction analysis identified monocytes/macrophages as the most interconnected cell type in sepsis patients (Fig. 1a). Sham and mild CLP groups restored diurnal patterns of oxygen consumption (VO_2) by postoperative day 1, while moderate CLP groups failed to recover rhythmicity within 5-day post-surgery whether treated with Imipenem or not, with similar patterns in activity measurements (Fig. 1b, c). Time-series RNA-seq identified NR1D1 as persistently upregulated following LPS stimulation (Fig. 2a). siRNA-mediated NR1D1 knockdown modulated BMAL1 expression (Fig. 2b). RNA-seq and proteomics revealed NR1D1 significantly suppressed IGF2BP2, with ChIP-seq and molecular docking confirming IGF2BP2 as a direct NR1D1 target (Fig. 2c, d). IGF2BP2, an RNA-binding protein critical for immune cell activation and cytokine production, regulates macrophage polarization and inflammatory responses, suggesting that its suppression contributes to immune dysfunction in sepsis [3].
We developed CLOCK-Lipo (Fig. 3a) by extracting cell membranes from LPS-stimulated macrophages (LM) and erythrocytes (RM), co-extruding them with siRNA-NR1D1 to form vesicles (HybridM@siNR1D1). Separately, we prepared cardiolipin-enriched vesicles (CCL@siNR1D1) for GSDMD-mediated release in pyroptotic macrophages (Fig. 3c) [4]. These vesicles were fused using DNA zippers [5], confirmed by FRET and electron microscopy (Fig. 3b). This method demonstrated superior drug loading efficiency. The incorporation of LPS-stimulated macrophage membranes enhanced lung targeting capability (Fig. 3d), suggesting that CLOCK-Lipo could modulate circadian rhythms while improving survival rates.
Conclusions: Our findings demonstrate that sepsis-induced immunosuppression is associated with disrupted circadian rhythms through NR1D1 upregulation in macrophages. The CLOCK-Lipo nanoparticle system effectively delivers siRNA–NR1D1 to target tissues, restoring circadian function and potentially improving sepsis outcomes through modulation of the NR1D1–IGF2BP2 pathway.

To minimize the occurrence of unintentional leak alarms associated with non-invasive positive pressure ventilation

HL. chia[1]
[1]Division of Respiratory Therapy, China Medical University Hospital, Taichung, Taiwan
Correspondence: H.L. chia

Introduction: Non-invasive positive pressure ventilation (NIPPV) is widely used for acute and chronic respiratory failure, such as pulmonary edema, pneumonia, and COPD, to improve oxygenation and gas exchange. However, leaks are a common issue.
Objectives: This study examines whether external oxygen placement and flow rate influence unintentional leaks and patient–ventilator asynchrony (PVA) to enhance NIPPV effectiveness and reduce troubleshooting time required by clinical staff.
Methods: In 2024, data were colected from a medical center in central Taiwan on patients receiving NIPPV for respiratory failure. The study analyzes the impact of external oxygen placement and flow rate on unintentional leaks and PVA.
Results: The findings indicate that placing the external oxygen connector at the rear of the ventilator and maintaining an oxygen flow rate $\leq$ 15 LPM effectively reduces the incidence of unintentional leaks and PVA. Before intervention: unintentional leak rate 7.14%. After intervention: unintentional leak rate 2.63%. Improvement rate: 63.14%
Conclusions: Conclusions proper circuit calibration, placing the external oxygen connector at the rear of the ventilator, and maintaining an oxygen flow rate $\leq$ 15 LPM effectively reduce unintentional leaks and PVA, improving NIPPV outcomes.

Topic: Acute respiratory failure and mechanical ventilation.

Examination of caring behaviors attitude and cultural competence levels of intensive care nurses

S. Gungor[1]; I. Dusak[2]; B. TOSUN[3]
[1]Vocational School of Health Services, Kahramanmaraş Sütçü İmam University, Kahramanmaraş, Turkey; [2]Palliative Care Department Nurse Manager, Şanlıurfa Mehmet Akif İnan Training and Research Hospital/ Haliliye, Şanlıurfa, Turkey; [3]Faculty of Nursing, Hacettepe University, Ankara, Turkey
Correspondence: I. Dusak
Intensive Care Medicine Experimental 2025,* 13(1)*:001362

Introduction: Cultural competence forms the foundation of nursing care. Providing quality care is not possible without considering the culture, values, and health beliefs of patients, families, and communities.
Objectives: The aim of this study is to determine the caring behavior attitudes and cultural competence levels of intensive care nurses.
Methods: This study was conducted as a descriptive, cross-sectional study involving 93 intensive care nurses working at a Training and Research Hospital located in a geopolitically strategic region in southeastern Turkey, bordering Syria, and Iraq. Data were collected by the researcher using the "Nurse Introduction Form" and two validated and reliable instruments: the "Caring Behaviors Attitude Scale in Intensive Care Nurses" and the "Nurse Cultural Competence Scale," through face-to-face interviews. Descriptive statistics, independent t tests to compare the means between two independent groups, one-way ANOVA to assess differences among more than two groups for normally distributed data, and the Kruskal–Wallis test for non-normally distributed data to determine differences between groups.
Results: Among intensive care unit nurses, 54.8% were male, and 84.9% held a bachelor's degree. A significant majority (79.6%) reported providing care to patients from diverse cultural backgrounds. The three most frequently reported challenges in delivering such care were language barriers (79.6%), culture-specific expectations (53.8%), and expectations directed specifically toward nurses (33.3%). The mean score on the Nurse Cultural Competence Scale was 48.89 $\pm$ 11.91. The mean score for the Cultural Skills subscale was 29.31 $\pm$ 7.78, for the Cultural Knowledge subscale was 14.69 $\pm$ 3.56, and for the Cultural Sensitivity subscale was 4.88 $\pm$ 1.43. The mean score on the Caring Behaviors Attitude Scale in intensive care nurses was 109.54 $\pm$ 12.03. A statistically significant difference was found between nurses' cultural competence scores and their gender ($t = 3.059$, $p = 0.003$), as well as their experience in providing care to patients from diverse cultural backgrounds ($t = -2.462$, $p = 0.016$). Strikingly, intensive care nurses who were associate degree graduates, worked in pediatric intensive care units, and expressed unwillingness to care for patients from diverse cultural backgrounds had higher levels on the Nurse Cultural Competence Scale. Similarly, nurses who were high school graduates, worked in surgical intensive care units, and also expressed unwillingness to provide care to patients from diverse cultural backgrounds showed higher scores on the Caring Behaviors Attitude Scale.
Conclusions: Intensive care nurses exhibited a high level of caring behaviors and a moderate level of cultural competence. Gender and providing care to patients from different cultural backgrounds were found to influence the nurses' cultural competence levels. Intensive care nurses need to be supported with in-service training to increase their cultural competence level.

Engineered exosomes delivering CD5L restore mitochondrial energetics via lipogenesis restriction in a Bama mini-pig model of septic acute kidney injury

Y. Li[1]; Z. Peng[2]
[1]Intensive care unit, Zhongnan Hospital of Wuhan University, Wu Han Shi, China; [2]Intensive care unit, Zhongnan Hospital of Wuhan University, Wuhan, China
Correspondence: Y. Li
Intensive Care Medicine Experimental 2025,* 13(1)*:001363

Introduction: Sepsis-induced acute kidney injury (S-AKI) exhibits high mortality, with renal lipid metabolism disorders and mitochondrial dysfunction being core pathologies, yet effective targeted therapies

are lacking clinically. Extracellular vesicles (EVs) show initial promise as potential therapeutic carriers; however, their efficacy, safety in large animal models, and specific mechanisms regulating renal metabolic disorders remain unclear.
Methods: This study constructed engineered EVs targeting the kidney to deliver the key functional protein CD5L and evaluated their therapeutic potential in a preclinically relevant porcine S-AKI model. We employed a combination of biochemical assays, histopathology, multi-omics analyses (lipidomics and proteomics), molecular biology techniques, mitochondrial function assays, and a specific fatty acid oxidation (FAO) inhibitor (Etomoxir) to systematically assess the in vivo distribution, safety, efficacy, and mechanism of action of the EVs.
Results: Results showed that the engineered EVs effectively targeted injured kidneys, demonstrated good safety in the porcine S-AKI model, and significantly improved renal function, alleviated tissue damage, and restored microcirculation. Mechanistic studies revealed that EVs reduced renal lipid accumulation and acylcarnitine buildup by inhibiting fatty acid synthesis (FAS) and promoting FAO. This metabolic reprogramming further restored mitochondrial bioenergetic function (TCA cycle and ETC activity) and mitochondrial homeostasis (dynamic balance and enhanced autophagy). Critically, pharmacological inhibition experiments confirmed that the nephroprotective effect of the engineered EVs was entirely dependent on the restoration of the FAO pathway.
Conclusions: This study demonstrates for the first time in a large animal model that engineered EVs delivering CD5L can effectively ameliorate S-AKI by regulating FAO-dependent lipid metabolism reprogramming. This reveals that targeting renal lipid metabolism is a highly promising new strategy for S-AKI therapy and provides key preclinical evidence for developing related treatments.

Effect of alarm sounds on sleep in icu patients: a scoping review

FW. Hiemstra[1]; MJ. Van Kekem[2]; L. Kervezee[3]; DJ. Van Westerloo[2]
[1]Department of Intensive Care & Department of Neurophysiology, Leiden University Medical Center, Leiden, France; [2]Department of Intensive Care, Leiden University Medical Center, Leiden, Netherlands; [3]Group of Circadian Medicine, Group of Neurophysiology, Leiden University Medical Center, Leiden, Netherlands
Correspondence: F.W. Hiemstra
Intensive Care Medicine Experimental 2025,* 13(1):*001364

Introduction: The Intensive Care Unit (ICU) is a noisy environment, largely due to frequent alarm sounds generated by medical monitoring equipment [1]. Although monitoring alarms are essential for alerting health care staff to potential changes in a patient's condition, the alarm sounds may adversely affect patient's sleep, potentially worsening their recovery process [2].
Objectives: This scoping review aims to explore the impact of alarm sounds on the sleep of ICU patients, providing a comprehensive overview of the subjective and objective effects of alarms on sleep of ICU patients.
Methods: We conducted a scoping review in accordance with the PRISMA–ScR guidelines. Studies were eligible if they included adult ICU patients (≥ 18 years) and addressed the impact of audible alarms on patient sleep. Reviews, non-peer-reviewed articles, studies not set in an ICU, or those involving paediatric or healthy subjects were excluded. A systematic search was developed in collaboration with a medical librarian and conducted across PubMed, Embase, Web of Science, and Ovid Emcare. Titles and abstracts were screened independently by two reviewers using Rayyan. Eligible full-text articles were assessed based on predefined inclusion and exclusion criteria. Data extraction followed the JBI manual for scoping reviews, using a modified tool tailored to the review's objectives. Extracted data were synthesised in tables and described narratively to address the review questions.
Results: Out of 323 identified articles, 16 met the inclusion criteria. Fourteen studies assessed ICU patients' perceptions of audible alarms in relation to their sleep. Most patients reported alarms as a major cause of sleep disruption, with average disturbance scores ranging from 1.9 to 6.3 on a 0–10 scale. Between 21% and 91% of patients indicated that alarms negatively affected their sleep. In seven studies, alarms were identified as the most disruptive source of noise. Two interview studies revealed mixed perceptions, with some patients also describing alarms as reassuring. Three studies used objective measures of sleep (i.e., polysomnography) to assess alarm impact. Alarms were associated with frequent arousals, sleep fragmentation, and reduced deep sleep. Odds ratios for arousal due to alarms ranged from 4.9 to 10.9. Although patients subjectively rated alarms as highly disruptive, objective data showed that alarms accounted for only ~ 20–30% of arousals, indicating potential bias in self-reporting. No studies were identified that assessed the impact of alarm management strategies on ICU patients' sleep.
Conclusions: Audible alarms are a major contributor to sleep disruption in ICU patients, both in subjective reports and objective measurements. Despite being crucial for patient safety, alarms frequently cause arousals, fragmented sleep, and poor subjective sleep experience. Reducing alarm noise is essential to improve well-being and sleep of ICU patients. Further research is need to explore the effect of alarm reduction strategies—such as smart alarm algorithms, adaptive alarm settings, and behavioural interventions—to improve patient sleep and outcomes.

Long-term mortality within 180 days after ICU discharge: a secondary analysis of the ERIC trial

CS. Franke[1]; B. Weiss[1]; JJ. Grunow[1]; SK. Piper[2]; CD. Spies[1]; N. Paul[1]
[1]Department of Anaesthesiology and Intensive Care Medicine (CCM/CVK), Charité – Universitätsmedizin Berlin, Berlin, Germany; [2]Institute of Biometry and Clinical Epidemiology, Charité—Universitätsmedizin Berlin, Berlin, Germany
Correspondence: N. Paul
Intensive Care Medicine Experimental 2025,* 13(1):*001366

Introduction: Clinical trials in critical care assess mortality mostly in the ICU, hospital, or within 28 days after admission as primary or secondary outcomes [Gaudry et al. 2017]. The long-term mortality after discharge is rarely assessed, although this may have a key impact on trial design, findings, and interpretation [Iwashyna et al. 2018].
Objectives: To assess the post-ICU mortality within 180 days after ICU discharge in a large cluster-randomized ICU trial.
Methods: Secondary analysis of the large-scale stepped-wedge cluster-randomized Enhanced Recovery after Intensive Care (ERIC) trial (ClinicalTrials.gov: NCT03671447) [Spies et al. 2023, Adrion et al. 2020]. In 12 medical, surgical, and mixed ICUs in the metropolitan area of Berlin, Germany, patients with an expected ICU length of stay of ≥ 24 h, ≥ 18 years of age and statutory health insurance coverage were enrolled. The trial assessed the impact of daily telemedicine rounding (intervention) on the adherence to evidence-based quality indicators compared to usual care (control) [Kumpf et al. 2017]. This analysis included all patients discharged from the ICU alive. Patients were grouped based on tertiles of the Simplified Acute Physiology Score II (SAPS II) on admission. The post-ICU mortality within 180 days was assessed and compared between

SAPS II strata using Kaplan–Meier estimates and log-rank tests adjusted for multiple comparisons using Sidak correction. In a Cox proportional hazards model, we analyzed the association of severity of illness [first SAPS II and Sequential Organ Failure Assessment (SOFA) scores] and age with the 180-day post-ICU mortality. The model was adjusted for the study group as well as ICU cluster and included an interaction between the study group and SAPS II (i.e., that the effect of the telemedicine intervention varied based on patients' illness severity).
Results: Ten ICU clusters enrolled 1463 patients, of whom 1 patient was excluded and 158 patients died in the ICU, leaving 1304 ICU survivors that were included in this analysis. ICU survivors had a mean age of 66.9 (SD 14.8) years and a median ICU length of stay of 5 (IQR 2–11) days. Within 180 days after discharge, 242/1304 ICU survivors (19%) died. The SAPS II tertiles were 0–23, 24–39, and > 39 points. Patients in the third SAPS II tertile had a higher mortality (120/425 patients [28%]) than patients in the first (48/432 patients [11%]) and second (74/447 patients [17%]) SAPS II tertiles (both $p < 0.001$) (Fig. 1). In the Cox regression, the SAPS II (HR 1.02, 95% CI 1.01–1.04; $p = 0.001$), the SOFA (HR 1.05, 95% CI 1.01–1.09; $p = 0.02$), and age (HR 1.04, 95% CI 1.03–1.05; $p < 0.001$) were associated with an increased mortality risk (Table 1). We did not find a significant association of the intervention with 180-day post-ICU mortality or a significant interaction between the SAPS II and study group.
.

Table 1 Cox proportional hazards model for mortality within 180 days after ICU discharge. ICU, intensive care unit; SAPS II, Simplified Acute Physiology Score II; SOFA, Sequential Organ Failure Assessment

Variable	HR	95% CI	*p*
Age, years	1.04	1.03–1.05	< 0.001
SAPS II at admission	1.02	1.01–1.04	0.001
SOFA at admission	1.05	1.01–1.09	0.02
Study group, telemedicine intervention	1.45	0.77–2.74	0.25
ICU cluster	0.99	0.93–1.05	0.71
Interaction between study group and SAPS II	0.99	0.98–1.01	0.21

Conclusions: In this secondary analysis of a large ICU trial, a substantial proportion of patients died within 180 days after their ICU discharge. This finding underscores the importance of analyzing long-term mortality in ICU trials.

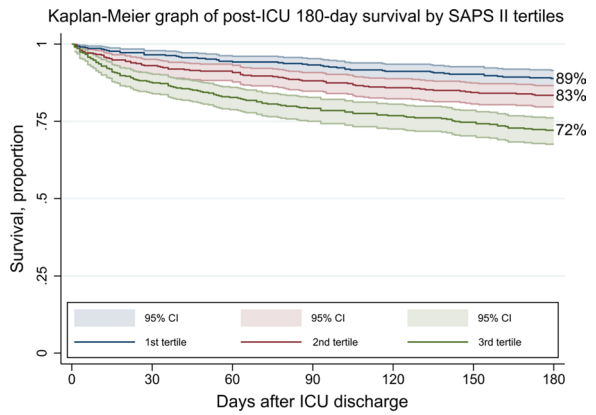

Figure 1 Kaplan–Meier estimate comparing the post-ICU survival within 180 days after discharge between SAPS II tertiles. First SAPS II tertile: 0–23 points; second SAPS II tertile: 24–39 points; and third SAPS II tertile: > 39 points

Correspondence: F.J. Ramírez Almaraz
Intensive Care Medicine Experimental 2025,* 13(1)*:001367

Introduction: Weaning is a process that accounts for almost 40% of the total duration of mechanical ventilation. Multiple strategies have been used to shorten this period: reduction of sedation and neuromuscular blockade doses, and spontaneous modes. Therefore, it is important to implement a series of strategies that favor the prompt removal of ventilatory support. In the weaning process, we use multiple predictors to determine which patients will have a successful extubation.
Objectives: To describe the clinical, ultrasonographic, and ventilatory variables associated with extubation failure during the weaning process.
Methods: A prospective, observational, single-center study was conducted over a 4-month period. Extubation predictors were collected, including NIF, P0.1, Tobin index, diaphragmatic ultrasound, IWI, CROP, and ExPreS scores, as well as swallowing and gag reflexes, and the cuff-leak test. After a successful spontaneous breathing trial, patients were extubated and monitored for 72 h to identify weaning failure. Statistical analysis was performed using IBM SPSS Statistics, version 29.0.1.1, applying Fisher's exact and Pearson's tests for qualitative variables. We use Kruskal–Wallis test for non-parametric variables.
Results: A total of 35 patients were included, 57% of whom were male, with a mean age of 44.4 years (range: 19–73 years). The average scores on mortality scales were SOFA 6.2, APACHE II 11.8, and SAPS II 30.4. Weaning was successful in 30 patients, while 5 experienced failure (14.29%). The causes of weaning failure were respiratory failure ($n = 3$) and excessive upper airway secretions ($n = 2$) (Fig. 1).
No statistically significant differences were found between the successful and failed weaning groups in terms of clinical or demographic characteristics. Among the evaluated predictors, only left diaphragmatic excursion and diaphragmatic velocity showed statistically significant differences ($p = 0.022$ and $p = 0.010$, respectively), as well as their association with the Visage scale ($p = 0.02$) (Table 1).

Conclusions: The incidence of weaning failure was 14.29%, lower than that reported in the literature (26–42%), possibly due to the use of a multidimensional approach involving multiple predictors. The only predictors that reached statistical significance were left diaphragmatic excursion and velocity, and their association with the Visage scale. Studies with larger sample sizes are needed to validate other predictors.

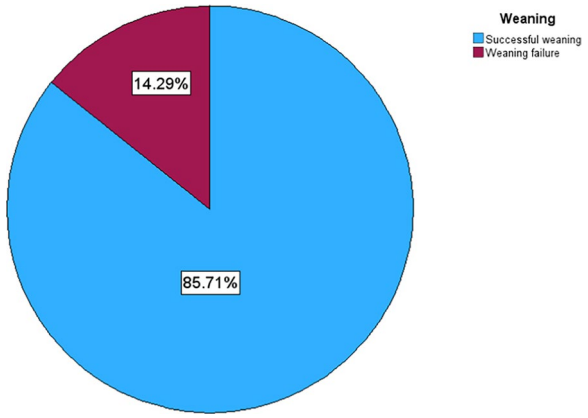

Figure 1 Incidence of weaning failure in the ICU

Intensive Care Medicine Experimental 2025,* 13(1)*:001369

Introduction: The management of severe trauma patients requires effective coordination and collaboration among healthcare teams. Leadership plays a key role and may influence the satisfaction of the professionals.

Objectives: To evaluate the impact of leadership frequency during the management of severe trauma on the satisfaction of healthcare professionals.

Methods: A survey was conducted during the "III Severe Trauma Symposium: Perspectives," using the Collaboration and Satisfaction About Care Decisions in Trauma (CSACD.T) tool. The survey included nine Likert-scale items (0–7), generating a total Satisfaction Score with the total score (Satisfaction Score) ranging from 9 (minimum collaboration) to 63 (maximum collaboration). Demographic and professional aspects of the participants were assessed, categorized according to the frequency of leadership during the care of trauma patients. Categorical variables were expressed as counts and percentages and compared using the χ^2 test or Fisher's exact test. Continuous variables were expressed as median and interquartile range (IQR) and compared using the Kruskal–Wallis test or ANOVA as appropriate. A two-tailed significance level of 5% was used.

Results: A total of 194 surveys were analyzed. 41% ($n = 79$) had never taken a leadership role, 29% ($n = 56$) had led in less than 50% of cases, and 30% ($n = 59$) had done so in more than 50%. The median age was 35 years (IQR: 30–46), with higher leadership frequency observed among older professionals (42 [33–41] years; $p < 0.05$). Women accounted for 68% ($n = 131$) of respondents. Among them, 49.6% had never led a trauma case, compared to 22% of men ($p = 0.001$). Conversely, 43% of men reported leading more than 50% of the time, vs. 24% of women ($p = 0.001$). The median Satisfaction Score was 36 points (IQR: 28–43), with significantly higher scores among those who led more frequently (non-leaders: 36 [27–40] vs. < 50%: 34.5 [26–42] vs. > 50%: 38 [32–49]; $p = 0.029$). The highest satisfaction quartile was more commonly reached by professionals who led in > 50% of their cases (15% vs. 31% vs. 39%; $p = 0.023$). Among those who had ever assumed leadership, men reported higher Satisfaction Scores (42 [34–52]) than women (32 [26–40]; $p < 0.001$). Regarding specialty, professionals in Critical Care had lower satisfaction levels compared to those working in Emergency Medicine or prehospital settings (ICU: 35 [28–42] vs. emergency: 50 [29–57] vs. prehospital: 48 [42–53]; $p < 0.001$). Table 1 summarizes the responses to each item in the survey.

Conclusions: The frequency of assuming leadership during the care of patients with severe trauma may influence healthcare professionals' satisfaction. Male professionals and those working in Emergency and Prehospital care reported higher satisfaction. Although overall levels of collaboration and communication were high, targeted strategies

may be needed to improve performance and integration within multidisciplinary teams, regardless of individual roles in trauma care.

Table 1 Responses to CSACD.T items according to leadership frequency.

CSACD.T Items	No Leadership n = 79	<50% Leadership n = 56	>50% Leadership n = 59	Total n = 194	p-value
Do nursing and medical staff jointly plan decisions regarding the initial care of patients? (Median [IQR])	4 (3–6)	4 (2.5–6)	4 (2–5)	4 (2–5)	0.028
Is there open communication between nursing and medical staff during patient care decisions?	4 (3–5)	4 (3–6)	5 (4–6)	4 (3–6)	0.095
Do nursing and medical staff share responsibility for patient care decisions?	3 (2–4)	3 (2–4)	3 (2–4)	3 (2–4)	0.926
Do medical and nursing staff cooperate in decision-making for patient care?	4 (2–4)	4 (3–5)	4 (3–5)	4 (3–5)	0.029
Are both nursing and medical concerns considered when making decisions about patient needs?	4 (3–5)	4 (3–5)	5 (3–6)	4 (3–5)	0,048
Are care decisions for patients coordinated between medical and nursing teams?	4 (2–4)	3 (3–5)	4 (3–5)	4 (3–5)	0.003
What is the level of collaboration between nursing and medical staff in patient care decisions?	4 (2–5)	4 (3–5)	5 (3–6)	4 (3–5)	0.004
What is your level of satisfaction with overall collaboration between medical and nursing staff during initial patient care?	4 (3–5)	4 (3–5)	5 (4–6)	4 (3–5)	0.023
What is your level of satisfaction with collaboration in your usual work setting?	4 (4–5)	5 (3–6)	5 (4–6)	5 (4–6)	0.058

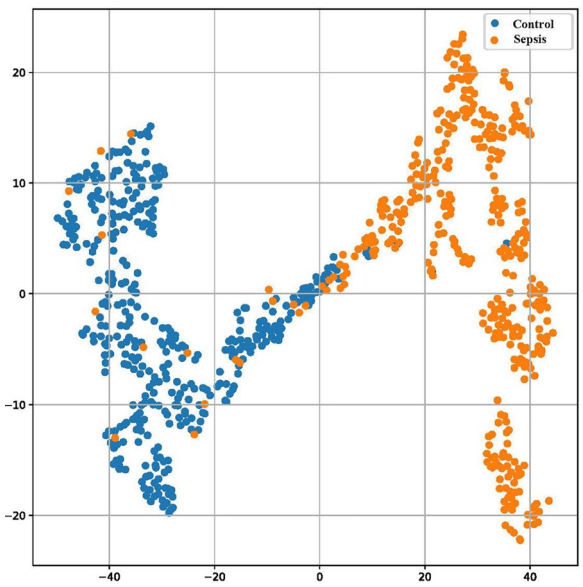
Rapid identification of pediatric sepsis using AI detection technology based on Raman spectroscopy

L. Wang[1]

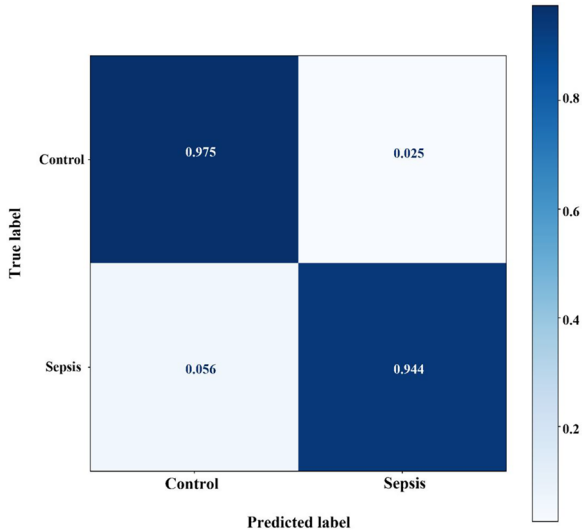
[1]National Children's Regional Medical Center, Zhejiang University School of Medicine, Hangzhou, China

Correspondence: L. Wang



Intensive Care Medicine Experimental 2025,* 13(1)*:001370

Introduction: Sepsis is a systemic inflammatory response syndrome caused by infections from bacteria or other pathogenic micro-organisms. The mortality risk in children with sepsis escalates exponentially with each hour of delayed treatment. Rapid and accurate diagnosis of pediatric sepsis is critical for reducing its associated high mortality. The Pediatric Sequential Organ Failure Assessment (pSOFA) score is widely employed for sepsis diagnosis in pediatric populations. However, its failure to incorporate infection-specific biomarkers necessitates supplementary time-consuming analyses, contributing to diagnostic delays and under-recognized cases. This study proposes an artificial intelligence (AI)-based Raman spectroscopy technique for the rapid diagnosis of pediatric sepsis.



Methods: Two microliters of serum were taken from 130 healthy pediatric controls and 180 children with sepsis. Raman spectra were collected for each serum, and a comprehensive spectral database was established. The spectra underwent preprocessing through self-normalization, and data sets were split into training, validation, and test sets at a 7:1:2 ratio. Utilizing the ResNet18 residual neural network architecture as a foundation, the 2D convolution in the network was adapted to 1D convolution to accommodate Raman spectrum. Optimal parameters were ascertained via simulation experiments. The model's weights were trained on the training set, followed by the selection of optimal hyperparameters grounded in the model's performance on the validation set. The trained convolutional neural network model underwent testing with the test set to appraise its classification efficacy.

Results: Raman spectrum is the fingerprint spectrum of matter. Sepsis can lead to significant changes in serum composition, including: elevated levels of inflammatory molecules and cytokines (e.g., IL-6 and TNF-α); abnormal concentrations of acute-phase proteins (e.g., C-reactive protein and procalcitonin); markers of metabolic disorders, such as lactic acid accumulation (indicating tissue hypoxia) and lipid peroxidation products (markers of oxidative stress); and pathogen-derived components, such as bacterial endotoxins (e.g., LPS) or fungal molecules (e.g., β-glucan). Raman spectroscopy can capture these sepsis-associated alterations with high sensitivity by the detection of children's serum. In this work, AI models were successfully constructed using serum Raman spectrum database of children with sepsis. The models achieved the following classification accuracies: 95.93% for distinguishing children with sepsis fromhealthy pediatric controls (Figs. 1 and 2).

Conclusions: This novel AI-based Raman spectroscopy technology provides a label-free, rapid, accurate, and cost-effective method for identifying children with sepsis. It holds a significant promise to reduce the high mortality rate caused by sepsis.

PCA score plots of the control and sepsis group.

Confusion matrix showing the maximum accuracy of 95.93%.

Exosomes derived from renal tubular cells drive the fibrotic progression from acute kidney injury to chronic kidney disease by activating the STING–Smo–Gli signaling axis

X. Dongxue[1]; Z. Peng[1]; Y. Li[2]

Introduction: The progression from acute kidney injury (AKI) to chronic kidney disease (CKD) represents a major clinical hurdle with incompletely defined molecular underpinnings. We investigated the role of exosomes derived from injured renal tubular cells, specifically focusing on their cargo Stimulator of Interferon Genes (STING), as key mediators in this transition.
Methods: We utilized unilateral ischemia–reperfusion (UIR) mouse models, including tubule-specific STING knockout (STING–CKO) mice. Methods involved exosome isolation and characterization, fibroblast co-culture experiments, in vivo administration of exosomes and pharmacological inhibitors (GW4869 for exosome release and CPN for smoothened), histological analysis, and molecular assessments of STING and Smo/Gli pathways.
Results: STING expression was upregulated in tubular cells post-AKI and enriched within secreted exosomes. These exosomes were internalized by interstitial fibroblasts, activating the smoothened–Gli (Smo–Gli) pathway and promoting fibrosis. STING–CKO mice exhibited significantly attenuated fibrosis, senescence, and maladaptive repair after UIR. Furthermore, inhibiting either exosome secretion (GW4869) or Smo/Gli signaling (CPN) mitigated kidney injury and fibrosis in vivo. The pro-fibrotic effects of tubular STING were confirmed to be predominantly mediated via this exosomal pathway.
Conclusions: This study identifies a critical tubular cell–STING–exosome–fibroblast Smo/Gli signaling axis driving the AKI-to-CKD transition. Our findings reveal a novel mechanism of intercellular communication in renal pathology and highlight targeting exosomal STING or the Smo/Gli pathway as potential therapeutic strategies to prevent CKD development after AKI.

This study unveils a critical and previously unrecognized intercellular communication axis in the progression from AKI to CKD: renal tubular epithelial cell-derived exosomes act as nanocarriers delivering functional STING protein to interstitial fibroblasts, thereby activating the pro-fibrotic Smo–Gli signaling pathway. We provide compelling evidence, demonstrating that STING is packaged into TEC exosomes following injury, and its subsequent transfer to fibroblasts is essential for driving maladaptive repair and fibrosis; this was substantiated by findings in STING conditional knockout mice and through pharmacological inhibition of either exosome secretion (GW4869) or smoothened activity (CPN), both of which significantly attenuated renal fibrosis. Crucially, our findings pivot the understanding of STING's pro-fibrotic role from a primarily intracellular mechanism to one significantly mediated by intercellular, nanoscale vesicle transport. These insights fundamentally reshape the mechanistic understanding of post-AKI fibrosis, highlighting a novel crosstalk between the innate immune sensor STING and the developmental Hedgehog pathway orchestrated by exosomes, and pinpoint the "TEC–STING–Exosome–Fibroblast Smo/Gli" axis as a high-potential target. Consequently, strategies aimed at inhibiting the release of STING-laden exosomes or specifically blocking downstream Smo–Gli activation in fibroblasts emerge as promising avenues for therapeutic intervention to halt the progression to CKD.

STING promotes metabolic rewiring-induced partial EMT in renal fibrosis

Y. LIU[1]
[1]Intensive Care Unit, Zhongnan Hospital of Wuhan University, Wuhan, China
Correspondence: Y. LIU
Intensive Care Medicine Experimental 2025,* 13(1)*:001372

Introduction: Studies have shown that the incidence of acute kidney injury (AKI) in critically ill patients is up to 40%, and about 10–30% of patients with AKI will develop chronic kidney disease (CKD). Renal fibrosis is the common pathophysiological process in the development of CKD, characterised by dedifferentiation of tubular epithelial cells, loss of peritubular capillaries, inflammatory cell infiltration, and fibroblast proliferation.
Tubular epithelial cells mediate renal fibrosis through partial epithelial–mesenchymal transition (EMT) and paracrine intercellular signaling. It is reported that metabolic reprogramming plays a key role in regulating tubular cell phenotype in renal fibrosis by impairing fatty acid oxidation (FAO) and generating ATP through aerobic glycolysis, which leads to intracellular lipid deposition and maladaptive repair.
Recently, studies have reported that the activation of stimulator of interferon genes (STING), an innate immune receptor, promotes pro-inflammatory responses in cisplatin-induced acute kidney injury. Researchers found that mitochondrial dysfunction can activate STING and cause tissue damage and fibrosis, while knocking out STING can significantly improve renal fibrosis. However, the tubular-specific role of STING in renal fibrosis remains unknown. It was found that STING can regulate the phenotypic changes of macrophages by inhibiting mitochondrial oxidative phosphorylation (OXPHOS) and promoting glycolysis, which illustrates the potential role of STING in regulating energy metabolism and cell fate. Here, in this study, we speculate that STING is activated in tubular epithelial cells during renal fibrosis and is involved in partial EMT through metabolic reprogramming.
Methods: The expression of STING was evaluated in human biopsies of hydronephrosis by IHC, and the downstream signaling was further investigated in murine kidneys after unilateral ureteral obstruction (UUO) by western blotting. In vitro, to elucidate the role of STING in tubules, we treated immortalized proximal tubular epithelial cells (IM-PTECs) with transforming growth factor-β (TGFβ) to induce partial EMT. The expression of STING and the downstream signaling were determined by western blotting and qPCR. The effect of STING activation on pEMT was investigated using STING inhibitor H-151 and was further explored through RNA sequencing analysis. Metabolic reprogramming was studied by the expression of FAO key enzymes and lactate production.
Results: STING activation and co-localization with fibrotic marker α-smooth muscle actin (αSMA) were observed in human biopsies of hydronephrosis and in murine kidneys after UUO by IHC and western blotting. In vitro, TGFβ-stimulated IM-PTECs presented the increased expression of STING. Moreover, STING inhibition rescued the TGFβ-induced partial EMT in vitro and attenuated early hallmarks of fibrosis in vivo, as determined by the reduced expression of αSMA and vimentin in UUO kidneys. RNA sequencing analysis revealed that the H151-mediated rescue of pEMT in IM-PTECs resulted from ameliorated mitochondrial functions, demonstrated by relieved mtDNA stress signaling, together with upregulated mtDNA content validated by qPCR. Further bioinformatic analysis among mitochondrial genes revealed enhanced FAO metabolism with STING inhibitor, which was further confirmed by overexpressed FAO key enzymes, such as *Cpt1a* and *Acox3*, while lactate production was significantly decreased by H-151.
Conclusions: STING is activated in tubular EMT during renal fibrosis, and the inhibition of STING alleviates tubular epithelial–mesenchymal transition through enhancing fatty acid oxidation, effectively improving mitochondrial abundance and reducing UUO-induced renal fibrosis.

Intensive Care Medicine Experimental 2025,* 13(1)*:001377

Introduction: Hemodynamic assessment is a cornerstone in the management of patients with severe trauma. However, the prognostic value of diastolic blood pressure (DBP) remains underexplored, particularly in patients with an initially stable hemodynamic profile.
Objectives: To evaluate the impact of DBP on clinical outcomes and resource utilization in hemodynamically stable patients with severe trauma.
Methods: A prospective cohort study including patients consecutively admitted to a Trauma and Neurocritical Care Unit between June 2023 and December 2024. We analyzed patients with severe trauma and initial hemodynamic stability, defined as a shock index (SI) < 0.9. The cohort was stratified into three groups according to DBP at the start of initial management: < 60 mmHg, 61–80 mmHg, and > 80 mmHg. Demographic variables, trauma severity, resource use, and complications were analyzed. The primary outcome was ICU mortality. Secondary outcomes included red blood cell (RBC) transfusion, activation of the massive transfusion protocol (MTP), hospital mortality, and length of stay in both ICU and hospital.
Categorical variables were expressed as counts and percentages and compared using the χ^2 test or Fisher's exact test. Continuous variables were reported as median and interquartile range (IQR) and compared using the Kruskal–Wallis test or ANOVA, as appropriate. A two-sided p value < 0.05 was considered statistically significant. Statistical analysis was performed using STATA version 13® (StataCorp LLC).
Results: A total of 391 patients were included. The median age was 54 years (IQR 33–71), and 77% (n = 300) were male, with no statistically significant differences between groups. Falls were the most frequent trauma mechanism (45%, n = 174), although high-energy trauma such as traffic accidents was more prevalent in the < 60 mmHg DBP group (40% vs. 37% vs. 25%; p < 0.05). Traumatic brain injury was present in 69% of patients, with no significant differences among groups. Abdominal trauma was more frequent in patients with DBP < 60 mmHg (37% vs. 21% vs. 11%; p < 0.05). No significant differences were found in severity scores (ISS, NISS, RTS, and TRISS), although patients with DBP < 60 mmHg had lower systolic and mean arterial pressures, reduced Diastolic Pressure Time Index, and higher SI values (Table 1). No differences were observed in ICU or hospital mortality, nor in length of stay. However, patients with DBP < 60 mmHg required more norepinephrine, RBC transfusions, and MTP activation, and had a higher incidence of trauma-induced coagulopathy (TIC) (Table 2).
Conclusions: In patients with severe trauma and initial hemodynamic stability, lower DBP at presentation does not appear to be associated with increased mortality. However, it may serve as an early marker of transfusion needs and higher risk of TIC, providing a potential value in early risk stratification and clinical decision-making.

Table 1 Hemodynamic status at initial assessment

Parameter	DBP < 60 mmHg (n=43)	DBP 60–80 mmHg (n=182)	DBP > 80 mmHg (n=166)	Total (n=391)	p-value
Shock Index, median (IQR)	0.71 (0.56–0.79)	0.63 (0.53–0.71)	0.59 (0.48–0.69)	0.62 (0.52–0.72)	< 0.001
Systolic BP (SBP), mmHg, median (IQR)	110 (95–120)	130 (120–140)	149 (135–160)	134 (120–150)	< 0.001

Introduction: Conscious sedation is a technique used to minimize discomfort and pain during invasive medical procedures, ensuring smoother execution. However, its application in bronchoscopy is still relatively uncommon.

Objectives: The aim of this study was to compare two sedative molecules: ketamine and midazolam during therapeutic and/or diagnostic bronchoscopy and to assess their efficacy and safety.

Methods: This was a prospective, single-blind interventional comparative study conducted in the Zaghouan's regional hospital over 9 months, including patients over 18 years with an indication for bronchoscopy with no contraindication to any of the proposed molecules. Patients' consent for sedation was obtained prior to the initiation of the procedure. After randomization (1:1), patients were divided into two groups: G1 = midazolam and G2 = ketamine. A comparison was made between both groups before, during, and after bronchoscopy. Sedation depth was assessed using the MOAAS score, and pain was measured on a numerical rating scale (NRS). The operator satisfaction was judged on a Likert scale.

Results: A total of 64 patients were included (32 patients in each group) with a median age of 62 years [51–72]. Epidemiological and clinical characteristics were similar between both groups. The median doses used were 18 mg of ketamine [16.5–20] and 1 mg [0.62–1] of midazolam. There was no significant difference in the degree of conscious sedation obtained according to the MOAAS score. The bronchoscopy duration was shorter in G2 (4 [3–5] min vs. 5 [3–6] min; $p = 0.026$). Pre- and post-procedural vital parameters were comparable. There were no differences in the minor adverse effects observed, except for tachycardia, which was more frequent with ketamine ($p = 0.006$), and cough with midazolam ($p = 0.014$). No major complications were observed. Pre-procedural pain was more intense in G1 (NRS = 2 [1–3.75] vs. 1 [0–2]; $p = 0.004$). Operator dis-satisfaction was more frequent with midazolam ($p = 0.011$).

Conclusions: Conscious sedation during bronchoscopy appears to be a safe and effective procedure. Both molecules proposed were comparable. However, ketamine provided greater operator satisfaction.

Topic: Sedation, analgesia and delirium.

Intensive Care Medicine Experimental 2025,* 13(1)*:001380

Introduction: Out-of-Hospital Cardiac Arrest (OHCA) remains a major global health challenge, significantly contributing to mortality and morbidity. Despite advances in pre-hospital management, OHCA is often associated with poor neurological outcomes and high mortality. In Portugal, there is limited information regarding post-OHCA survival, quality of life (QoL), and functional status. This study aims to address this gap by analyzing these outcomes.

Objectives: To evaluate survival, QoL, and performance status after OHCA.

Methods: This retrospective, single-centre study included consecutive adult OHCA patients admitted to an Intensive Care Unit (ICU) from January 2017 to December 2019. Data were collected from clinical records (pre-hospital, emergency room, ICU, and post-discharge) and telephone interviews with survivors. QoL was assessed using the Cerebral Performance Category (CPC) scale and EQ-5D-5L questionnaire, while performance status was measured with the Eastern Cooperative Oncology Group (ECOG) scale.

Results: Of the 72 patients (mean age 61 ± 15 years), 26 (36.1%) survived to hospital discharge. Most OHCA events (84.7%) were witnessed, with 70.8% receiving basic life support (BLS) and 22.1% BLS with automated external defibrillator (AED). The most common OHCA

location was at home (43.1%), and cardiac causes accounted for 68.1% of cases. A shockable rhythm was present in 51.4%. Higher Glasgow Coma Scale (GCS) scores after return of spontaneous circulation (ROSC) were associated with improved ICU ($p < 0.001$, V-Cramer = 0.565) and hospital ($p < 0.001$, V-Cramer = 0.625) survival rates.
At hospital discharge, 65% of survivors had a CPC score of 1 or 2. Five years later, 19 patients were alive, with 92.5% of interviewed survivors maintaining CPC scores of 1 or 2. Most survivors (50%) reported "no problems" in EQ-5D-5L domains. However, declines were noted in "Mobility," "Usual Activities," and "Anxiety/Depression." The EQ-5D-5L index was 0.903 (SD = 0.193). Regarding performance status, 64.3% of survivors were able to perform at least sedentary work (ECOG score ≤ 1).
Conclusions: A total of 36.1% of OHCA patients survived to hospital discharge, with higher GCS scores after ROSC linked to improved outcomes. Long-term follow-up revealed that most survivors reported good QoL and functional performance.

Intensive Care Medicine Experimental 2025,* 13(1)*:001386

Introduction: Recent evidence suggests that patients who respond to fluid administration may still have a sign of venous congestion. However, the behavior of the microcirculation in relation to venous congestion remains unclear. This study aimed to assess sublingual microcirculation before and after fluid challenge in critically ill patients with and without clinical signs of venous congestion.
Methods: Sublingual microcirculation was evaluated using the Cytocam at baseline and post-fluid challenge to measure Proportion of Perfused Vessels (PPV), Total Vessel Density (TVD), Perfused Vessel Density (PVD), and Microvascular Flow Index (MFI). The three highest-quality videos per timepoint, according to Massey Score, were manually analyzed using AVA 3.2 software. Patients were classified as congested based on the presence of ≥ 2 of the following criteria: VExUS score > 1, LUS score ≥ 10, central venous pressure > 10 mmHg, or lateral E/e' > 10. Patients with none or only one of these findings were categorized as non-congested. Fluid challenge consisted of 500 mL of crystalloids infused over 15 min.
Results: Ten critically ill patients were included in the interim analysis (median age 73.5 [59.4–79.6], SOFA score 7 [5–10.5], and SAPS II 53 [38.9–69.3]). A total of 60 microcirculatory videos were analyzed. Four patients showed no signs of venous congestion, two exhibited one sign, three had two signs, and one patient presented with three. At baseline, there were no significant differences in PPV, PVD, TVD, or MFI between groups. However, the mean MFI was lower in the congested group [mean 2.33 ($\pm$ 0.93)] compared to the non-congested group [mean 2.69 ($\pm$ 0.29)], suggesting impaired microvascular flow, albeit without statistical significance. Following fluid administration, PPV significantly increased in the non-congested group (from 95.43 [86.90–97.81] to 98.18 [96.44–98.78], $p = 0.03$, Fig. 1), whereas a slight, non-significant decrease was observed in the congested group (from 97.99 [77.69–99.01] to 94.81 [92.14–97.46], $p = 0.87$, Fig. 2). MFI increased no-congestion group after fluid challenge [from 2.69 ($\pm$ 0.30) to 2.89 ($\pm$ 0.15), $p = 0.06$], and a similar pattern was observed in patients with venous congestion, although values remained below 2.6 [from 2.33 ($\pm$ 0.93) to 2.54 ($\pm$ 0.37), $p = 0.59$]. TVD and PVD remained unchanged in both groups before and after fluid challenge.
Conclusions: In critically ill patients undergoing fluid resuscitation, those without signs of venous congestion demonstrate improvement in microcirculatory parameters, particularly PPV. Conversely, in the presence of two or more indicators of venous congestion, microvascular flow does not significantly improve following fluid administration.

Predictors of ICU mortality following a cardiac arrest: a retrospective study from a tertiary care centre

MG. Kaya[1]; R. Mahroof[1]; A. Conway Morris[1]
[1]Department of Intensive Care Medicine, Cambridge University Hospitals NHS Foundation Trust, Cambridge, United Kingdom
Correspondence: M.G. Kaya
Intensive Care Medicine Experimental 2025,* 13(1)*:001387

Introduction: Cardiac arrest (CA) is a leading cause of death globally with poor hospital survival, ranging from 8% for out of hospital CA (OOHCA) to 34% for in-hospital CA (IHCA)[1]. Initial measures such as high-quality CPR and early defibrillation improve survival [2]. Identifying predictors of good outcomes would optimize patient care and aid decision-making.
Objectives: The aim was to retrospectively analyze data on patients admitted to the ICU after OOHCA or IHCA to assess for predictors of ICU survival.
Methods: Patients admitted to a 32 bed UK University tertiary centre adult ICU after a CA from 1/23 to 1/25 were included. Electronic medical records (EMRs) were used to obtain data. A multivariable logistic regression analysis was performed. Odds ratios (OR) and 95% confidence intervals (CI) were calculated.
Results: 77 patients were identified in total. Median age was 61 (IQR 46–74) and 60% were male. Median ICU length of stay was 4 days (IQR 1–7). 60% had had an OOHCA. A majority of patients had a non-shockable primary cardiac rhythm (71%). The median downtime was 18 min (IQR 10–32.5) with shorter downtimes in the IHCA subgroup (median 10.5 min, IQR 5–30). Mean admission pH and lactate were 7.22 ± 0.16 and 5.54 ± 4.84, respectively. Eleven variables showed a significant association with ICU mortality in univariate analysis (Table 1) and entered the logistic regression model.
Stepwise model construction identified acute kidney injury (AKI; OR = 17.67, 95% CI 1.13–275.63, $p = 0.041$) and the use of neuromuscular blockade (NMB; OR = 8.27, 95% CI 1.01–67.88, $p = 0.049$) was independently associated with mortality, whereas the duration of inotrope use (OR = 0.928, 95% CI 0.884–0.975, $p = 0.003$), a more positive base excess on admission (OR = 0.837, 95% CI 0.709–0.989, $p = 0.035$), was associated with an increased survival. None of the other variables were significantly associated with outcome in this model.

Table 1 Variables identified as significant predictors of mortality in univariate analysis and following adjustment in multivariable logistic regression

Variable	Survivors	Non-survivors	Univariate *p* Value	Multivariate *p* Value
Downtime (mins)	14.5 (5–18)	25 (13–35)	0.013	0.503
Shockable rythm	40%	7.7%	0.01	0.315
Admission pH	7.34 (7.25–7.4)	7.18 (7.05–7.28)	< 0.001	0.714
Admission P/F ratio	31.7 (21–44.2)	21.99 (12.98–32.88)	0.018	0.136
Admission lactate	1.98 (1.50–3.03)	5.07 (2.79–10.18)	0.025	0.742
Admission base excess	− 4.1 (− 8.9– − 0.9)	− 10.85 (− 15.68– − 7.40)	< 0.001	0.036
Pyrexia in first 72 h	68%	36.5%	0.029	0.204
NMB use	12%	50%	0.006	0.049
Duration of inotrope infusion (hrs)	39 (16.5–83.5)	12 (0–50.5)	< 0.001	0.003
AKI	16%	51.9%	0.002	0.041

Conclusions: This study found that post-cardiac arrest AKI and the use of NMB were predictors of ICU mortality. Interestingly, factors thought to be predictive such as admission pH and lactate, downtime and fever were not found to be independent predictors of mortality in this cohort. Sample size and high number of variables are some of the limitations of this study.

Introduction: Continuous renal replacement therapy (CRRT) is widely used in critically ill patients. Different CRRT modalities—hemofiltration (CVVH), hemodialysis (CVVHD), and hemodiafiltration (CVVHDF)—as well as employed dialysis fluid bags, including citrate-containing fluids for regional anticoagulation, impact plasma electrolytes and strong ion difference (SID) differently. This in-vitro study was designed to investigate these effects.
Methods: The PrisMax (Baxter), an ST150 filter, and a 2L fluid reservoir ([Na +] = 140 mmol/L, [Cl-] = 99 mmol/L) were employed, with a constant blood flow (150 ml/min) without weight loss. Biphozyl (Baxter) (Na = 140 mmol/L, Cl = 122 mmol/L) and Phoxilium (Baxter) (Na = 140 mmol/L, Cl = 116 mmol/L) were used as dialysis and reinfusion fluids, respectively. Regiocit (Baxter) (Na = 140 mmol/L, Cl = 86 mmol/L) was used in predilution, mimicking regional citrate anticoagulation (RCA). Four in-vitro experiments were carried out as follows. CVVH: Regiocit 1500 ml/h, Phoxilium 1500 ml/h; CVVHD: Regiocit 1500 ml/h, Biphozyl 1500 ml/h; CVVHDF: Regiocit 1500 ml/h, Biphozyl 750 ml/h, Phoxilium 750 ml/h; CVVHD-noRCA: Biphozyl 1500 ml/h. Samples were collected from the fluid reservoir at baseline and every 30 min, up to 210 min. Electrolytes were measured using the Radiometer ABL800 Flex analyzer. Each experiment was repeated in triplicate.
A simplified SID was calculated as [Na +]- [Cl-].
Results: Although [Na +] decreased in all experiments, the reduction was smaller with CVVHD-noRCA (**Panel A**). A slight decrease in [Cl-] was observed in all experiments, except for CVVHD-noRCA, where [Cl-] increased by nearly 15 mmol/L (**Panel B**). As a result, the simplified SID was reduced in all experiments. Its reduction seems associated with the use of the chloride-rich biphozyl and was thus particularly pronounced in CVVHD-noRCA (**Panel C**).
Conclusions: CRRT has a marked effect on plasma electrolytes and acid–base, which depends upon the chosen modality and the employed dialysis fluid bags.

White: CVVHD-noRCA.
Red: CVVHD.
Blue: CVVHDF.
Black: CVVH.
& = $p < 0.05$ T210 vs.T0* = $p < 0.05$ vs. CVVHD at T210$ = $p < 0.05$ vs. CVVHD-noRCA at T 210.

Predicting ICU outcome after traumatic brain injury in patients admitted to a polyvalent ICU

L. Gaspar[1]; E. Lourenço[1]; J. Moreno[1]; S. Castro[1]; A. Binnie[1]
[1]Serviço de Medicina Intensiva 1, Unidade Local de Saúde do Algarve, Faro, Portugal, Faro, Portugal
Correspondence: A. Binnie
Intensive Care Medicine Experimental 2025,* 13(1):*001389

Introduction: Traumatic brain injury (TBI) is a frequent indication for intensive care unit (ICU) admission. Studies have shown that patients with TBI have better outcomes when cared for in specialized neurocritical care units (Sekhon et al., 2017). However, such specialized units are not available in many regional hospitals. In this study, we analyzed sequential TBI patients admitted to a polyvalent ICU in Portugal in 2024 to identify variables associated with good and poor outcomes in this population.
Objectives: 1. To characterize TBI patients admitted to a polyvalent ICU.
2. To identify variables associated with ICU survival and length of stay.
Methods: We conducted a retrospective observational cohort study of TBI patients admitted to a level 2 and level 3 polyvalent intensive care unit in Portugal in 2024. Patients with catastrophic brain injury admitted for organ donation assessment were excluded. Clinical and demographic data were collected from the electronic medical record. We used logistic and linear regression to analyze variables associated with ICU mortality and ICU length of stay (measured as days alive and out of the ICU to day 28), respectively.
Results: In 2024, 84 TBI patients were admitted to the polyvalent ICU with treatment intent. The median age of TBI patients was 57 (interquartile range [IQR]: 39, 72), and 24/84 (27%) were female. The median APACHE II score on admission was 7 (IQR: 3, 16), and the initial sequential organ failure (SOFA) score was 4 (IQR: 2.7). Invasive mechanical ventilation (IMV) was required in 40/84 (48%) patients for a median of 4.6 days (IQR: 1.6, 19.0), and an intracranial pressure (ICP) monitor was inserted in 21/84 (24.6%) patients for a median of 3.4 (IQR: 2.6, 4.7) days. At ICU discharge, 63 (75%) patients had improved, 11 (13%) were unchanged, 3 (3.6%) had worsened, and 7 (8.3%) had died. Non-survivors were older (77 vs. 56 years, $p < 0.001$), had higher APACHE II scores (median 28 vs. 7, $p < 0.001$), were more likely to be admitted to the level 3 ICU (100% vs. 36%, $p < 0.001$), were more likely to be mechanically ventilated (100% vs. 43.0%, $p = 0.004$), and were more likely to have an ICP monitor inserted (71.0% vs. 20.9%, $p = 0.006$). In regression models, the best predictor of ICU mortality was APACHE II score (ajusted r2 = 0.29), while the best predictors of ICU length of stay were male sex, SOFA score on admission, and the need for an ICP monitor.
Conclusions: In this TBI population, cared for in a polyvalent ICU, mortality was strongly associated with higher APACHE II scores on admission. Further studies are required to compare outcome prediction with existing scores such as the IMPACT score (Steyerberg et al., 2008; Yue et al., 2024).

Intensive Care Medicine Experimental 2025,* 13(1)*:001390

Introduction: Many intensive care unit (ICU) patients have heart failure. ICU treatments increase right heart load, requiring reliable parameters to assess right heart dysfunction (RHD).
Objectives: This study aims to investigate the degree of the right ventriculo-pulmonary artery (RV-PA) uncoupling [tricuspid annular plane systolic excursion (TAPSE)/pulmonary artery systolic pressure (PASP)] in the place of diagnosis of RHD in ICU patients.
Methods: We retrospectively analyzed ICU patients' echocardiographic and clinical data. 133 patients were included and stratified into tertile groups based on TAPSE/PASP ratio as < 0.30%, 0.30–0.50 and > 0.50. The diagnostic value of TAPSE/PASP was compared with other RHD parameters (figure).
Results: This study showed that as the TAPSE/PASP ratio decreased, the dimensions of both the right and left chambers of the heart progressively increased and left ventricle outflow tract velocity time integral and right ventricle outflow tract velocity time integral, stroke volume, cardiac output, and ejection fraction decreased. Compared with other RHD parameters, TAPSE/PASP better reflects right and left cardiac structural and functional changes and diagnoses in more patients. If TAPSE < 16 mm or RV-FAC < 35% is accepted as the gold standard for RHD, the matching TAPSE/PASP value was 0.48 mm/mmHg in this study population.

Table Echocardiographic characteristics by TAPSE/PASP tertile

TAPSE/PASP mean ± SD	Tertile 1 < 0.30	Tertile 2 0.30–0.50	Tertile 3 > 0.50	*p*

Intensive Care Medicine Experimental 2025,* 13(1)*:001392

Introduction: With chimeric antigen receptor-*T* (CAR-*T*) cells being a growing therapeutic strategy for a variety of hematological diseases [1], intensivists are increasingly confronted with severe clinical complications. The two most common ones result from an overwhelming release of cytokines like IL-6 and are termed CAR-T-associated cytokine release syndrome (CRS) and the immune effector cell-associated neurotoxicity syndrome (ICANS) [2, 3]. CRS almost always precedes ICANS, which is characterized by neurological symptoms that can vary from light encephalopathy, up to cerebral edema and death [3]. As of today, tocilizumab (TOCI) is the treatment of choice against CRS, as it antagonizes peripheral IL-6 receptors [2]. However, TOCI is unable to cross the BBB [4], to the contrary to the rather small molecule IL-6. Both the rise of circulating IL-6 levels following TOCI administration [5] and its potential neurotoxic effects have been described [6]. Thus, it has been postulated that TOCI might worsen ICANS [7].
Objectives: The objective is to investigate first the predictive value of IL-6 kinetics through TOCI application and second of IL-six levels before TOCI for the later development of ICANS.
Methods: In the participating centers, Zurich (Switzerland) and Hannover (Germany), data were extracted retrospectively from patients diagnosed with CRS after CAR-T cell therapy, who received TOCI and had information about disease severity and longitudinal IL-6 levels. IL-6 levels within 24 h before TOCU administration, IL-6 levels up to 48 h after Toci administration, as well as the difference of these values were analyzed in respect of the occurrence of high-grade ICANS (grade 4) and the administered CAR-T product. The prediction of high-grade ICANS was evaluated with a logistic regression model and receiver operating characteristic (ROC) curves with Youden index.
Results: In a pre-analysis of 98 CAR-T cell patients of the University Hospital Zurich, 34 individuals that received TOCI and had available IL-6 and outcome data were included. Patients had a median age of 62 [interquartile range (IQR) 58–69] years and were predominantly male (65%). The most common indication for CAR-T cell therapy was diffuse large B-cell Lymphoma in 28 (82%) patients. Hospital survival in this cohort was 100%. ICANS grade 4 occurred in 12 (35%) patients. These patients had a significantly higher IL-6 increase across TOCI administration (Table 1). Furthermore, the prevalence of ICANS grade 4 was significantly higher in patients with Yescarta® ($p = 0.014$, Table 1).
Logistic regression with IL-6 difference as only predictor resulted in an ROC with area under the curve of 72%. The best treshold was found at 1734 ng/L with a sensitivity of 83% and a specificity of 73% for ICANS grade 4. Including the CAR-T product as a second predictor in the logistic regression model led to an area under the curve of 92% (Fig. 1). For presentation at Lives 2025, the final analysis for all patients from both centers will be available.
Conclusions: The kinetics of IL-6 before and after the application of TOCI has a predictive value for high-grade ICANS. Consideration of CAR-T cell product may further improve the predictive ability. This should be confirmed in prospective studies, as it could enable the timely identification of high-risk patients potentially allowing for early prophylactic treatment.

A decade of automated data: what can it tell us about risk factors for reintubation?

S. Manrique[1]; P. Orts[1]; G. Sirgo[2]; J. Berrueta[1]; L. Pérez-áLvarez[1]; A. Rodriguez[1]; M. Bodi Saera[1]

Intensive Care Medicine Experimental 2025,* 13(1)*:001393

Introduction: Reintubation is a common complication in critically ill patients and is associated with worse outcomes, including increased mortality, longer ICU stays, and higher rates of ventilator-associated pneumonia. Classical studies have explored its risk factors, but often relied on limited data sets and manual data collection. The use of real-world data extracted automatically over extended periods offers a

unique opportunity to gain deeper, more comprehensive insights into this clinically relevant event.
Objectives: To explore risk factors for reintubation using clinical variables automatically extracted from the Clinical Information System (CIS). Secondary objectives included analyzing the clinical impact of reintubation and examining trends in reintubation rates over a 10-year period.
Methods: We conducted a retrospective, single-center observational study in a 28-bed polyvalent ICU at Hospital Universitari de Tarragona Joan XXIII (Spain) from January 2014 to December 2024. We included all patients over 18 years of age who received invasive mechanical ventilation (IMV) for more than 48 h. Exclusion criteria were: limitation of life-sustaining treatment before extubation, never extubated (due to tracheostomy, transfer, or death), or unplanned extubation. Reintubation was defined as extubation failure occurring within 48 h after extubation. Data were automatically extracted from the CIS using SQL and Python. Univariate analysis was performed using the Kruskal–Wallis test for continuous variables and chi-square for categorical variables. A multivariate logistic regression analysis was also conducted. Statistical significance was set at $p < 0.05$.
Results: A total of 62 clinically relevant variables were selected and successfully extracted automatically with a mean missing data rate of 6.5%, which decreased progressively over time. Among 1329 patients included, 152 (11%) were reintubated. Univariate analysis showed that reintubated patients had longer exposure to midazolam, lower Glasgow Coma Scale scores, higher heart rate (HR), higher pressure support (PS), and lower median SpO_2 in the 6 h preceding extubation. They also had longer duration of IMV and ICU stay prior to extubation. Antibiotic administration within 24 h prior to extubation was associated with a lower risk of reintubation. Classical risk factors—such as age, COPD, obesity, or heart failure—were not significantly associated with reintubation, except for prolonged IMV duration.
In the multivariate model, only higher HR and PS were independently associated with increased risk of reintubation. Recent antibiotic use showed a protective effect (Fig. 1). Reintubated patients had significantly longer ICU stay, longer duration of IMV, higher rates of ventilator-associated pneumonia, and higher ICU mortality, consistent with findings from previous studies.
Over the 10-year study period, reintubation rates declined from 10% to 20% in the early years to 6–8% in recent years, and from 12% before protocol implementation to 7% after (Fig. 2).

Conclusions:

1. Automated extraction of clinical data about reintubation is feasible and enables robust identification of reintubation risk factors in critically ill patients.
2. Longer mechanical ventilation, higher PS, and elevated heart rate increased risk of reintubation, while antibiotic seems to reduce it.
3. Reintubated patients have worse clinical outcomes.
4. Reintubation rates have declined over the past decade, coinciding with structured protocol implementation.

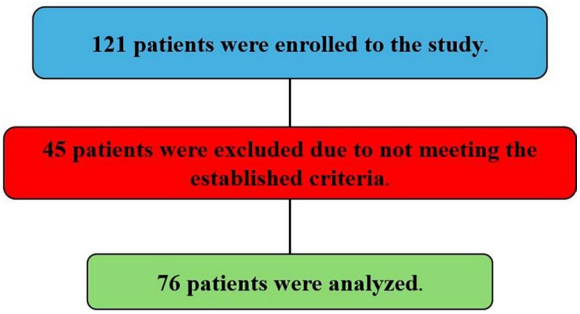
Intensive Care Medicine Experimental 2025,* 13(1)*:001394

Introduction: The EASIX, a prognostic tool utilized for predicting mortality and outcomes in hematological malignancies, has been demonstrated to be useful in risk stratification for sepsis in a limited number of retrospective studies (1–3). However, further validation is necessary to ascertain its efficacy in predicting mortality and prognosis in patients with sepsis.
Methods: The study was conducted between 09.01.2024 and 03.31.2025. Adult patients (≥ 18 years) with a diagnosis of sepsis were included in study after ethics committee approval (date: 03.09.2024, IRB no: 2744). Sepsis/septic shock and AKI were defined based on SEPSIS 3 and KDIGO guidelines, respectively (4.5). The EASIX score was calculated as follows: serum LDH U/L x creatinine level mg/dL/platelet



count × 109/mL. The relationship between the EASIX score and mortality was assessed using multivariate logistic regression and decision trees.
Results: Of the 76 patients included in the study, 42 (55.3%) survived (Fig. 1). The analysis revealed that deceased patients exhibited significantly higher rates of shock and the necessity for invasive mechanical ventilation ($p < 0.001$) and higher LDH, BUN, lactate, and EASIX scores and lower albumin levels compared to survivors (Table 1).

Table 1 Unadjusted vs. adjusted

	Mortality			Mortality		
Predictors	***Odds Ratios***	***std. Error***	***Statistic***	***Odds Ratios***	***std. Error***	***Statistic***
(Intercept)	0.31 ** (0.14–0.62)	0.12	-3.10	0.29 (0.00–33.94)	0.71	-0.51
Albumine				0.86 (0.72–1.00)	0.07	-1.88
MV: none	*Reference*			*Reference*		
MV: int				56.50 ** (6.14–1642.05)	76.86	2.97
EASIX	1.38 ** (1.14–1.79)	0.16	2.73	1.61 * (1.17–2.57)	0.33	2.37
Lactate				1.40 * (1.05–2.04)	0.23	2.09
Observations	76			76		
R2 Tjur	0.203			0.533		

*MV: Mechanical Ventilation, * $p < 0.05$ ** $p < 0.01$ *** $p < 0.001$*

The univariate logistic regression revealed that an increase in EASIX scores was significantly associated with increased risk of mortality (OR = 1.38; 95% CI 1.14–1.79; $p < 0.01$; Tjur's $R^2 = 0.203$). This association remained statistically significant after adjusting for albumin, the necessity for mechanical ventilation, and lactate levels. The decision tree method (Fig. 2) validated the effect of EASIX score and mechanical ventilation in predicting mortality.
Conclusions: The preliminary findings of the present study, which are scheduled for completion in January 2026, demonstrate that EASIX score can be easily used to predict mortality in sepsis patients. Future studies should evaluate its validation in other settings such as postoperative patients.

Intensive Care Medicine Experimental 2025,* 13(1)*:001395

Introduction: Ventilator-associated pneumonia (VAP) due to Enterobacteriaceae represents a serious complication in burn patients, contributing to important morbidity and mortality.
Objectives: To determine the incidence, associated risk factors, and mortality related to Enterobacteriaceae-induced VAP inburn patients.
Methods: A retrospective study was conducted over a 2-year period (2022–2023) in Intensive Burn Care Department in Tunisia. Adult burn patients who developed VAP caused by Enterobacteriaceae were included. VAP diagnosis was based on the criteria established by the French Society of Anesthesia and Intensive Care (SFAR). Patients with VAP due to Enterobacteriaceae were compared to those with VAP from other pathogens to identify associated risk factors.
Results: During the study period, 856 patients were hospitalized burn patients, and 214 (25%) required invasive mechanical ventilation. A total of 79 VAP episodes were recorded in 64 patients, averaging 1.23 episodes per patient. Of these, 50 episodes (63.3%) were attributed to Enterobacteriaceae. The median patient age was 44 years [31.2–45 years], with a male-to-female ratio of 3.88. A majority of patients

(n = 35; 79.5%) were transferred from other hospitals. Thermal burns accounted for 91% of cases, and 57% were due to self-immolation. The mean total body surface area (TBSA) burned was 42.7 ± 20.3%. Polymicrobial VAP was observed in 72.7% of cases. The most frequently isolated Enterobacteriaceae were *Klebsiella pneumoniae* (52%), *Providencia stuartii* (34%), *Proteus mirabilis* (14%), *Enterobacter cloacae* (8%), *Escherichia coli* (6%), *Klebsiella oxytoca* (4%), and *Enterobacter aerogenes* (2%). These isolates were multidrug-resistant bacteria in 64% of cases, with resistance to carbapenems in 46% of cases, fluoroquinolones in 68% of cases, and aminoglycosides in 54% of cases. Independent risk factors associated with Enterobacteriaceae-related VAP included a history of psychiatric disorders (OR: 5.786; 95% CI [1.218–27.491]; p = 0.027), higher APACHE II scores (p = 0.028), and eosinopenia with a cutoff of 35 cells/mm^3 (p = 0.013, AUC: 0.669, sensitivity: 74%, and specificity: 65.5%) (Fig. 1). Septic shock was observed in 96% of cases and acute respiratory distress syndrome (ARDS) in 56% of cases. Recurrence of infection was reported in 22% of cases. Attributable mortality for Enterobacteriaceae-related VAP was 50%.

Conclusions: In our series, VAP due to Enterobacteriaceae is frequent (63%) in burn patients, commonly caused by Klebsiella pneumoniae, Providencia stuartii, and Proteus mirabilis, with high antimicrobial resistance and attributable mortality of 50%.

Correspondence: H. Li
Intensive Care Medicine Experimental 2025,* 13(1)*:001396

Introduction: Acute respiratory distress syndrome (ARDS), caused by inflammation-mediated alveolar and endothelial injury, is a life-threatening condition with high mortality rates in the intensive care unit [1, 2]. Since the COVID-19 epidemic, ARDS cases surged around the globe, raising significant concerns regarding the absence of clearly defined therapeutic strategies [3]. In addition, the underlying pathophysiology of COVID-19-related ARDS remains unclear. In recent years, proteomic analysis has become a powerful tool to explore the host's molecular response to viral infections [4]. Longitudinal serum proteomic profiling in patients with COVID-19-related ARDS holds promise for identifying biomarkers and potential therapeutic targets.

Objectives: In this study, we investigate the dynamic changes in serum proteomic profiles of COVID-19-related ARDS patients and identify differentially expressed proteins associated with different clinical outcomes.

Methods: This is a prospective cohort study on critically ill COVID-19 ARDS patients without coexisting lung infections. After the diagnosis of ARDS, serum samples were collected at the baseline, 3 days after the diagnosis, and 6 days after the diagnosis. Mass spectroscopy was used to identify and quantify protein expressions. Differential expression analysis between the three timepoints and the subgroups stratified by ventilator-free days (VFD) was conducted using the Welch's t test. Multiple testing correction was applied using the Benjamini–Hochberg method. Functional enrichment analysis, such as gene ontology and KEGG pathway analysis, was used to characterize the biological activities of differentially expressed proteins.

Results: We collected serum samples from 17 patients diagnosed with COVID-19-related ARDS at three timepoints for proteomic profiling. In total, 5075 proteins were identified (Fig. 1). A marked shift in protein expression was observed between baseline and day 3, with 132 proteins upregulated and 45 proteins downregulated. In contrast, only three proteins were significantly upregulated between day 3 and day 6 (adjusted $p < 0.05$, $|\log_2 FC| > 1$). Gene ontology analysis showed that the most enriched upregulated proteins were associated with membrane, cytoplasmic, and mitochondrial activities (Fig. 2). Subgroup analysis between patients with different ventilator-free days within 28 days (VFD > 7 vs. VFD ≤ 7) further identified multiple differentially expressed proteins (Fig. 3). Several proteins were differentially expressed at more than one timepoint, and two proteins, NDUFAF3 and KIF1B, were consistently differentially expressed at all three timepoints.

Conclusions: This study demonstrates a significant proteomic shift in the disease progression of COVID-19-related ARDS, particularly within the first 3 days after diagnosis. Proteins associated with membrane, cytoplasmic, and mitochondrial activities were notably upregulated. Subgroup analysis based on ventilator-free days identified several proteins differentially expressed across multiple timepoints, suggesting their potential as biomarkers for different clinical outcomes.

The impact of intra-abdominal pressure on urine output in postoperative cardiac surgery patients: insights from continuous monitoring

F. Günther[1]; A. Prasad[1]; SCS. Rivrud[1]; M. Van Meurs[1]; MW. Nijsten[1]; J. Koeze[1]; M. Smit[1]
[1]Department of Critical Care, University Medical Center Groningen, Groningen, Netherlands

***Intensive Care Medicine Experimental 2025,* 13(1)**:001397

Introduction: Acute kidney injury (AKI) is a multifactorial condition, with postoperative cardiac surgical patients representing a distinct subgroup of critically ill patients. This study aims to investigate the effect of intra-abdominal pressure (IAP) on urine output (UO) in postoperative cardiac surgery patients during the stay in the Intensive Care Unit (ICU).
Methods: In this prospective pilot study, patients aged 18 years or older undergoing cardiac surgery with subsequent postoperative admission to the ICU of the University Medical Center Groningen (UMCG) were considered eligible for inclusion. UO and IAP were measured continuously via the bladder using the Accuryn Monitoring System (Accuryn Medical, Hayward, CA, USA) during ICU stay. Trends in IAP and UO were explored, and correlations between both their absolute values and their changes over time were assessed using Spearman's rank correlation. Finally, a linear mixed effect model was fitted to assess the fixed effect of IAP on UO while accounting for inter-patient variability through random effects.
Results: Thirty-six patients were included in this study, with a total of 3531 observations (Fig. 1). Eighteen patients developed AKI based on UO, according to the Kidney Disease: Improving Global Outcomes (KDIGO) criteria [1]. The median ICU length of stay was 18.3 h at the ICU (IQR 12–25). The median UO per 15 min was 0.5 ml/kg/hr (IQR 0.3–0.8), and the median IAP was 15.2 mmHg (IQR 12.4–18.5). The correlation between IAP and UO was − 0.3 ($p < 0.001$), while the correlation between changes in IAP and changes in UO was not statistically significant (0.02, $p = 0.25$) (Fig. 2). The linear mixed-effects model showed that IAP was negatively associated with logarithmically transformed hourly UO ($\beta = -0.067$, 95%CI − 0.08–(− 0.05), $p < 0.001$) (Fig. 3). One mmHg increase in IAP was associated with an estimated 6% decrease in UO.
Conclusions: In this exploratory pilot study, a linear mixed-effects model revealed a significant negative association between increased intra-abdominal pressure and urine output. Urine output in postoperative cardiac surgery patients during their ICU stay appears to be influenced by multiple factors, highlighting the need for further research to better understand these relationships.

Introduction: The use of steroids in severe community acquired pneumonia (CAP) has been shown to reduce mortality, and the society of Critical Care Medicine (SCCM) recommends the administration of corticosteroids in patients with septic shock and also patients hospitalized with severe CAP [1, 2].
Objectives: To investigate the use of corticosteroids in patients admitted to our intensive care unit (ICU) with severe CAP and the association of steroid use with vasopressor requirements, acute kidney injury (AKI) and ICU length of stay (LOS).
Methods: Patients admitted to ICU with CAP between April 2024 and April 2025 were identified using our electronic patient system. The use of steroids in these patients was investigated and summarized using descriptive statistics. Severe CAP was defined as per Dequin et al. [1], and steroid and vasopressor dose were described as hydrocortisone and noradrenaline equivalent, respectively [3]. Numerical variables were analysed using Wilcoxon rank sum test.
Results: We identified 29 patients admitted to our ICU with severe CAP. Fourteen (48%) had no vasopressor requirements, 15 (52%) required vasopressors, and 11 (38%) had a significant vasopressor requirement with noradrenaline equivalent dose of > 0.1 mcg/Kg/min. Of the patients with no vasopressor requirements, 6 (43%) received steroids and all survived. ICU LOS for the patients with severe CAP and no vasopressor requirements was 4.5 [3.25, 5] vs. 6 [5, 7.5] days, $p = 0.04$ for those that had steroids vs. those that did not (Fig. 1). Mean maximum steroid dose for those patients was 160 mg for 6 [3.5, 10.75] days. The incidence of AKI was similar in the patients with severe CAP who received steroids and those that did not (29% vs. 27%).
Of the patients that required vasopressors, eight (53%) received steroids and of the patients that had a significant vasopressor requirement, and six (55%) received steroids. Vasopressor dose for patients with severe CAP that survived ICU admission was 0.111 [0.036, 0.261] for those that had steroids vs. 0.184 [0.178, 0.21] for those that did not, $p = 0.56$ (Fig. 2).
Conclusions: Despite SCCM recommendations, under half of patients with severe CAP received steroids, and only about half with septic shock and significant vasopressor requirements were prescribed them. Our analysis showed significantly lower ICU LOS in severe CAP patients without septic shock who received steroids. Given the demonstrated mortality benefit of corticosteroids and the cost and bed pressures of prolonged ICU stays, education on their use in severe CAP—with or without septic shock—must be improved.

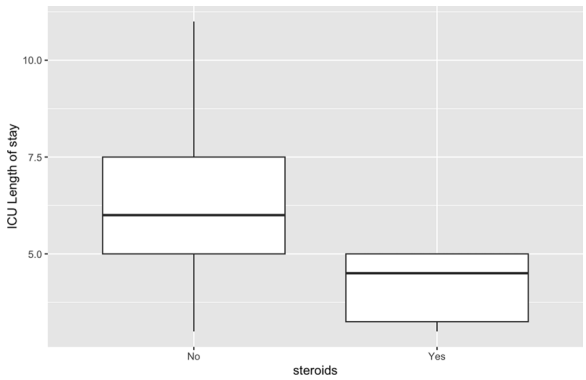

Figure 1 Boxplot of ICU LOS (days) for patients with severe CAP and no septic shock who did not and did receive corticosteroids

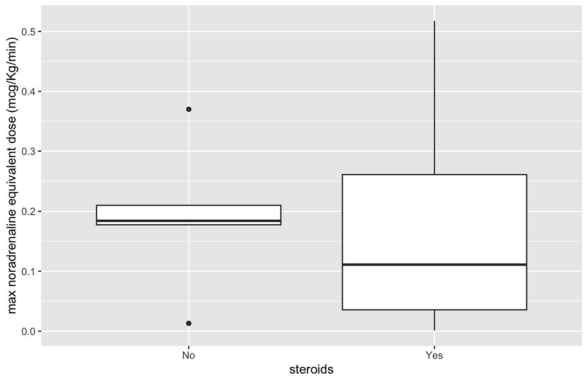

Figure 2 Boxplot of maximum noradrenaline equivalent dose (mcg/Kg/min) for patients with severe CAP who survived ICU admission and did not or did receive corticosteroids

Intensive Care Medicine Experimental 2025,* 13(1)*:001400

Introduction: Sepsis diagnostics rely on blood cultures to identify bloodstream infections and guide antibiotic treatment. However, blood culture results may take 2–5 days, possibly delaying targeted therapy and leaving Intensive Care Unit (ICU) patients on broad-spectrum antibiotics without a confirmed source (1). Moreover, blood cultures may be unreliable after antibiotic use or for uncultivable pathogens (2).
Objectives: To evaluate a DNA-based method for broad-range bacterial detection in whole blood, delivering same-day results.
Methods: In an ongoing ICU study, 274 blood samples from 115 patients suspected of sepsis were collected alongside routine blood cultures. After human DNA depletion (Polaris, Philips), a broad-range PCR-based method targeting the 16S-23S bacterial DNA interspace (Molecular Culture®, Inbiome) was used, delivering results within 6 h. Molecular findings were compared with blood cultures and further validated using other patient cultures and clinical data.
Results: Blood cultures detected a pathogen in 47/274 samples; the molecular method in 63/274 samples. At the patient level, 24/115 patients had at least one positive blood culture vs. 34/115 by the molecular method. Overall, there was an 84% concordance between the molecular method and blood cultures (Fig. 1). Of these 84%, 79% were direct matches between molecular results and blood cultures taken simultaneously from the same anatomical location. An additional 3% of matches occurred when the molecular method identified bacteria missed by the corresponding blood culture but confirmed by other patient cultures taken at different times or from different anatomical sites. Another 2% of matches involved cases, where the molecular method did not detect bacteria, while blood cultures did, but these were classified as contaminants rather than true pathogens. Outside of the 84% concordance, in 5% of cases, the molecular method failed to detect a pathogen found by blood culture due to factors, such as low bacterial signal, the presence of yeast (not included in the bacterial molecular method), or other technical limitations. In 1% of the cases, each method identified different pathogens. In addition, the molecular method detected bacteria in an extra 10% of samples that were negative by blood culture. These additional detections seem to align with the patient's clinical course, including fever episodes and increases in inflammatory markers such as CRP, suggesting their potential clinical relevance.
Conclusions: This DNA-based method allows rapid bacterial detection from the same blood volume as cultures, shows strong concordance, and identified bacteria in an additional 10% of cases missed by blood cultures. This speed and knowledge could provide greater insights into the infection process of patients suspected of sepsis.

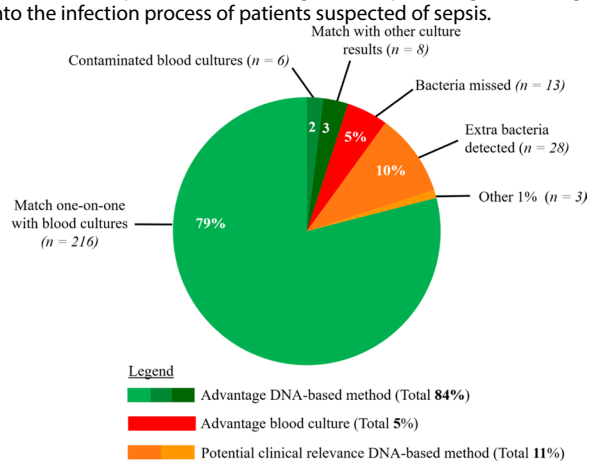

Figure 1 *Comparison of results from DNA-based method compared to traditional blood culture.*

Intensive Care Medicine Experimental 2025,* 13(1)*:001401

Introduction: Frailty is a multidimensional syndrome characterized by the loss of physiological reserves, which predisposes individuals to increased mortality, dependency, and institutionalization. It is independent of age and can occur in younger patients (< 65 years), although most studies exclude this group. The aim of this study is to analyze the impact of frailty and pre-frailty on the prognosis of critically ill patients and the factors associated with hospital mortality.
Methods: Prospective observational cohort study in a medical–surgical ICU. All patients admitted between October 2016 and May 2019 were included, except those transferred from other centers. Frailty was assessed based on the patients' pre-ICU physical condition using the nine-point Canadian Clinical Frailty Scale (CFS). Patients were categorized as non-frail (CFS $\leq$ 3), pre-frail (CFS = 4), and frail (CFS $\geq$ 5).
Categorical variables were described using frequencies and percentages, and continuous variables using medians and interquartile ranges or means and standard deviations. A multivariable logistic regression analysis was performed to evaluate significant differences between the three frailty categories, particularly regarding mortality. In addition, a univariable logistic regression was conducted to identify risk factors for hospital mortality in the frail–pre-frail group, followed by a multivariable analysis including statistically significant variables.
Results: A total of 1462 patients were included: 1141 non-frail, 250 pre-frail, and 71 frail. Median age was 66 years (range 15–93). ICU survival was 96.8% and hospital survival 93.8%. Higher hospital mortality was observed in pre-frail patients (RR 4.04 [2.11–7.74]) and frail patients (RR 5.88 [2.45–14.10]).
In the frail–pre-frail group, four factors were associated with increased hospital mortality, with no statistically significant differences in age: days of hospital stay prior to ICU admission (RR 1.08, CI 1.01–1.16), higher severity on admission (SAPS 3) (RR 1.07, CI 1.03–1.12), and the development of neurological deterioration (RR 4.14, CI 1.23–13.98) and/or thrombocytopenia (RR 11.46, CI 2.21–59.42) during ICU stay.
Conclusions: These findings support the identification of frailty and pre-frailty in all ICU patients, regardless of age, due to their association with increased hospital mortality. Mortality-related factors include pre-ICU hospital stay, illness severity at admission, and the occurrence of neurological deterioration and/or thrombocytopenia during ICU admission.

Intensive Care Medicine Experimental 2025,* 13(1)*:001402

Introduction: The triglyceride–glucose (TyG) index is regarded as a dependable biomarker to gauge insulin resistance. The present work utilized standard blood tests to evaluate this cost-effective biomarker for its efficacy in predicting acute kidney injury (AKI) prognosis and the severity of acute pancreatitis (AP).
Methods: In the present retrospective cohort study, AP patients were recruited from the First College of Clinical Medical Science of China Three Gorges University between January 2019 and October 2023; a total of 1470 patients were included in the study. The TyG index was calculated as follows: ln [serum triglyceride (mg/dL) × serum blood glucose (mg/dL)/2]. Logistic regression models, curve fitting, sensitivity analyses, subgroup analyses, and receiver operating characteristic (ROC) curves were employed to assess the predictive efficacy of the TyG index.
Results: Among the included 1470 AP patients, 250 (17%) and 166 (11.3%) patients had AKI and severe acute pancreatitis (SAP), respectively. TyG was positively correlated with AKI and AP severity. TyG showed a positive linear relationship with both A*P* severity (P for non-linearity: 0.491, OR 2.06, 95% CI 1.04–4.1) and AKI (P for non-linearity: 0.966, OR 2.34, 95% CI 1.2–4.54). In addition, the correlation strengths of the TyG index with AP severity and AKI were revealed through sensitivity analyses and subgroup analyses. Significant interactions were not observed for age, sex, hypertension, diabetes mellitus, SOFA score, or AP severity (all p values for interaction > 0.05).
Conclusions: This work is the first attempt to indicate that the TyG index is crucial for evaluating the risk of AKI, and early severity screening is recommended in patients suffering from acute pancreatitis.
Topic: Acute kidney injury and haemofiltration.

Intensive Care Medicine Experimental 2025,* 13(1)*:001404

Introduction: Aneurysmal subarachnoid hemorrhage (aSAH) is a critical neurovascular emergency affecting 2–16 per 100,000 individuals annually, with women at a 1.24-fold higher risk than men. 1 Complications arise in approximately 40% of cases, often leading to significant morbidity. Early diagnosis and timely intervention via neurosurgical clipping or endovascular coiling are vital to minimize secondary brain injury. Delayed cerebral ischemia (DCI), occurring in about 30% of patients within 3–14-day post-aSAH, contributes substantially to poor outcomes, with 50% of these individuals developing cerebral infarction. 2–4 Its multifactorial pathophysiology makes early prediction crucial. NT-proBNP, a marker of myocardial stress, may reflect neurogenic injury post-aSAH5. This study aimed to evaluate the prognostic role of preoperative NT-proBNP in predicting DCI in aSAH patients.
Objectives: Primary: To assess if elevated pre-op NT-proBNP levels predict DCI in aSAH patients. Secondary: To correlate NT-proBNP with troponin T, ECG changes, clinical grades, and long-term neurological outcomes (mRS, GOSE) and to determine its additive value to existing prediction models.
Methods: A prospective observational cohort study was conducted at PGIMER, enrolling 184 adult patients with angiographically confirmed aSAH undergoing clipping/coiling within 4 days of ictus after institutional ethics committee approval (IEC-INT/2023/MD-1326) and CTRI registration (CTRI//2023/11/059850). Patients with significant systemic illness were excluded. Pre-op NT-proBNP, troponin T, and ECGs were obtained. DCI was defined clinically and radiologically. Functional

outcomes were assessed using mRS and GOSE. Data were analyzed using logistic regression and ROC curves.
Results: DCI occurred in 56 patients (30.4%). NT-proBNP levels were significantly higher in DCI patients (mean: 1091.05 pg/mL vs. 328.90 pg/mL, $p < 0.001$) (Fig. 1). NT-proBNP correlated positively with severity scores (Hunt and Hess, WFNS, and MFS) (Fig. 2). In multivariate analysis, NT-proBNP (OR 1.11 per 100 pg/mL, $p < 0.001$), age (OR 1.07, $p = 0.004$), smoking, and MFS were independent predictors of DCI. ECG abnormalities (e.g., *T*-wave inversion) were more frequent in the DCI group and associated with elevated NT-proBNP. Higher NT-proBNP levels were linked to poorer mRS and GOSE scores at follow-up (Table 1).

Table 1 Association between serum NT-proBNP levels and DCI

Serum NT-Pro BNP (pg/mL)	DCI		Wilcoxon-Mann–Whitney *U* Test	
	Present	**Absent**	**W**	***p* value**
Mean (SD)	1091.05 (1408.58)	328.90 (548.60)	6045.000	< 0.001
Median (IQR)	**655 (381.75–1138)**	**163 (108.75–325)**		
Min–Max	**101–9045**	**10–4017**		

Table 2 Logistic regression for predictors of DCI

Variable	Adjusted OR	95% CI	*p*-value
NT-proBNP (× 100 pg/mL)	1.11	1.05–1.18	< 0.001
Age (years)	1.07	1.02–1.12	0.004
Smoker	20.94	1.63–625.43	0.034
Modified Fisher Score	1.68	1.04–2.90	0.046

Conclusions: Preoperative NT-proBNP is a valuable predictor of DCI in aSAH, particularly due to its high negative predictive value. Its integration into clinical risk models may enhance early risk stratification and guide patient management. While Trop T reflects disease severity, it does not independently predict DCI.

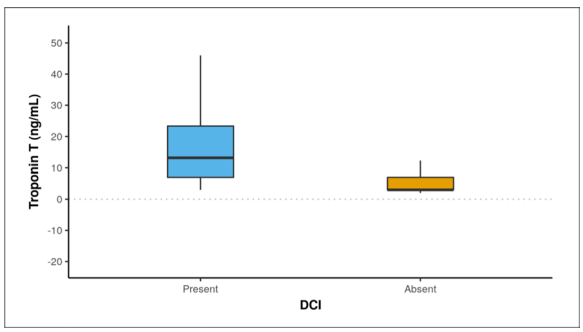

Figure 1 Box-and-whisker plot comparing NT-proBNP levels between patients with and without delayed cerebral ischemia (DCI)

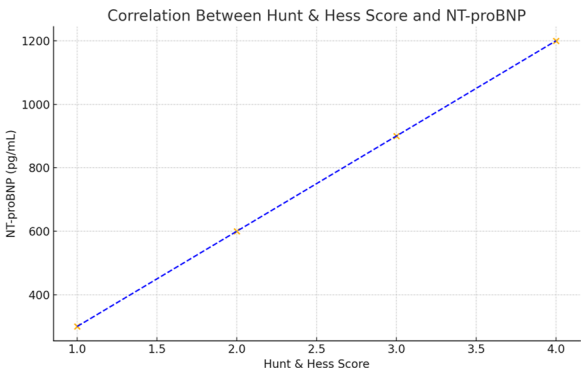

Figure 2 Scatter plot that shows a relationship between the Hunt and Hess score and NT-proBNP levels, indicating that higher biomarker levels are linked to more severe clinical conditions

Intensive Care Medicine Experimental 2025,* 13(1):*001405

Introduction: Advances in intensive care have improved intensive care unit (ICU) survival but also increased the need for prolonged mechanical ventilation (PMV) [1]. PMV is defined as being mechanically ventilated for at least 21 consecutive days, 6 h or more daily [2]. Patients with PMV experience poor long-term outcomes and consume disproportionate amount of healthcare resources [3–4]. In 2010, USD$3.5 M was spent annually per independent survivor [5]. Beyond the financial burden, PMV survivors often face cognitive decline, impaired mental health, and reduced quality of life [6–9].
Objectives: Given the high healthcare burden and poorer outcomes associated with PMV, this study aims to characterize the epidemiological profile of PMV patients, identify clinical phenotypes, and evaluate their association with survival.
Methods: A retrospective single-center cohort study was conducted across the ICUs within Singapore General Hospital, a tertiary national referral hospital. Descriptive statistics were used to characterize the patients on PMV. K-modes clustering using R was performed to identify underlying patient subgroups based on comorbidity patterns.

Results: There were 8170 patients admitted to the ICUs from year 2000 to 2024. Of which, 48 patients required PMV. Mortality rate was 38/48 (79.2%) and readmission rate was 9/48 (18.8%). The average ICU and hospitalisation lengths of stay were 30.6 days and 88.3 days, respectively (Table 1). We identified five classes of patients (Table 2). With Class 1 as reference group, all the other four classes of patients demonstrate significantly higher mortality. *K*-mode clustering with $k = 5$ was selected based on the elbow method applied to the within-cluster dissimilarity metric to achieve optimal cluster cohesion and separation.

Table 1 Number of patients on PMV and their healthcare burden

Total number of patients requiring PMV	**48**
Readmission cases	18.8%
Mortality	79.2%
Average duration of ICU admission (days)	30.6
Average duration of hospitalisation (days)	88.3

Table 2 Comorbidity distribution by patient cluster and corresponding mortality

Class	**Characteristics**	**Mortality**	***P*-Value**
Class 1 ($n = 8$)	Neurological comorbidities	0.375	1
Class 2 ($n = 14$)	Respiratory comorbidities	0.857	0.018*
Class 3 ($n = 8$)	Cardiac and Endocrine comorbidities	0.875	0.041*
Class 4 ($n = 9$)	Oncological comorbidities	0.889	0.026*
Class 5 ($n = 9$)	Cardiac, Endocrine, Haematology and Oncological comorbidities	0.875	0.041*

Conclusions: PMV patients can be stratified by clinical phenotypes. Patients with only neurological comorbidities (Class 1) appear to have better survival than those in Classes 2–5 with other comorbidities. We aim to validate this classification in a larger ICU population over a longer time frame and develop a predictive algorithm for PMV outcomes. This may guide clinical management and support goal-of-care discussions for this unique patient group.

Intensive Care Medicine Experimental 2025,* 13(1)*:001407

Introduction: Acute-on-chronic liver failure (ACLF) refers to a syndrome observed in patients with acutely decompensated cirrhosis, characterized by a pronounced systemic inflammatory response, single or multiple organ failure, and high short-term mortality [1, 2]. In liver cirrhosis, alterations occur in both the classical and alternative pathways of the renin–angiotensin–aldosterone system (RAAS) [3, 4]. However, few data exist in ACLF about changes that contribute to elevated serum levels of renin and aldosterone.
Objectives: To evaluate the concentrations and kinetics of renin and aldosterone in patients with ACLF.
Methods: Adult (> 18 years) patients, admitted to the ICU between June 2024 and April 2025 with ACLF and included in a prospective ongoing registry (REAL registry, protocol SRB2024160), were analysed. We analyzed blood samples to evaluate renin concentrations at enrolment and at 24, 48, and 72 h after. We considered 172.7 pg/mL as the upper threshold for plasma renin levels ("high" renin), as indicated in the literature for patients with refractory shock [5]. We also recorded the clinical and demographic data of the patients.
Results: A total of 19 patients were enrolled, with 68.4% male, and a median age of 57 (IQR: 49–61) years. Patients with moderate-to-severe ACLF (grades 2–3, n = 16) exhibited significantly higher renin levels compared to patients with mild ACLF (grade 1, $n = 3$) at each timepoint (Fig. 1). Demographic and clinical characteristics were comparable between patients with high ($n = 14$) and normal ($n = 5$) renin levels (Table 1). High renin group also had significantly aldosterone levels [418 (141–618) pg/ml vs. 56 (49–82) pg/ml, $p = 0.01$]. The high renin group showed significantly higher CLIF-C organ failure [median 13 (min 10–max 17) vs. median 10 (min 9–max 12), $p = 0.01$] and SOFA score [median 14.5 (min 8–max 18) vs. 8 (min 7–max 15), $p = 0.02$] at T0 and over the study period than others (Fig. 2). More patients in the high renin group developed shock (79% vs. 20%, $p = 0.04$), with a significantly higher vasoactive–inotropic score at T0 [median 35 (min 0–max 86) vs. 0 (min 0–max 65), $p = 0.04$].
Conclusions: These preliminary analysis showed that most of the ACLF patients had high renin and aldosterone levels on ICU admission, in particular among those with greater ACLF severity.

Table 1 Demographic and clinical characteristics of patients in high and low renin group

CHARACTERISTICS	All patients (n 19)	High Renin (n 14)	Low Renin (n 5)	*p*

Intensive Care Medicine Experimental 2025,* 13(1)*:001408

Introduction: The impact of obesity on outcomes in critically ill patients remains controversial, particularly with the emergence of the "obesity paradox," which suggests a potential protective effect in certain ICU settings.

Objectives: This study aimed to compare the characteristics and outcomes of obese vs. non-obese patients admitted to the ICU and to identify factors associated with poor prognosis.

Methods: We conducted a retrospective, single-center study in the medical ICU of Zaghouan Regional Hospital between December 2022 and December 2024. Adult patients (≥ 18 years) with a documented body mass index (BMI) were included. Obesity was defined according to World Health Organization criteria (BMI ≥ 30 kg/m^2). Collected data included demographics, comorbidities, severity scores (Acute Physiology and Chronic Health Evaluation II [APACHE II], Simplified Acute Physiology Score II [SAPS II], Charlson Comorbidity Index, and 4C Mortality Score), therapeutic interventions, complications, and outcomes. The primary endpoint was in-hospital mortality.

Results: Of the 412 patients included (228 obese and 184 non-obese), obese patients were older (58 ± 12 vs. 56 ± 13 years, $p = 0.02$) and more frequently female. The mean BMI in the obese group was 34.2 ± 3.8 kg/m^2. They had significantly more cardiovascular comorbidities, notably hypertension and obstructive sleep apnea ($p = 0.01$ for both). While APACHE II and SAPS II scores were comparable, Charlson Comorbidity Index and 4C Mortality scores were higher in the obese group ($p = 0.02$ and $p = 0.04$, respectively). The primary causes of admission included respiratory failure (42%), septic shock (28%), and cardiogenic shock (18%). Complementary examinations, such as chest imaging and echocardiography, were performed in 85% of patients. Mechanical ventilation was utilized in 60% of cases, with no significant differences in ventilation modalities (invasive vs. non-invasive) or duration between groups. ICU-acquired complications, including ARDS severity, thromboembolic events, and healthcare-related infections, were similar in both groups. In-hospital mortality and ICU length of stay were also comparable. Cardiogenic shock occurred more frequently in obese patients and was independently associated with mortality ($p = 0.01$; OR = 2.52; 95% CI [1.3–4.87]). Interestingly, the incidence of post-COVID pulmonary fibrosis at 3 months was lower in obese patients ($p = 0.01$; OR = 0.50; 95% CI [0.30–0.85]). No significant difference was observed regarding post-traumatic stress disorder.

Conclusions: Obesity was not associated with increased mortality, ventilation duration, or ICU stay, reinforcing the "obesity paradox." However, this study highlights a reduced incidence of post-COVID pulmonary fibrosis in obese patients, suggesting a potential protective effect in this specific context. Further research is needed to explore the underlying mechanisms of these findings.

Intensive Care Medicine Experimental 2025,* 13(1)*:001409

Introduction: Hypoxia is one of the potentially modifiable mechanisms of secondary brain injury in patients with subarachnoid hemorrhage (SAH) (1) (2). In fact, avoiding hypoxemia by supplementing oxygen is part of the management of these patients. However, hyperoxemia is potentially deleterious due to the excessive production of reactive oxygen species leading to increased cell death by apoptosis and increased release of endogenous damage-associated molecular pattern molecules (DAMPs) that stimulate an inflammatory response and vasoconstriction (3). However, studies in other acute brain injury etiologies have showed conflicting results regarding the impact of hyperoxemia on outcome and many gaps in the management of patients with SAH still exist (4).
Objectives: The objective of this study is to assess the impact of hyperoxemia on the neurological outcome of SAH patients.
Methods: This is a retrospective single-center study of subarachnoid hemorrhage patients admitted to the Intensive Care Unit (ICU) of Erasme Hospital from 2015 to 2023. We included only patients that had at least one arterial blood gas analysis per day in the first 21 days of their hospitalization or until discharge/death, whichever came first. We defined hyperoxemia as PaO2 > 120 mmHg. We calculated the % time spent with a PaO2 > 120 mmHg weighted by the duration of monitoring. Neurological outcome was measured by the Glasgow Outcome Scale (GOS) at 3 months. Unfavorable outcome was defined as GOS 1–3 (death, vegetative state/minimally conscious state, and severe disability.)
Results: We included 251 patients; the mean age was 55 years (± 14) and 153 (61.0%) patients were female. Most aneurysms were located in the anterior circulation (167, 66.5%), and 144 (57.4%) patients had poor clinical grade on admission. The median % of time spent in normoxemia, hyperoxemia, and hypoxemia was 88% (IQR 71–95%), 9% (IQR 0–29%), and 0 (IQR 0–1) of the duration of monitoring, respectively. Patients with unfavorable outcome (21% [IQR 9–41]) had a higher % of time spent in hyperoxemia compared to patients with favorable outcome (3% [IQR 0–11]) at 3 months ($p = 0.001$). In a multivariate logistic regression model adjusted for age, poor clinical grade on admission, presence of seizure, re-bleeding, delayed cerebral ischemia, and intracranial hypertension, the % of time spent in hyperoxemia was independently associated with unfavorable neurological outcome at 3 months (OR 1.04 95% CI 1.01–1.06).
Conclusions: In this study, a longer duration of hyperoxemia defined as a PaO2 > 120 mmHg was associated with short-term unfavorable outcome. Targeting normoxemia seems to be beneficial for SAH patients**.**

Intensive Care Medicine Experimental 2025,* 13(1)*:001410

Introduction: Central venous catheters (CVCs) are frequently used in intensive care units (ICUs) for hemodynamic monitoring, medication administration, and renal replacement therapies. However, CVC use carries a risk of complications, including infections, thrombosis, and mechanical injuries, which can adversely impact patient outcomes.
Objectives: This study aims to prospectively evaluate the frequency of catheter-related complications in ICU patients and identify clinical and laboratory factors associated with these complications.
Methods: This prospective observational study included 213 ICU patients who had CVCs inserted. Demographic data, comorbidities, ICU admission characteristics, and various clinical/laboratory parameters were recorded. Patients were divided into two groups based on the presence or absence of catheter-related complications. Statistical analyses were performed to identify significant differences between the groups.
Results: Complications occurred in 17% ($n = 36$) of the catheters. The complication group had a significantly younger median age (62 vs. 67 years; $p = 0.032$) and longer ICU stay (11 vs. 8 days; $p = 0.002$). Mechanical ventilation duration and vasopressor use were also significantly longer in patients with complications ($p = 0.031$ and $p = 0.039$, respectively). The Charlson Comorbidity Index was significantly lower in the complication group ($p = 0.038$). Blood–urea–nitrogen (BUN) levels were also lower in this group ($p = 0.020$), while other laboratory markers showed no statistically significant differences.
Conclusions: CVC-related complications in ICU patients are associated with younger age, prolonged ICU stay, and increased duration of mechanical ventilation and vasopressor therapy. Recognizing these factors may guide the development of strategies to reduce complication rates. Future studies should focus on identifying modifiable risk factors and implementing targeted protocols to prevent catheter-related complications in critically ill populations.

Introduction: Body weight and BMI are known to influence outcomes in critical illness, but evidence remains mixed regarding their independent prognostic value. This single-centre study investigates the relationship between admission weight, BMI category, and mortality in a large, unselected ICU cohort over a period of 4 years.
Methods: A retrospective analysis was conducted on adult patients admitted to the Intensive Care Unit at East Surrey Hospital, a UK District General Hospital, between January 2020 and December 2024. Weight and height were recorded on ICU admission, and BMI was calculated and categorized per WHO criteria. Patients were then stratified into 5-kg weight brackets, by which mortality was assessed, and rates were calculated per BMI and weight bracket. A polynomial regression model was then fitted to identify trends.
Results: Out of 3995 patients included in the study:

- Mortality rates ranged from 21% to 32% across BMI categories, with the **highest mortality observed in the mildly underweight group (32%).**
- In contrast, mortality in absolute weight brackets peaked in the 30–34.9 kg group (67%) but remained relatively stable (~ 20–28%) across the 45–124.9 kg range. The trendline indicates a **modest decline in mortality with increasing weight** until approximately 80–84.9 kg, beyond which rates plateau.
- Increased mortality was observed at both extremes:

  - **< 40 kg**—up to **67%** mortality
  - **> 110 kg**—up to **26%**

Conclusions: Mid-range weight brackets (e.g., 60–84.9 kg) have a consistent but moderate mortality rate (~ 23–29%), while both extremes (< 35 kg and > 115 kg) show mortality fluctuations, possibly indicating that both underweight and very high weight carry elevated risk of mortality. This suggests a potential U-shaped association between weight and mortality, and the existence of a protective weight ranges in critical care patients. Despite assumptions of worse outcomes with obesity, this study shows relatively consistent mortality from 45 kg up to 124.9 kg, supporting the hypothesis that having an underweight BMI, rather than overweight, may be a more critical risk factor in ICU settings.

Intensive Care Medicine Experimental 2025,* 13(1)*:001413

Introduction: In the ICU plasma, creatinine and urea are typically measured daily in blood samples sent to the clinical chemistry laboratory (CCL). We evaluated the use of point-of-care (POC) measurements of creatinine and urea in ICU patients.
Objectives: POC measurements of creatinine and urea performed in bloodgas samples were compared with CCL measurements.
We also assessed the ability of POC measurements to detect acute kidney injury (AKI) at an earlier stage [1].
Methods: Over a 10-week period in our mixed tertiary ICU, all POC blood gas measurements included creatinine and urea. These measurements were performed on the ABL90 radiometer analyzer in Li–heparin anticoagulated blood. The CCL measurements were performed on Roche Cobas PRO platforms in Li–heparin anticoagulated plasma. AKI was defined according to the KDIGO criteria [1]. POC and plasma samples were time-matched before linear correlation analysis.
Results: In 433 patients, a total 9779 POC creatinine/urea measurements were performed, with a mean (± SD) of 6.7 ± 3.9 assays/

day, during the study period. These were time matched with 1306 CCL measurements. Upon comparison of POC with CCL, for creatinine, R^2 was 0.994 with a 5.1% lower value of POC vs. CCL. For urea, R^2 was 0.987, with a 7.8% lower result for POC compared to CCL (both $P < 0.001$) level compared to the CCL.
The development of AKI was observed in 69 patients of whom 17 received renal replacement therapy. Another 85 patients showed apparent recovery from early AKI. The lab-based diagnosis of AKI could be made 11 ± 7 h (mean ± SD) earlier with the POC creatinine values. Furthermore, the high time resolution of POC measurements also facilitated the detection of pre-analytical errors.
Conclusions: The creatinine and urea levels reported by the POC system showed a good relation with those from the clinical chemistry laboratory. The considerably higher sampling density with POC measurement allowed earlier creatinine-based diagnosis of AKI, as well as the detection of other phenomena, such as early resolution from AKI.

Intensive Care Medicine Experimental 2025,* 13(1)*:001415

Introduction: *Stenotrophomonas maltophila*, a human opportunistic pathogen, was associated with increasing incidence of nosocomial and community-acquired infections in immunocompromised patients, such as burn victims. It represents a significant challenge for microbiologists and clinicians.
Objectives: To study clinical, bacteriological, and evolutionary characteristics of *Stenotrophomonas* infections in severely burned patients.
Methods: A retrospective observational study conducted in the intensive burn care department in tunisia over a period of 4 years (June 2020–June 2024). All burn patients which had a *Stenotrophomonas* isolated from a microbiological sample were included. Demographic, clinical, microbiological, and evolutionary data were collected and analyzed.
Results: During the study period, 54 positive samples for *Stenotrophomonas* were recorded in 49 patients. The average age of our patients was 39 ± 15 years, with a male-to-female ratio of 1.52. Burns were thermal in the majority of cases (92%), resulting from domestic accidents in 54% of cases ($n = 26$) and suicide attempts in 33% of cases ($n = 16$). Seventy percent of patients ($n = 34$) were transferred from another hospital. The mean total burned surface area (TBSA) was 45 ± 20%. Seventy-one patients required invasive mechanical ventilation (IMV). *Stenotrophomonas* infection was confirmed in 20 patients (40% of samples) with a median onset of 9 days [5–12], associated with catheter-related infection in 10 patients, bacteremia in 7 patients, and ventilator-acquired pneumonia in 5 patients. Colonization was identified in 60% of cases ($n = 29$). The isolated species in all cases was *Stenotrophomonas maltophilia* ($n = 54$). Fifty-one (95%) strains were sensitive to minocycline, while 47 (87%) were sensitive to cotrimoxazole. All strains were sensitive to levofloxacin. Among the 20 patients with an infection, septic shock was observed in 90% of cases ($n = 18$). All infected patients were treated with levofloxacin. Mortality rate was 70%.
Conclusions: In severely burned patients, nosocomial infections with *Stenotrophomonas maltophilia* is reported in 40% of cases and is associated with septic shock in 90% of cases. Prevention remains the cornerstone of management, emphasizing adherence to hygiene, and the rational use of broad-spectrum antibiotics.

Topic: Infections and prevention.

Intensive Care Medicine Experimental 2025,* 13(1)*:001416

Introduction: Venovenous extracorporeal membrane oxygenation (VV-ECMO) has emerged as a life-saving intervention for patients with severe respiratory failure unresponsive to conventional therapies. However, prognostication remains challenging due to the heterogeneity in patient characteristics and clinical trajectories (1).
Objectives: This study aimed to identify independent predictors of in-hospital mortality in patients with acute respiratory distress syndrome supported with venovenous extracorporeal membrane oxygenation (VV-ECMO).
Methods: We conducted a retrospective cohort study of adult patients (≥ 18 years) who received VV-ECMO at a quaternary academic center in São Paulo, Brazil, from January 2012 to December 2022. To identify independent predictors of in-hospital mortality, we performed multivariable logistic regression analysis using a backward stepwise selection approach. Variables with $p < 0.10$ in univariable analysis were considered for inclusion in the model. Results were reported as adjusted odds ratios (aORs) with 95% confidence intervals (CIs). Statistical significance was defined as $p < 0.05$.
Results: A total of 74 patients were included, of whom 34 (46%) survived hospitalization and 40 (54%) did not. Non-survivors were significantly older than survivors (60 [51–63] vs. 52 [39–60] years; $p = 0.047$) and had a longer duration of invasive mechanical ventilation (IMV) prior to ECMO (5 [1–9] vs. 2 [0–6] days; $p = 0.045$). No significant differences were observed between groups in terms of sex, SAPS 3 score, COVID-19 status, comorbidities (e.g., hypertension, diabetes, solid tumors, COPD, and immunosuppression), laboratory markers, or ventilatory parameters prior to ECMO. There was a trend toward lower pH levels in non-survivors (median 7.14 vs. 7.24; $p = 0.066$), and a higher prevalence of norepinephrine use (70.0% vs. 47.1%; $p = 0.077$) and inhaled nitric oxide administration (25.0% vs. 5.9%; $p = 0.057$) prior to cannulation among non-survivors compared to survivors. In multivariable analysis, age ≥ 60 years (aOR 5.22; 95% CI 1.47–21.81; $p = 0.015$), prolonged IMV duration prior to ECMO (aOR 1.21; 95% CI 1.06–1.45; $p = 0.012$), and norepinephrine use (aOR 4.71; 95% CI 1.27–20.54; $p = 0.027$) were independently associated with increased in-hospital mortality (Table 1). The model showed good calibration (Hosmer–Lemeshow test: $p = 0.135$) and discrimination (AUROC = 0.81). Odds ratios for in-hospital mortality increased significantly with pre-ECMO IMV duration > 7 days, while shorter durations showed no significant association (Fig. 1).
Conclusions: In this 10-year single-center cohort, older age and clinical deterioration prior to VV-ECMO—as reflected by prolonged mechanical ventilation and vasopressor requirement—were independently associated with higher in-hospital mortality. These findings underscore the prognostic relevance of pre-ECMO physiological status and support the importance of early identification and careful selection of candidates to optimize outcomes.

Table 1 Logistic regression for hospital mortalilty

	OR	5%	95% IC	P-value
Age				
<60 years	reference			
≥60 years	5.22	1.47	21.81	0.015
IMV days prior to ECMO	1.21	1.06	1.45	0.012
Norepinephrine use	4.71	1.27	20.54	0.027

IMV: invasive mechanical ventilation.

IMV: invasive mechanical ventilation.

Introduction: Healthcare-associated infections (HAIs) are a global public health concern and represent the most frequent adverse event in hospitalized patients. Most HAIs are caused by multidrug-resistant micro-organisms and lead to high morbidity and mortality rates, prolonged hospital stays, and significant healthcare costs. HAIs are particularly prevalent in immunocompromised patients, that, as a result of medical advances, currently are a substantial proportion of ICU admissions.
Objectives: This study aims to epidemiologically characterize ICU-acquired infections (ICU-AI) and compare the mortality rates between immunocompromised and immunocompetent patients affected by such infections.
Methods: Observational study including patients admitted to an ICU of a Portuguese tertiary university hospital between January 1st and June 30th, 2025. Collected data included demographic variables (age and sex), immunosuppression status, invasive mechanical ventilation, development of ICU-AI, as well as the responsible pathogens, management, and patient outcomes. A patient was considered immunocompromised in case of active solid or haematological neoplasm, or current immunosuppressive therapy. The primary endpoint was defined as the development of ICU-AI and the secondary endpoint as in-hospital and ICU mortality.
Results: As shown in Table 1, 167 patients were included in the study, of whom 63 (37.7%) developed ICU-AI, resulting in 82 documented infections. Of the 167 patients, 125 (74.8%) were immunocompetent and 42 (25.1%) were immunocompromised. Of the 125 immunocompetent patients, 49 (39.2%) developed ICU-AI. In the immunocompromised group, 14 out of 42 patients (33.3%) developed infections during ICU stay. In immunocompetent patients, the most common infections were respiratory and urinary infections, whereas in immunocompromised patients, respiratory infections and bloodstream infections were the most frequently observed. In both groups, the predominant pathogens were Gram-negative bacteria. Of the 34 patients who died either in the ICU or in other hospital ward, 15 (44.1%) had developed ICU-AI, of whom 8 were immunocompromised and 7 immunocompetent.

Table 1 Characterization of study patients and ICU-acquired infections

	Immunocompetent	Immunocompromised
Number of patients	125	42
Sex	74 males; 51 females	29 males; 13 females
Mean Age	62 ± 15.9 years	64 ± 13.9 years
Number of patients with ICU-AI	49 (39.2%)	14 (33.3%)
Predominant type of ICU-AI	Respiratory and urinary	Respiratory and bloodstream
Predominant pathogens	Gram-negative bacteria (mainly P. aeruginosa, K. pneumoniae and E. coli)	Gram-negative bacteria (mainly *E. coli, P. aeruginosa,* and *K. pneumoniae*)
Outcome of patients with ICU-AI	7 died (14.3%)	8 died (57.1%)

Conclusions: The incidence of ICU-AI was similar in immunocompetent and in immunocompromised patients admitted to the ICU. However, mortality was higher in the immunocompromised group, with results demonstrating statistical significance ($p < 0.01$). It should be noted that this is a single-center on-going study and that only interim results are presented here.

Intensive Care Medicine Experimental 2025,* 13(1)*:001419

Introduction: Milrinone is widely used as an inotropic and vasodilator in the ICU. In a previous pharmacokinetic study, we compared milrinone dosing with milrone plasma levels and the measured creatinine clearance. We found that the so-called intact nephron hypothesis holds for milrinone. This allows the estimation of milrinone levels when creatinine clearance is known. The current pharmacodynamic study examined the relation between milrinone levels and its vasodilatory effects.
Objectives: Assess the relation between milrinone levels and its vasodilatatory effects. This was done by relating the administered norepinephrine dose with milrinone plasma levels and the temperature difference (ΔT).
Methods: Only patients that received a continuous milrinone infusion were studied. Milrinone levels were determined from spent Li-heparined blood gas samples that were centrifuged before further plasma analysis by liquid chromatography–tandem mass spectrometry (LC–MS/MS). Norepinephrin dose was expressed as µg/kg/m and ΔT in ◦C. ΔT was calculated as the difference between the central temperature and the peripheral temperature of the patient. Recorded ΔT values were verified by two investigators. Recorded norepinephrin rates and ΔT were only compared with plasma levels determined within 90 min.
Results: 26 patients (38% females) with a mean ± SD age of 58 ± 13 years and a body weight of 77 ± 17 kg, received a continuous infusion of milrinone at rates varying from 0.09 to 1.0 µg/kg/m. In these patients, 432 milrinone plasma levels were determined from blood gas samples. Norepinephrine rates could be compared with 230 milrinone plasma levels and validated ΔT measurements. Median (IQR) ΔT was 3.5 (2.7–6.3)◦C, the median norepinephrine infusion rate was 0.07 (0–0.33), and the median milrinone levels were 162 (133–202) µg/L. Upon multivariate linear regression analysis, the milrinone level and ΔT were both independently related to the norepinephrine rate ($R = 0.57$; $P < 0.001$).
Conclusions: Measured milrinone levels are quantitatively related to its vasodilatatory effects. This underscores the utility of taking the renal function into account in milrinone dosing.

Cardio-cerebral triangulation: a POCUS-guided approach to hemodynamic optimization in severe TBI

M. Nasr[1]; S. Vlachos[1]; A. Bellini[1]; J. Lavrador[2]; M. Tanaka[1]; A. Wong[1]
[1]Critical Care, King's College Hospital, London, United Kingdom; [2]Neuro-Oncology Surgery, King's College Hospital, London, United Kingdom

Intensive Care Medicine Experimental 2025,* 13(1)*:001421

Introduction: Echocardiography is routinely performed in patients with severe traumatic brain injury (TBI) at King's College Hospital. In this population, optimizing neuroprotection requires real-time integration of cerebral and systemic hemodynamics. ICP alone may become less reliable post-decompression. Transcranial Doppler (TCD) has been used to assess cerebral hemodynamics (5, 6) before and after decompressive craniectomy, though its utility is influenced by technical and physiological variables (1–4). Meanwhile, cardiac dysfunction—manifested as regional or global dysfunction, or even valvular abnormalities—can complicate cerebral perfusion optimization.
Objectives: We aimed to describe a hypothesis of a novel triangulated approach combining TCD, echocardiography, and cardiac output monitoring to guide neuroprotective hemodynamic optimization while preventing myocardial strain.
Methods: The triangulation method design involved daily integration of three data streams in severe TBI with escalating vasopressor requirements: (1) TCD metrics (PI and EDV of the MCA), (2) focused echocardiography using the BSE Level 2 protocol to assess systolic and diastolic function, structural valve abnormalities, regional wall motion abnormalities, and signs of pulmonary congestion, and (3) advanced cardiac output monitoring (PiCCO). MAP was adjusted to maintain PI > 1.3 and EDV > 20 cm/s while preserving CI > 2.0 L/min/m^2(7).
Results: The triangulation strategy provided a systematic approach to assess for focal or global dysfunction and structural abnormalities, including identification of a stress cardiomyopathy. Lung USS was required to further establish the extent of pulmonary congestion. The overall PI trends followed that of the ICP trace. This POCUS approach was observed in a patient post-decompressive craniectomy with increasing vasopressor needs. ICP-guided escalation to maintain

CPP > 60 mmHg led to myocardial strain—evidenced by troponin rise, ECG changes, pulmonary oedema, and impaired LV function. Introduction of our POCUS-guided strategy in a systematic approach enabled tailoring of noradrenaline and milrinone and reduction of the stress cardiomyopathy while maintaining adequate EDV and PI (Ch@art 1).
Conclusions: There is a need for a real-time, POCUS-guided cardiocerebral triangulation method for neuroprotective hemodynamic optimization in severe TBI. While individual components—TCD, echocardiography, and cardiac output monitoring—are established and have been in our hospital regularly, their dynamic integration at the bedside in a systematic manner is novel. Lung USS was found to be a pivotal addition to the protocol. Further work is warranted to validate this hypothesis across broader populations and clarify the outcome measures needed (such as imaging) to identify its impact on clinical outcomes.

Trends of ICP, MAP, CI, and PI over 9 days in a post-decompressive craniectomy patient.

Role and mechanisms of Trex1 in mediating Irf3 nuclear translocation to enhance immune tolerance in sepsis

L. Qilan[1]; X. Jiqian[1]; Y. Shang[1]
[1]Department of Critical Care Medicine, Wuhan Union Hospital, Tongji Medical College, Huazhong University of Science and Technology, Wuhan, China
Correspondence: Y. Shang
***Intensive Care Medicine Experimental 2025,* 13(1)**:001422

Introduction: Sepsis, a prevalent post-traumatic complication, is defined as a life-threatening syndrome of organ dysfunction caused by a dysregulated host response to infection [1]. In 2017, approximately a mortality rate of 22.5%, accounting for nearly 20% of all deaths worldwide, was reported [2–4]. Immunosuppression is increasingly recognized as a critical determinant of sepsis-related mortality. TREX1, a critical mammalian exonuclease, is an upstream regulator of the STING–TBK1–IRF3 pathway. Loss of TREX1 function triggers autoinflammatory diseases [5]. However, the specific regulatory mechanisms of TREX1 in sepsis-induced immune tolerance remain unclear.
Objectives: To investigate the role and underlying molecular mechanisms of Trex1 in sepsis-induced immune tolerance.
Methods: To examine the intracellular localization of IRF3 and Trex1 proteins during the inflammatory and immunosuppressive phases, immunofluorescence and nuclear-cytoplasmic fractionation assays were performed. An endotoxin-induced immune tolerance model was established, and genomic DNA was extracted from cells for immediate agarose gel electrophoresis to evaluate DNA fragmentation. In addition, alkaline comet assays were utilized to further quantify single- and double-strand DNA breaks. The endogenous interaction between Trex1 and PARP1 was investigated using immunofluorescence, co-immunoprecipitation, and Coomassie Brilliant Blue staining. Prokaryotic and eukaryotic expression vectors tagged with EGFP and Cherry, respectively, were constructed, and droplet formation assays were conducted to assess whether Trex1 and PARP1 interact through liquid–liquid-phase separation. Subsequently, RAW264.7 cells were treated with the phase separation inhibitor 1,6-hexanediol, and the extent of genomic DNA damage was evaluated using agarose gel electrophoresis and alkaline comet assays.
Results: During endotoxin tolerance (ET), Irf3 and Trex1 predominantly localize to the nucleus, with reduced genomic DNA fragmentation and shorter comet tails observed (Fig. 1). Immunofluorescence staining revealed the co-localization of Parp1 and Trex1 in the nucleus of the endotoxin-tolerant group, and co-immunoprecipitation and Coomassie Brilliant Blue staining confirmed their interaction, identifying the NTF domain of Trex1 as critical for this interaction. In vivo and in vitro droplet formation assays demonstrated that Trex1 and Parp1 form liquid–liquid phase-separated condensates, which are disrupted by the phase separation inhibitor 1,6-hexanediol. Concurrently, treatment with the phase separation inhibitor led to increased genomic DNA fragmentation and reduced genomic stability (Fig. 2).
Conclusions: During endotoxin tolerance, Trex1 protein expression is upregulated and translocated to nucleus with Irf3, where IRF3 phosphorylation levels are reduced. Concurrently, PARP1 interacts with

Trex1 via liquid–liquid phase separation, enhancing genomic DNA stability. This mechanism likely contributes to immune tolerance in sepsis.

Potential organ donors in the ICU: a 10-year retrospective analysis in a Portuguese center

A. Albuquerque[1]; C. Roriz[1]; A. Abreu[1]; M. Silva[1]; C. Cunha[1]; O. Gomes[1]; L. Pereira[1]

[1]Intensive Care Unit, Unidade Local de Saúde da Região de Leiria, Leiria, Portugal

Correspondence: A. Albuquerque

Intensive Care Medicine Experimental 2025,* 13(1)*:001423

Introduction: Organ transplantation remains the only effective treatment for many end-stage organ failures. Identifying and optimizing potential organ donors in the intensive care unit (ICU) are a cornerstone of donation systems. Portugal applies a presumed consent policy; however, legal limitations currently restrict donation after circulatory death (DCD). Only uncontrolled DCD (Maastricht II) is permitted, while controlled DCD (Maastricht III)—involving patients who die after planned withdrawal of life-sustaining therapy—is not authorized under current national law. Understanding the characteristics

of potential donors who did not progress to brain death may inform future policy considerations.
Objectives: To characterize patients admitted to the ICU as potential organ donors between 2013 and 2023, describe donation outcomes, identify reasons for non-donation, and evaluate patients potentially eligible for Maastricht type III DCD.
Methods: A retrospective descriptive analysis was conducted using data from the Portuguese National Transplant Registry (RPT) and clinical records. All patients admitted to a single ICU during the study period and recorded as potential donors were included. It is important to note that this registry does not capture all ICU admissions of patients with potential for organ donation—particularly those who did not progress to brain death and were not identified as potential donors during their ICU stay. Collected variables included demographics, comorbidities, presumed neurological cause, donation outcomes, and causes for non-donation. Patients were stratified into effective donors, non-effective donors (with confirmed brain death), and non-donors. A subgroup of patients who did not progress to brain death but died after withdrawal of life-sustaining therapy was analyzed for potential Maastricht type III eligibility.
Results: A total of 91 patients were identified. The mean age was 61.4 years (range 19–86), and 66% were male. Brain death was confirmed in 35 patients (38%), of whom 27 (77%) became effective donors. Kidneys (84%) and liver (63%) were the most frequently considered organs for procurement. Non-donation occurred in 56 patients (62%), with main reasons, including medical exclusion criteria, lack of progression to brain death, or intraoperative findings. Among non-donors, 14 patients (15%) fulfilled clinical criteria compatible with Maastricht type III DCD (mean age 63.7 years; 64% male). The most frequent comorbidities in the overall cohort were hypertension (63%), dyslipidemia (43%), cardiac disease (31%), and diabetes mellitus (22%).
Conclusions: This 10-year single-center study reveals that, although a substantial proportion of potential donors became effective, many patients did not progress to organ donation despite supportive clinical profiles. The identification of patients compatible with Maastricht type III DCD highlights the relevance of re-evaluating current legal frameworks to potentially expand the donor pool and improve transplant availability.

Intensive Care Medicine Experimental 2025,* 13(1)*:001425

Introduction: Occupational therapists (OT) provide functional rehabilitation to reduce ICU-acquired delirium and reduce ICU and hospital length of stay (LOS) and holistic outcomes (1, 2).
Objectives: To evaluate the role of OT in a Critical Care Physiotherapy Rehabilitation Team (CCRPT) and their impact on patient outcomes.
Methods: The CCPRT provides enhanced daily rehabilitation to patients requiring > 4 days of mechanical ventilation (MV), excluding those with traumatic or neurological injuries. Before the QIP, OT was staffed at a ratio of 1:30 level 3 beds, reviewing patients on a priority basis. Retrospective data were collected between September 2022 and August 2023 and compared to data post-implementation of an OT, between December 2023 and June 2024.
Results: 133 patients were included in analysis. No difference in patient demographics, acuity of illness, or ICU management was observed between cohorts (Table 1). A non-statistical reduction in MV days (21 v 18, P = < 0.05) and incidence of delirium was observed (76 vs. 61.3% post). All patients were reviewed by an OT post-QIP, seen 8 days earlier (23 vs. 15), with an increased number of contacts (2 vs. 5), and interventions (50 v 296). Postural management and cognitive and perceptual interventions were most frequently provided.
.

Table 1 .

Demographics		Statistic			*p* value
	N	**Pre OT**	***N***	**Post OT**	
Age at Admission (Years)	71	60 (44–69)	62	59 (51–72)	0.246
Gender (% Male)	71	41 (58%)	62	46 (74%)	0.364
APACHE II	69	17.6 ± 5.6	62	18.9 ± 6	0.185
Outcomes					
Duration of MV (days)	68	21 (10–32)	56	18 (11–28.5)	0.667
ICU Length of Stay (days)	67	25 (17–40)	56	26 (16–35)	0.728
Incidence of delirium	71	54 (76.1%)	62	38 (61.3%)	0.43

Intensive Care Medicine Experimental 2025,* 13(1)*:001426

Introduction: Fluid management remains a cornerstone in the treatment of septic shock, but excessive positive fluid balance (FB) may have deleterious effects. Identifying optimal fluid balances may help guide resuscitation practice.
Objectives: To assess the association of cumulative fluid balance during the first 72 h of Intensive Care Unit (ICU) admission with in-hospital mortality in septic shock patients. Secondary outcomes included evaluating the association between fluid balance and weaning from invasive mechanical ventilation and vasopressor support.
Methods: This single-center retrospective study included 45 adult patients with septic shock admitted to a polivalent ICU between January and December 2023. Patients were stratified by cumulative fluid balance (< 4 Liters vs. ≥ 4 Liters) in the first 72 h. Demographic, clinical, and outcome data were compared between groups. Survival analysis and Mann–Whitney or chi-square tests were used as appropriate.
Results: Higher fluid balances in the first 72 h of ICU admission were associated with higher severity of illness, more vasopressor use and more prolonged mechanical ventilation. A fluid balance ≥ 4L in the first 72 h was significantly associated with increased intra-hospital mortality (89% vs. 11%; $p < 0.001$), even after adjustment for illness severity. No differences were noted between surgical and non-surgical patients. The strongest predictor of mortality was a persistently positive daily fluid balance on each of the first 3 days of ICU admission (73.5% vs. 18.2% mortality, $p < 0.001$).
Conclusions: In this single-center retrospective study, a cumulative positive fluid balance ≥ 4L during the first 72 h of ICU admission was associated with significantly higher in-hospital mortality. Moreover, a persistently positive fluid balance over the first 3 days of ICU admission appeared to be an independent marker of poor prognosis. While there was a trend toward greater vasopressor dependence and more prolonged mechanical ventilation in patients with FB ≥ 4L, a larger sample size is required to confirm these associations. Larger, multicenter prospective studies are needed to validate these findings and assess whether earlier fluid restriction can improve patient outcomes.

Intensive Care Medicine Experimental 2025,* 13(1)*:001427

Introduction: Aneurysmal subarachnoid hemorrhage (aSAH) is a critical neurological condition with high morbidity and mortality. Delayed cerebral ischemia (DCI) is one of its most severe complications that could to be influenced by inflammatory processes. Identifying early biomarkers of inflammation could improve the prediction and management of DCI.
Objectives: To identify plasma inflammatory biomarkers associated with the development of DCI in patients with aSAH using high-throughput proteomic analysis.
Methods: Prospective study including 16 aSAH adult patients admitted to the ICU, of which 8 developed DCI and 8 did not (controls), matched by age, sex, and clinical severity. Plasma samples were collected within 24 h of ICU admission. Protein expression profiling was performed using Olink Proteomics' proximity extension assay (PEA) across 8 panels (2943 proteins total). Statistical analysis involved linear Bayes models (limma package) with false discovery rate (FDR) correction. Significant proteins ($p < 0.01$) were visualized using volcano plots and heatmaps.
Results: There were no statistically significant differences in baseline characteristics—such as sex, age, comorbidities, or severity scores—among the 16 SAH case patients.
The 11 proteins showing the lowest expression levels in DCI patients compared to controls ($p < 0.01$) were CA3, PROK1, THSD1, and MYL4 which are the only biomarkers belonging to the neuroloinflammatory panel, whereas the remaining proteins belong to the oncologic biomarcer panel (Fig. 1).
Conclusions: This exploratory analysis identified inflammatory and metabolic biomarkers potentially involved in the pathogenesis of DCI following aSAH. Further validation in larger cohorts is needed to confirm these findings and explore their clinical utility.

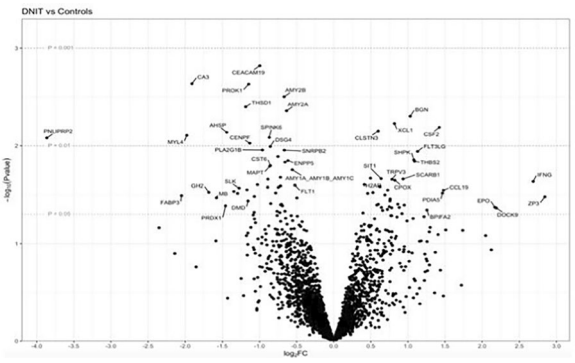

Figure 1 Volcano plot showing differentially expressed proteins between patients with DCI and controls obtained by Olink proteomics assay

Multi-omics study reveals postoperative risk of critically ill patients after cardiac surgery with cardiopulmonary bypass

W. Ding[1]
[1]Department of Intensive Care Unit, Peking Union Medical College Hospital, Beijing, China
Correspondence: W. Ding
Intensive Care Medicine Experimental 2025,* 13(1)*:001428

Introduction: Patients undergoing cardiac surgery with cardiopulmonary bypass (CSCPB) are at substantial postoperative risk, which may be influenced by alterations in gut microbiota and metabolites. The roles of these biological changes in postoperative outcomes remain inadequately explored.
Methods: We collected 54 preoperative samples and 33 postoperative samples from 60 CSCPB patients. Metagenomic and metabolomic sequencing were performed to identified the gut microbiota and serum and fecal metabolites. We examined the dynamics pattern of these microbiota and metabolites, as well as their associations with the postoperative risk. In addition, we developed a predictive model for postoperative risk based on preoperative microbiome and metabolome data.
Results: We revealed significant alterations of gut microbiota (P = 0.012), serum metabolites (P = 3.50e-10), and fecal metabolites (P = 0.0081) in patients following CSCPB, among which lysophosphatidylcholines (LPCs) exhibited notable changes. Particularly, we identified a potential regulatory function of the microbiota on LPC metabolism, which further influence the postoperative risk. The predictive model for ICU stay duration achieved a mean absolute error (MAE) of 1.27 days and R^2 of 0.63, suggesting its utility in assessing postoperative risk. In addition, this study provides a valuable resource (catalogue GM3C) for further investigation into potential medical targets in CSCPB patients, comprising more than 2000 metagenome-assembled genomes and 3 million unigenes.
Conclusions: This study provides valuable insights and resource for understanding the gut microbiome and metabolome in CSCPB patients. The findings highlight the potential of microbiome and metabolite analysis in predicting postoperative outcomes, offering opportunities for improved risk management and patient care.

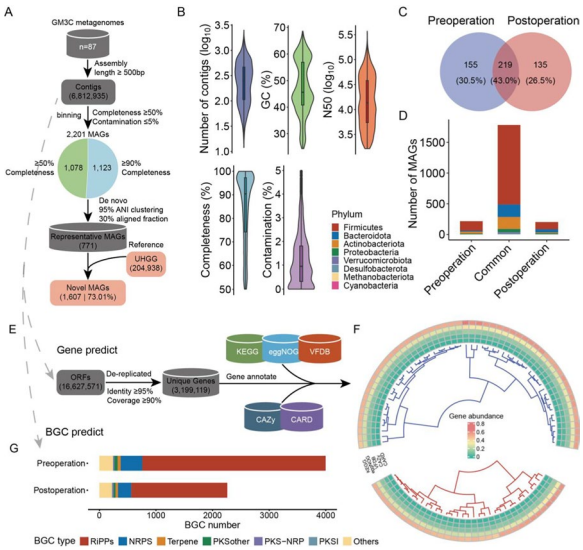

Figure 1 . Gut microbial genome and gene profile of patients undergoing CSCPB. **A** A total of 2201 MAGs were recovered from 87 gut microbial community samples in the GM3C. All MAGs have a completeness of at least 50% and a contamination level of less than 5%. These 2201 MAGs were clustered based on 95% ANI and 30% AF, resulting in 771 OTUs. Compared with the UHGG database, 1607 MAGs were identified to be novel MAGs. **B** Distribution of quality metrics for the MAGs (n = 2201), showing minimum, first quartile, median, third quartile, and maximum values. **C** 219 OTUs were shared between patients in preoperative and postoperative group. **D** Microbiota composition of the MAGs in the preoperative and postoperative group. **E** 3,199,119 unigenes were identified, which are annotated based on eggNOG, KEGG, CARD, CAZy, and VFDB. **F** Distribution of the functional profile in samples of preoperative and postoperation group. **G** Composition of the identified BGC in the preoperative and postoperative group. MAG, metagenome-assembled genome; GM3C: Gut Microbiome Catalog of patients undergoing Cardiac Surgery with Cardiopulmonary Bypass; ANI, average nucleotide identity; AF, alignment fraction

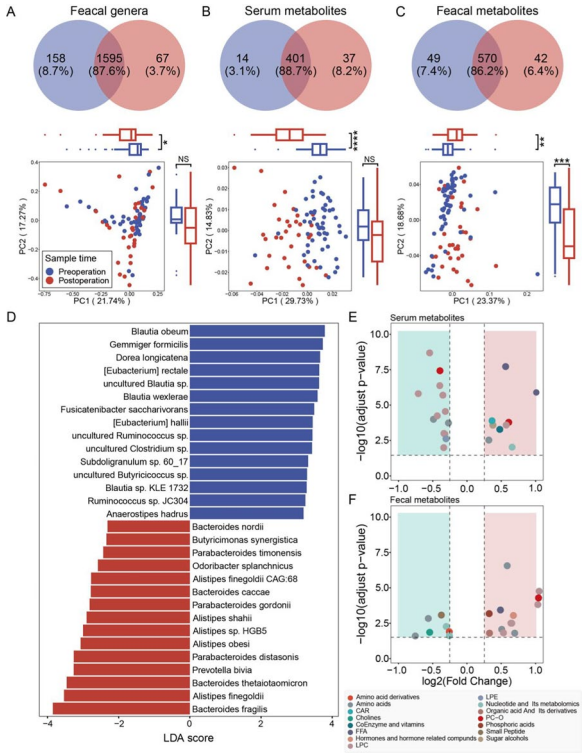

Figure 2 . Alterations of gut microbiome and metabolome in patients undergoing CSCPB. A–C Significant difference were observed between the preoperative and tpostoperative samples in microbiome (**A**) and serum (**B**) and fecal (**C**) metabolome. *P* values are calculated by two-sided Mann–Whitney test. * P < 0.05, ** P < 0.01, *** P < 0.001, **** P < 0.0001. **D** Identification of differential gut microbiota at the species level in preoperative and postoperative groups using LDA coupled with effective size measurement. The top 15 species with the highest LDA scores in each group are shown. **E, F** Volcano plots illustrate the differential serum (**E**) and fecal (**F**) metabolites between preoperative and postoperative groups. Metabolites with P < 0.05 and |log2 (Fold Change)|> 0.25 are shown. The Benjamini–Hochberg method was used to adjust *p* values for multiple testing

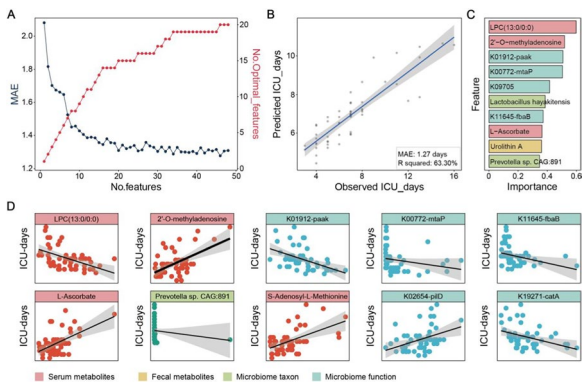

Figure 3 Integrative microbiome and metabolome biomarkers for prediction of postoperative risk using random forest model. A Model performance is improved with greedy feature selection. The blue line represents the variation in MAE value, and the red line indicates the number of features in the optimal feature set (refer to the "Methods" section) during the feature selection. **B** Performance in ICU-day prediction of the model trained using the optimal features. Linear regression was applied between the observed ICU days and predicted ICU days, with a 95% confidence interval in shadow. **C** Permutation importance of features in the prediction model. Top 10 features are shown. **D** Strong associations between microbiome and metabolome biomarkers and postoperative risk with fitted linear regression line and 95% confidence interval in shadow (Spearman correlation > 0.4 are shown)

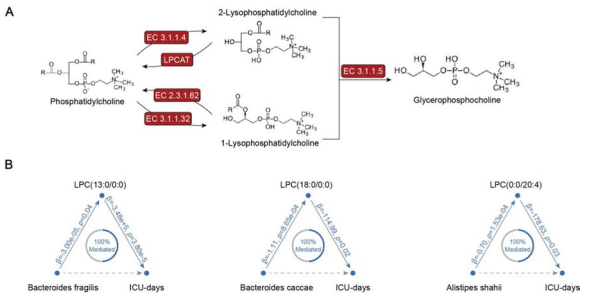

Figure 4 Metabolite LPCs link the gut microbiota with postoperative risk. A Schematic diagram illustrates the LPC metabolism pathways and the critical enzymes involved in these processes. EC 3.1.1.4, phospholipase A2; EC 3.1.1.32, phospholipase A1; LPCAT, lysophosphatidylcholine acyltransferase; EC 2.3.1.62, 2-acylglycerol-3-phosphorylcholine acyltransferase; EC 3.1.1.5, lysophospholipase. **B** Gut microbiota influence postoperative risk of CSCPB patients though specific LPC biomarkers. The blue lines represent significant associations, with corresponding beta values and *p* values. The gray dashed lines indicate insignificant associations

Assessing microcirculatory dysfunction in septic shock: the role of noradrenaline, peripheral temperature, and perfusion index—pilot study

M. Klibus[1]; D. Smirnova[2]; O. Sabelnikovs[2]
[1]Department of Anesthesiology, Intensive Care and Clinical Simulations, Riga Stradins University, Riga, Latvia; [2]Department of Anesthesiology, Intensive Care and Clinical Simulations, Riga Stradins University, Rīga, Latvia
Correspondence: M. Klibus
Intensive Care Medicine Experimental 2025,* 13(1)*:001430

Introduction: Septic shock is characterized by profound circulatory, cellular, and metabolic abnormalities, with microcirculatory dysfunction playing a pivotal role in organ failure. Noradrenaline (NA) is commonly administered to restore mean arterial pressure; however, high doses of vasoactive drugs can impair microcirculatory function and perfusion, which are crucial for organ viability.
Objectives: To investigate the relationship between NA dose, peripheral temperature (PT), and perfusion index (PI) and lactate levels as alternative markers of microcirculatory status in patients with septic shock.
Methods: In this single-center, prospective observational pilot study, we included nine patients with septic shock. Patients received varying dosages of noradrenaline. Peripheral temperature (PT), perfusion index (PI), and serum lactate were recorded by the means of thermography (PT) and photoplethysmography (PI).
Results: A significant relationship was observed between NA dose and both peripheral temperature and PI. Patients receiving higher doses of NA (from 0.05mcg/kg/min to 0.3mcg/kg/min) demonstrated lower peripheral skin temperatures (from 33.3 ◦C to 24.4◦C) and reduced PI values (from 0.42a.u. to 0.25a.u.), and higher lactate levels were associated with higher NA dose (from 2.2 mmol/l to 5.8 mmol/l) suggesting compromised peripheral perfusion.
Conclusions: This pilot study shows that increasing NA doses are associated with impaired peripheral perfusion, as evidenced by decreased peripheral temperature and perfuison index and increased lactate levels.

Intensive Care Medicine Experimental 2025,* 13(1)*:001431

Introduction: Bronchoesophageal fistulas are rare pathological communications between the bronchial tree and the esophagus. Congenital BEF is significantly less common than tracheoesophageal fistula (TEF), and the incidence of acquired BEF is not well-established. Reported causes of acquired BEF include malignancies, infections such as tuberculosis and HIV, and traumatic factors, including prolonged intubation, blunt chest trauma, or foreign bodies [1, 2]. BEF secondary to lymphoma is exceedingly rare. Clinical suspicion is often delayed, which can result in respiratory failure, recurrent pneumonia, or fatal complications.
Objectives: To raise awareness in diagnosing bronchoesophageal fistula as a post-intubation sequele presenting as tidal volume leak.
Methods: We report a rare case of bronchoesophageal fistula of the left main bronchus associated with underlying lymphoma. A 50-year-old male was admitted with acute symptoms of 1-week duration inclusive of cough and shortness of breath. Found to be severely hypoxic on arrival, initially given respiratory support with non-invasive ventilation and high flow nasal cannula, and subsequently required intubation. Fistulous communication was suspected when immediately post-intubation he failed to deliver exhaled tidal volumes showing persisting leak. Despite high ETT cuff pressures, change of ETT, repositioning of ETT, and tidal volume leak were noted. Abdominal gaseous and small bowel distention on radiographic images were seen, and nasogastric tube placement was attempted but failed. Subsequent laryngoscopy revealed air leak and suspicion of communication. Confirmed upon CT chest with contrast a bronchoesophageal fistula was seen, alongside pulmonary infection with effusion, multiple extensive lymphadenopathy. Esophageal stenting was done and patient was deemed clinically unstable for surgical repair by cardiothoracic team. Cervical lymph node biopsy performed histopathology of which revealed diffuse large B-cell lymphoma. Patient failed spontaneous breathing trial for extubation and code was revised to comfort care when bronchoscopy revealed worsening of tear. He expired upon extubation. In conclusion, this is a rare presentation of a post-intubation etiology for bronchoesophageal fistula, with an underlying lymphoma as a potential cause of friability to predispose formation once positive pressure ventilation was initiated.
Results: Bronchoesophageal fistula in adults is an uncommon and often overlooked diagnosis, with malignancy being the most frequent cause [2]. Benign etiologies include infections (e.g., tuberculosis, syphilis, and actinomycosis), trauma, and iatrogenic injuries. Prolonged intubation has been cited as a cause of BEF, yet this case demonstrates an atypical scenario, where fistula formation followed shortly after intubation—likely triggered by barotrauma in the setting of an underlying friable mediastinal lymphoma [3].
BEF can present subtly with recurrent respiratory infections, cough while eating (Ohno's sign), or unexplained air leaks on mechanical ventilation. Early diagnosis is vital to prevent complications such as mediastinitis, pneumomediastinum, and respiratory compromise [4]. CT imaging with contrast remains the gold standard for diagnosis.
Our case illustrates the potential for acute BEF formation post-intubation in a patient with mediastinal lymphadenopathy and suspected malignancy. The presence of persistent air leak, failed NG tube placement, and abdominal distension should prompt consideration of a fistula.
Early multidisciplinary involvement is crucial, including input from pulmonology, gastroenterology, thoracic surgery, and critical care. While surgical repair is often definitive, endoscopic stenting may be an effective temporizing or palliative measure in unstable patients.
Conclusions: This case highlights that the need for high clinical suspicion of BEF in patients with persistent tidal volume leaks post-intubation, especially in the context of mediastinal masses. Underlying malignancy may predispose airway tissue to injury, and positive pressure ventilation can precipitate fistula formation. Prompt imaging, multidisciplinary evaluation, and individualized management are key to optimizing outcomes. Consent to publish had been obtained.

Intensive Care Medicine Experimental 2025,* 13(1)*:001433

Introduction: Lung transplantation (LT) improves survival and quality of life in patients with end-stage lung disease, but ischemia–reperfusion injury (IRI) remains a significant problem. This condition is associated with longer ICU stays, higher long-term problems, and mortality. This is because one of the main causes of early postoperative complications is primary graft dysfunction (PGD), especially grade 3 PGD. As a vasodilator and antioxidant, iNO has been considered for the management of IRI and the severity of PGD3. Some studies have proposed its preventive use and some clinical guidelines, but presently, there

is no sufficient evidence and the drug has not been approved by the regulators.

Methods: Between August and September 2024, four electronic databases—PubMed, Web of Science, Scopus, and Cochrane—were searched. Two independent researchers evaluated every study that was searched against predetermined search criteria. First, titles and abstracts were evaluated for relevancy before conducting a full-text assessment using predefined inclusion criteria. The following types of studies were considered for analysis: prospective non-randomized trials and double blinded or non-blinded randomized controlled trials (RCTs). The participants were critically ill adults (18 years or older) who had undergone a lung transplant, and the comparisons were made between the control group and the inhaled nitric oxide group. Third investigator resolved any study selection discrepancies to provide an unbiased assessment procedure. The chi-square and I2 statistics were used for evaluating the degree of heterogeneity and either fixed-effects or random-effects models were used for statistical analysis. To determine possible bias, Cochrane risk of bias 2 (ROB2) tool was used.

Results: Six of the 2503 studies that were identified met the inclusion criteria, and 420 patients were included (212 patients in the iNO treatment group and 208 patients in the control group). The time of iNO doses was 12–48 h after transplantation and the iNO doses used ranged from 10 to 20 ppm. Analysis showed a non-significant tendency to a lower risk of PGD3, but there was no significant impact on the length of hospital stay in general (MD = − 0.72, 95% CI = − 4.65–3.22) or the length of stay in the ICU (MD = − 0.21, 95% CI = − 3.78–3.36). An analysis by fixed effects showed that there was a statistically significant decrease in the duration of mechanical ventilation (MV) (MD = − 0.23 days, 95% CI = − 0.36–0.10). Nevertheless, the observed reduction was not statistically significant when random effects model was used (MD = − 0.20 days, 95% CI = − 0.69–0.28). No statistically significant difference was observed in 30-day mortality (RR = 0.97, 95% CI = 0.36–2.57).

Conclusions: As the results show, iNO can be well tolerated and may be of benefit for lung transplant recipients to have a shorter duration of mechanical ventilation. However, there was no significant effect on 30-day mortality, ICU stays, total hospital stays, and the incidence of PGD3. Hence, based on the available data, there is a possibility of its therapeutic benefit, and large-scale, high-quality randomized controlled trials are needed to substantiate this and develop standard guidelines for its use in lung transplantation. Although the reduction in the duration of MV suggests some potential benefit, further investigation is required to determine its wider therapeutic value.

Introduction: Sepsis is a life-threatening condition that remains a major cause of morbidity and in-hospital mortality worldwide [1]. Early detection is crucial for improving patient care and survival. Recent advancements suggest that machine and deep learning approaches used in structured clinical data, such as lab results, vital signs, and patient medical history, can predict sepsis onset with high precision. Incorporating clinical notes, which can contain early indicators of sepsis not reflected in structured data, may enhance the predictive performance beyond what is achievable using structured clinical data alone. Summarizing the clinical notes using large language models (LLMs) may reduce noise while preserving clinical relevance.
Objectives: We aimed to develop a convolutional neural network (CNN)-based model for early sepsis prediction using structured data and unstructured clinical notes. We also intended to compare the performance of models trained with unsummarized (full-text) notes vs. those using LLM-generated summaries of the notes.
Methods: We utilized ICU data from the MIMIC-IV database [2], consisting of time-series and static patient features, along with associated clinical notes. Adults (≥ 18 years) without sepsis in ICU admission were included. Sepsis onset was defined according to Sepsis-3 criteria. The model was trained on two data sets: one including full clinical notes, and another using notes summarized by the DeepSeek-R1 model with 32 billion parameters. The notes were truncated to contain information known up to the point of admission to the ICU. Structured features included hourly vitals, laboratory tests, demographics, and comorbidities. The evaluation was performed using a leave-group-out approach to imitate a real-world scenario.
Results: Utilizing an observation window of 48 h and a prediction window of 24 h, the patients with enough available data were 7591 with 1011 of them developing sepsis. The CNN model using unsummarized notes achieved an area under the receiver operating curve (AUROC) of 0.82 (± 0.015), specificity of 0.76 (± 0.023), and sensitivity of 0.72 (± 0.041). Similarly, the summarized-note model demonstrated an AUROC of 0.819 (± 0.016), specificity of 0.78 (± 0.07), and sensitivity of 0.69 (± 0.125). However, the time required to generate summaries using an LLM was substantial (mean generation per note = 1.5 min), increasing the overall model development time.
Conclusions: Both raw and LLM-summarized clinical notes demonstrated strong performance in predicting sepsis within a 24-h window, achieving comparable scores. These findings suggest that while large language models can enhance signal extraction from clinical narratives, the computational cost of summarization may limit their practicality in time-sensitive clinical applications. Future work should explore more efficient summarization techniques or real-time strategies to fully leverage the potential of LLMs in clinical prediction tasks.

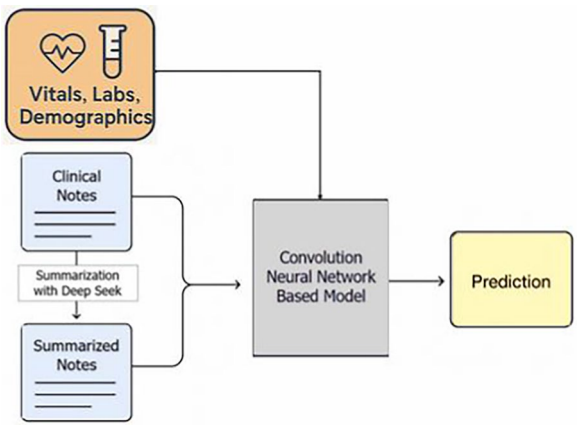

Figure 1 Proposed sepsis prediction framework. The CNN-based model utilizes MIMIC-IV data (vitals, labs, and demographics) and clinical notes (summarized or full text) within a 48-h observation window to predict sepsis risk over a 24-h prediction window

Introduction: The differences in physiological effects of changes in trunk inclination on respiratory mechanics in patients with acute respiratory failure with and without obesity remain poorly understood [1, 2].
Objectives: To evaluate whether increasing body mass index (BMI) is associated with reducing respiratory system compliance (CRS) in response to greater trunk inclination. To identify the BMI cutoff point beyond which the CRS significantly deteriorates with increased trunk inclination.
Methods: A secondary analysis of two physiological studies evaluated changes in CRS in response to increased trunk inclination. One study evaluated 22 patients who changed trunk inclination from 10° to 45° [3], while the other assessed 21 patients transitioning from 30° to 45° [4]. Data from 43 patients under passive ventilation with acute respiratory failure were included in the analysis. PEEP levels were maintained unchanged throughout the study.
Results: Increasing the angle of trunk inclination revealed an association between body mass index (BMI) and changes in respiratory system compliance (ΔCRS).
Linear regression analysis showed an inverse relationship between BMI and ΔCRS ($\beta = -0.439$, $p = 0.00328$). CRS decreased by 0.43 mL/cmH_2O per unit increase in BMI. The model explained that an increase in the trunk inclination angle accounted for 19% of the variance in ΔCRS ($R^2 = 0.19$) per unit increase in BMI (Fig. 3).
Figure 1. Correlation between changes in BMI and CRS after an increase in the angle of trunk inclination.
Receiver operating characteristic (ROC) curve analysis identified a BMI cutoff of 28.2 kg/m^2 (sensitivity of 70% and a specificity of 80%) as the optimal threshold for predicting a reduction in CRS following an increasing trunk inclination angle (Fig. 1).
Figure 2. ROC curve.
When stratified by this cutoff, patients with BMI < 28.2 kg/m^2 experienced a mean increase in CRS (ΔCRS = + 2.2 (± 6.4) mL/cmH_2O), whereas those with BMI ≥ 28.2 kg/m^2 showed a mean decrease (ΔCRS = − 4 (± 4.6) mL/cmH_2O). Independent samples t test of two groups ($t = 3.3$, df = 22, $p = 0.003$) with a mean difference of − 6.29 [95% CI 2.3–10.1] (Fig. 2).
Figure 3. CRS in patients with BMI < 28.2 kg/m^2 and BMI ≥ 28.2 kg/$m.^2$
Conclusions: In this analysis, increasing the angle of trunk inclination in patients receiving invasive mechanical ventilation, under passive breathing conditions and without changes in PEEP, significantly reduced CRS. This effect was partially explained by BMI, suggesting that patients with higher BMI values are more likely to experience a decline in compliance when the trunk is elevated. These findings highlight the importance of implementing individualized respiratory management strategies, including adjusting bed inclination angles based on each patient's physiological profile.

Intensive Care Medicine Experimental 2025,* 13(1)*:001437

Introduction: Acute kidney injury (AKI) is a frequent and severe complication in polytraumatized patients, with an incidence of 20–24% worldwide.1 It is associated with increased morbidity, prolonged hospitalization and higher mortality. Development of AKI in trauma patients is multifactorial, involving factors such as Injury Severity Score (ISS), shock, nephrotoxic drugs, and sepsis.2

Objectives: Aim of this study was to describe the incidence of AKI during the first ICU week after trauma and address the main risk factors.

Methods: This is a retrospective single-center study performed at the Niguarda Hospital from January to October 2024. Trauma patients aged > 14 years admitted to the ICU were included. AKI occurring within the first week of admission was defined according to KDIGO criteria.3 Data collected included demographics, trauma severity scores, used drugs, and red blood cell transfusions. Standard base excess (SBE) and lactate were measured at admission in the shock room. The highest creatine phosphokinase (CPK) and myoglobin concentrations recorded during the first ICU week were recorded.

Results: Fifty-five trauma patients were enrolled, with an AKI incidence of 13% (57% stage 1, 14% stage 2, and 29% stage 3 requiring RRT). AKI was more frequent in females ($p = 0.03$) and was primarily associated with abdominal, pelvic, and long bone trauma. While ISS did not differ between groups, patients developing AKI had significantly higher TASH scores and were transfused more frequently ($p = 0.003$ and $p = 0.01$, respectively). SBE, but not lactate, was significantly associated with AKI development ($p = 0.007$ and $p = 0.39$, respectively). AKI patients had also higher CPK and myoglobin levels during their ICU stay ($p = 0.04$ and $p = 0.002$, respectively) and exhibited increased mortality ($p = 0.007$). Detailed results are presented in Table 1.

Conclusions: AKI development in trauma patients is multifactorial. Abdominal trauma, pelvic and long bone fractures, along with transfusion requirements and exposure to nephrotoxic drugs emerged as possible risk factors.

***Intensive Care Medicine Experimental 2025,* 13(1)**:001438

Introduction: Intracranial hypertension (ICHT) is a frequent and challenging complication in patients with acute brain injury (ABI). While factors such as agitation, posturing and coughing are known to exacerbate ICHT, sedation and non-depolarizing neuromuscular blockers (NMB) have been shown to reduce intracranial pressure (ICP) and are classified as second-tier interventions [1]. However, current guidelines and most of the available literature primarily focus on traumatic brain injury (TBI) [2, 3], with limited data regarding the use of NMBs in other forms of ABI, such as subarachnoid hemorrhage (SAH) [4].
Objectives: To assess the impact of NMB administration on intracranial pressure in a broader ABI population.
Methods: This retrospective, single-center observational cohort study included consecutive patients with ABI, admitted to the ICU of a Belgian university hospital between 2015 and 2024. All patients received an NMB (either as a bolus or continuous infusion) and were monitored concurrently with invasive ICP measurement via external ventricular drain or intraparenchymal probe. ICP, cerebral perfusion pressure (CPP) and mean arterial pressure (MAP), were recorded at baseline (T0) and at 1, 2, 3, and 4 h following NMB administration. Patients were stratified into two groups based on ICP at T0: a high-ICP group (ICP $\geq$ 20 mmHg) and a low-ICP group (ICP < 20 mmHg).
Results: Out of a total of 814 patients with ABI admitted to the ICU, 96 met the inclusion criteria: 52 (54.2%) with SAH and 44 (45.8%) with TBI. The median age was 48 years ($\pm$ 16.2) and 62 (64.6%) were male. The clinical and demographic profiles were comparable between the high and low ICP groups. The overall population exhibited a reduction in ICP from a median of 14.5 mmHg (IQR 8–22) at T0 to 12 mmHg (IQR 9–18) at T4, although this change was not statistically significant ($p = 0.35$), alongside a significant increase in both CPP and MAP (Table 1, Fig. 1). Subsequently, when comparing ICP trends between the high and low ICP groups, after NMB administration a greater reduction over time was observed in the high ICP group ($p = < 0.0001$), with values decreasing from 27 mmHg (IQR 23–35) at T0 to 17 mmHg (IQR 12–26) at T4 (Fig. 2). Between groups, an increase in CPP over time was also observed, although it did not reach statistical significance ($p = 0.35$). Considering the responder patients—those who achieved at least a 20% reduction in ICP within the first hour—the majority belonged to the high ICP group: 19 (65.5%) vs. 18 (26.9), $p < 0.001$. In patients without intracranial hypertension, ICP values remained below 20 mmHg at all timepoints, with no significant change following NMB administration.
Conclusions: The administration of NMB was associated with a reduction in ICP in patients with ABI and ICH.

Intensive Care Medicine Experimental 2025,* 13(1)*:001439

Introduction: Postcardiotomy cardiogenic shock is a significant entity with very high mortality despite the use of mechanical circulatory support devices available in our community for no more than 13 years.
Objectives: To analyze the mortality and complications in patients undergoing cardiac surgery who have received a ventricular assist device (excluding IABP) in Andalusia during two time periods, from 2010 to 2017 and 2017 to 2024.
Methods: Retrospective, multicenter observational study of all patients included in the ARIAM registry of cardiac surgery from 2009 to November 2023 who underwent major cardiac surgery and in whom a ventricular assist device was implanted. They have been divided into two groups according to the years of intervention based on the periods in which the technique has been introduced, considering the early years within the learning curve and the later years as a period of maturity in the technique. The clinical profile, severity, and mortality of both groups, as well as mortality, complications, and length of stay, have been analyzed. Qualitative variables are expressed as number and percentage, and quantitative variables as mean and standard deviation. For the analysis, chi-square and Student's *t* tests were used as needed with a maximum alpha error of 5%.

Results:

30,519 patients undergoing cardiac surgery were registered during this period, with an overall mortality of 6.8% (2110 patients). **LVADs (left ventricular assist devices) were used in 246 patients, 78 of them in the early years and 168 in the second period analyzed**. Table 1 shows the clinical-epidemiological variables of both groups, which are comparable except for the functional class at admission and the urgency of the intervention:
No differences were found in the type of surgery in both groups, whether CABG, Valve, or mixed surgery ($p = 0.86$). **Mortality in the ICU was 78.1% in the first period and 51.2% in the second period [$p = 0.002$ OR 1.4 95%CI (1.14–1.71)]**. The analyzed complications are shown in Table 2

Conclusions: The mortality of cardiac surgery patients undergoing left ventricular assist devices shows significantly lower mortality in the most recent period probably derived by better selection of the candidates to judge by the more favorable NYHA functional status prior to surgery or the lower use in urgent/emergent surgery in this period. **Patients treated in recent years presented more complications of the sepsis type or acute kidney injury requiring dialysis**, which associated with lower mortality and similar lengths of stay in both periods translate into better management of these patients and their complications once the units have refined the indications.

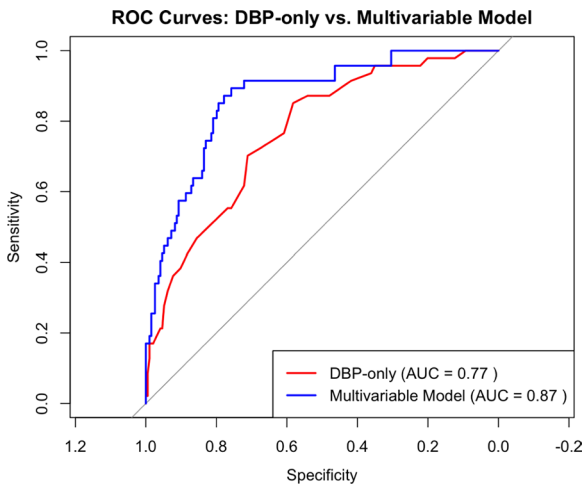
Using blood pressure to detect low stroke volume and vascular resistance in critical illness

E. Pálsdóttir[1]; O. Cavefors[2]; J. Oras[2]
[1]Anaesthesia and Intensive Care Medicine, Sahlgrenska University Hospital, Gothenburg, Sweden; [2]Anesthesiology and intensive care medicine, Sahlgrenska University Hospital, Gothenburg, Sweden
Correspondence: E. Pálsdóttir
***Intensive Care Medicine Experimental 2025,* 13(1)**:001441



Introduction: Although the classical physiological links between pulse pressure and stroke volume and between diastolic blood pressure (DBP) and systemic vascular resistance are well-established, these relationships may behave differently in the dynamic, complex ICU environment. Critically ill patients often experience rapid hemodynamic fluctuations due to both underlying disease and the treatments they receive.
Objectives: We aimed to evaluate two associations in a mixed ICU population: (1) the relationship between pulse pressure and low stroke volume index (SVI < 35 mL/m^2) and (2) the association between DBP and low systemic vascular resistance index (SVRI < 1200 dynes·s·m^2/cm^5). We further assessed whether multivariable logistic regression models—incorporating heart rate, noradrenalin, sepsis, respiratory failure, mechanical ventilation, age, hypertension, diabetes, peripheral arterial disease, and kidney disease—improve prediction as several of these factors might influence this associations.
Methods: This was a secondary analysis of a prospective echocardiographic study in which echocardiography was performed within 24 h of ICU admission following initial resuscitation, alongside concurrent clinical data collection. We first constructed logistic regression models using pulse pressure and DBP as sole predictors for low SVI and low SVRI, respectively. Forward stepwise selection was then employed to build enriched models that included additional predictors. Model performance was evaluated using receiver operating characteristic (ROC) curves and area under the curve (AUC) analyses.
Results: For SVI < 35 mL/m^2, the forward stepwise model retained pulse pressure, heart rate, and respiratory failure. Higher pulse

pressure was linked to lower odds of low SVI ($\beta = -0.038$, $p < 0.001$), whereas higher heart rate ($\beta = 0.030$, $p < 0.001$) and respiratory failure ($\beta = 0.731$, $p = 0.016$) increased the odds. Multivariable analysis improved the AUC from 0.72 (pulse pressure only) to 0.80 ($p = 0.001$) with the multivariable model. In the crude model, a PP < 40 mmHg had a sensitivity of 29% and a specificity 91%. In our adjusted multivariable model for predicting low SVI, a sensitivity of 90% corresponded to a specificity of 54%. For SVRI < 1200 dynes·s·m^2/cm^5, the final model included DBP, heart rate, respiratory failure, and noradrenalin. Lower DBP ($\beta = -0.143$, $p < 0.001$) and higher heart rate ($\beta = 0.056$, $p < 0.001$) were significant, as was respiratory failure ($\beta = -0.883$, $p = 0.040$), while noradrenalin was borderline significant ($\beta = -1.996$, $p = 0.051$). In this analysis, the AUC increased from 0.77 (DBP only) to 0.87 in the mulitvariable model ($p = 0.001$). In the crude model, a DBP < 40 mmHg had a sensitivity of 21% and a specificity of 96%. In our adjusted multivariable model for predicting low SVRI, a sensitivity of 90% corresponded to a specificity of 72%.

Conclusions: In critically ill patients, our findings suggest clinically relevant associations between pulse pressure and stroke volume, as well as between diastolic pressure and systemic vascular resistance. Using multiple variables may increase the ability to identify patients in need of hemodynamic optimization and echocardiography.

Pulse pressure only vs. multivariable model.

Diastolic blood pressure only vs. multivariable model.

Intensive Care Medicine Experimental 2025,* 13(1):*001442

Introduction: Pulmonary shunt is a major contributor to hypoxemia in ARDS. Shunt fraction is considered a marker of disease severity, especially in patients undergoing venovenous extracorporeal membrane oxygenation (V-V ECMO), where the ratio between arterial partial pressure of oxygen and inspiratory oxygen fraction (PaO2/FiO2) may be an unreliable indicator of oxygenation. The measurement of shunt using Berggren equation requires both arterial and mixed venous blood gas analyses. However, central venous samples obtained from standard venous catheters are not suitable for shunt calculation due to substantial discrepancies in oxygen content compared to pulmonary artery samples. This difference may be even more pronounced during ECMO support. As a result, a pulmonary artery catheter is necessary, although it may not always be available or indicated.

Objectives: This study aims to develop a mathematical model to predict the shunt fraction in V–V ECMO patients using only arterial blood gas (ABG) data obtained increasing FiO2 to 1.0.

Methods: This is a retrospective analysis of prospectively collected data from ARDS patients treated with V–V ECMO at the intensive care unit at IRCCS San Gerardo Hospital (Monza, Italy) between 2003 and 2024.

According to our institution's clinical practice, the same FiO2 is applied both to mechanical ventilator and extracorporeal oxygenator. Pulmonary shunt is assessed daily after increasing FiO2 to 1.0, to minimize the impact of ventilation/perfusion mismatch.

We first performed univariabe linear regression analyses to identify which oxygenation parameter, assessed at both clinical FiO_2 and FiO_2 1.0, had the strongest correlation with measured shunt fraction. Subsequently, we conducted a multivariable linear regression analysis to determine whether additional parameters were independently associated with shunt. Based on the regression coefficients and intercept, we derived a linear equation to estimate shunt values using these variables. We then evaluated the accuracy of the model by assessing the correlation between the estimated and measured shunt values.

Results: We analyzed 242 ARDS patients undergoing V–V ECMO, pneumonia accounted for 89% of cases. Mean PaO2/FiO2 ratio before ECMO was 77 ± 29. We analyzed 1976 shunt measurements paired with ABGs at both clinical and 1.0 FiO_2. The PaO_2/FiO_2 ratio at FiO_2 1.0 demonstrated a stronger correlation with shunt fraction in univariable analysis ($r^2 = 0.67$, $p < 0.001$) compared to ratio at clinical FiO_2 ($r^2 = 0.60$, $p < 0.001$). In the multivariable model, both PaO_2/FiO_2 at

FiO_2 1.0 and the ECMO blood flow to cardiac output ratio (BF/CO) were independently associated with shunt ($p < 0.001$), resulting in an overall model $r^2 = 0.75$. Due to a non-linear relationship between PaO_2/FiO_2 at FiO_2 1.0 and shunt (Fig. 1), an inflection point was identified at $PaO_2/FiO_2 = 100$ (corresponding to shunt 0.65). We developed two separate multivariable models for data above and below this threshold. We derived the following equations to calculate the estimated shunt (Qs/Qt EST):

If PaO_2/FiO_2 at 1.0 $\geq$ 100—> **Qs/Qt EST** = (– 0.0011 × PaO_2/FiO_2 + 0.339 × BF/CO) + 0.61.

If PaO_2/FiO_2 at 1.0 < 100—> **Qs/Qt EST** = (– 0.0051 × PaO_2/FiO_2 + 0.519 × BF/CO) + 0.89.

Qs/Qt EST showed a strong correlation with measured shunt (r2 = 0.79, $p < 0.001$) (Fig. 2).

Conclusions: In a large retrospective cohort of ARDS patients undergoing V–V ECMO, arterial oxygenation measured at FiO_2 1.0 and BF/CO ratio was used to derive an equation for indirect pulmonary shunt estimation. In our population, this model demonstrated a strong correlation with measured shunt values. The proposed equation may offer a practical alternative for assessing shunt severity in situations, where the placement of a pulmonary artery catheter is not feasible or indicated. External validation is required to confirm the accuracy and the generalizability of these findings.

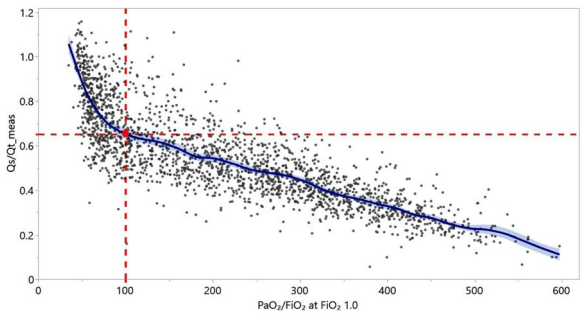

Figure 1 Non-linear relationship between PaO_2/FiO_2 ratio at FiO_2 1.0 and shunt fraction measured with Berggren equation (Qs/QtMEAS). The inflection point at $PaO_2/FiO_2 = 100$ (highlighted in red) delineates two distinct segments of the curve, each characterized by a different slope

. .

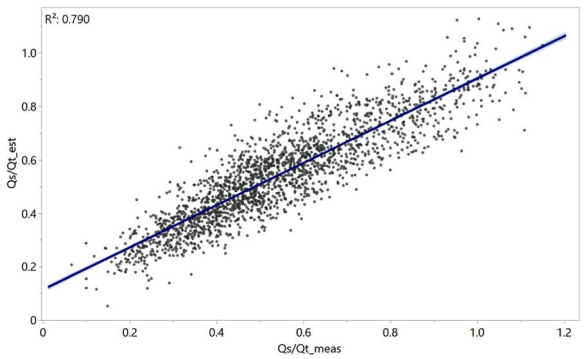

Figure 2 Linear correlation between the shunt fraction estimated by the model (Qs/QtEST) and the shunt fraction measured using the Berggren equation (Qs/QtMEAS)

Predictive modeling for ICU mortality in traumatic brain injury: insights from a level 1 trauma centre

G. Morgan-O'Brien[1]; R. Plant[2]; M. O'sullivan[3]; V. Healy[4]; C. Forrest[5]
[1]Department of Medicine, University College Cork, Cork, Ireland; [2]Department of Anaesthesia and Intensive Care Medicine, Cork University Hospital, Cork, Ireland; [3]Department of Neurological Surgery, Cork University Hospital, Cork, Ireland; [4]Department of Neurological Surgery, Beaumont Hospital, Beaumont Road, Dublin, Ireland; [5]Department of Medicine, Cork University Hospital, Cork, Ireland
Correspondence: G. Morgan-O'Brien
Intensive Care Medicine Experimental 2025,* 13(1):*001443

Introduction: Traumatic brain injury (TBI) remains a leading cause of neurocritical care admissions and mortality worldwide. Accurate prediction of in-hospital, or more specifically, in-ICU mortality is crucial for optimizing clinical decision-making, resource allocation, and individualized patient management. This study aims to develop and validate a predictive model for ICU mortality in TBI patients using statistical and machine-learning approaches.

Methods: A retrospective, cross-sectional cohort study was conducted, analyzing 222 TBI patients admitted to the ICU between January 2013 and December 2018. Predictor variables included patient demographics, injury characteristics, pre-existing comorbidities, neuroimaging severity, and ICU management parameters. ICU mortality was the primary outcome measure. Predictive modeling was performed using conditional inference tree analysis and multivariable logistic regression.

Results: ICU mortality was 22.1% ($n = 49$). Non-survivors were significantly older (median 57 vs. 42 years, $p = 0.019$), and mortality increased with age (> 66 years: 34.7% vs. < 18 years: 6.1%, $p = 0.016$). Direct admission to the trauma centre was more common in non-survivors (71.4% vs. 52.6%, $p = 0.029$). The leading injury mechanisms were falls > 2 m (36.7%) and road traffic accidents (26.5%). Charlson Comorbidity Index (CCI) > 2 was associated with higher mortality ($p = 0.026$). In the conditional inference tree analysis, Rotterdam CT score was the strongest predictor ($p < 0.001$), with scores > 4 linked to a 67.0% mortality rate. Among patients with Rotterdam Scores ≤ 4, age > 50 years ($p = 0.006$) and direct trauma centre admission ($p = 0.013$) further stratified risk. For Rotterdam Scores > 4, CCI > 2 ($p = 0.04$) identified the highest risk subgroup. Multivariable logistic regression confirmed Rotterdam CT score as the most significant predictor across all models (OR: 2.24–2.28 per unit increase, 95% CI 1.60–3.30, $p < 0.001$). Age, which was significant in univariate analysis, was not an independently significant predictor of ICU mortality in the logistic regression model ($p = 0.770$). CCI (OR: 1.02, 95% CI 0.78–1.32, $p = 0.905$) and admission type (OR: 0.50, 95% CI 0.22–1.08, $p = 0.085$) also showed trends but did not reach statistical significance. The lowest pre-intubation GCS was

not independently significant (OR: 0.95, 95% CI 0.85–1.06, $p = 0.351$) across the multivariate models.

Conclusions: This study presents a validated predictive model for ICU mortality in TBI, incorporating key clinical and radiological variables. The findings support the integration of data-driven prognostication into neurocritical care decision-making.

To enhance the clinical applicability of our findings, future research should focus on developing a standardized mortality prediction 'score' based on the key prognostic factors identified in this study. A validated risk stratification tool would allow clinicians to rapidly estimate ICU mortality risk in TBI patients, facilitating early intervention and optimizing critical care resource allocation. Such a 'score' could be integrated into electronic health records to provide real-time, data-driven clinical decision support, improving bedside prognostication and guiding neurocritical care strategies. In addition, our findings suggest that traditional statistical approaches, such as logistic regression and conditional inference trees, may fail to fully capture the intricate, non-linear interactions of some predictors. This underscores the need for more flexible modeling approaches, such as machine learning algorithms (e.g., Random Forests and Gradient Boosting Machines [XGBoost]) that can dynamically account for these complexities. Future research should explore complex machine learning-driven predictive models to refine TBI outcome prediction, potentially surpassing conventional methodologies in accuracy and reliability.

Introduction: Nutrition support is essential in the management of critically ill patients. Nevertheless, it is underrecognized, being considered an adjunctive rather than a primary therapy.
Objectives: This study aimed to evaluate nutritional practices in Tunisian public ICUs and identify areas for improvement.
Methods: A nationwide, cross-sectional point-prevalence study was conducted on March 14, 2024, including all adult patients admitted to public hospital ICUs in Tunisia on that day. Data were collected via an online questionnaire (Google Forms) distributed via email to ICU departments, focusing on:
-The number of hospitalized patients and modalities of nutrition support (enteral and/or parenteral).
-Mode of administration (continuous or intermittent).
-Unplanned interruptions and their causes.
-Recommendations to improve alignment between prescribed and delivered nutrition.
An Excel sheet was included to collect patient-specific data: admission date, weight at admission and on the study day, and caloric intake (prescribed and delivered, in kcal). Statistical analysis was performed using SPSS, with descriptive statistics and paired comparisons.
Results: A total of 121 patients from 13 ICUs were included. The median number of patients per ICU was 10.5 with an interquartile range of 5.25–11.75. The median day of ICU stay on the day of data collection was 6, with an interquartile range of 3–21.5. A total of 62.81% of patients were mechanically ventilated. Regarding nutritional practices, 54% of patients (n = 65) received enteral nutrition, 29% of patients (n = 35) received parenteral nutrition, and 5% of patients (n = 6) received both enteral and parenteral nutrition. 12.4% of patients (n = 15) did not receive any artificial nutrition. Audited intensivits declareted that patients did not receive the full amount of prescribed calories, for the following reasons: patient refusal in 26% of cases and technical problems in 16% of cases. Enteral nutrition was significantly more prescribed among intubated patients compared to non-intubated patients (69% vs. 42%; p = 0.004). Furthermore, EN was less frequently interrupted in intubated patients (63% vs. 45%; p = 0.002). Continuous feeding was the most commonly used method. Clinicians provided several recommendations to improve the administration of nutritional support, as follows: equipping ICU beds with integrated weighing systems to allow daily monitoring of patient weight (n = 4); the use of combined enteral and parenteral nutrition to ensure adequate daily caloric intake (n = 6), the use of infusion pumps to guarantee precise and consistent delivery rates (n = 6); plan regular training sessions for healthcare staff (n = 5); routine bedside verification of nutrition delivery during medical rounds (n = 3), and the implementation of standardized nutrition protocols (n = 5).
Conclusions: This first nationwide audit of ICU nutrition in Tunisia highlights significant gaps between prescribed and delivered artificial nutrition. A considerable number of patients received insufficient or no nutritional support. These findings call for urgent measures, including daily nutritional monitoring, protocol implementation, investment in equipment, and staff training, to improve nutritional care and patient outcomes in critical care settings.

Introduction: Pulmonary arterial capacitance (PAC), accounting for the pulsatile component of afterload, may serve as a more informative indicator of pulmonary vascular dysfunction compared to pulmonary resistances (PVR) alone.
Methods: Forty-three pigs (53.6 ± 6.0 kg) were randomized to undergo endotoxic shock (LPS, n = 19), or serve as controls (n = 24). Shock was defined as mean arterial pressure (MAP) < 60 mmHg despite a sustained catecholamines administration. PAC was defined as stroke volume/pulmonary arterial pulse pressure, measured through right heart catheterization. Hemodynamic and respiratory variables were collected every 3 h for 24 h.
Results: The LPS group cumulatively received 0.75 ± 0.71 mg/kg of LPS and showed a lower MAP (65 ± 10 vs. 72 ± 11 mmHg, p < 0.001) despite a larger noradrenalin infusion (0.58 ± 0.24 vs. 0.02 ± 0.07 mcg/kg/min, p < 0.001). PaO2/FiO2 decreased (309 ± 79 vs. 472 ± 31 mmHg, P < 0.001) paralleling the respiratory system compliance (Crs, 27.7 ± 7.3 vs. 43.5 ± 8.2 ml/cmH2O, p < 0.001), while the cardiac output (CO) increased (6.0 ± 1.7 vs. 3.5 ± 1.0 l/min, p < 0.001). PVR were not different (4.0 ± 1.8 vs. 4.1 ± 2 WU, p = 0.85). Conversely, PAC decreased significantly (2.6 ± 1.1 vs. 4.4 ± 1.7, p < 0.001, **Panel A**) following Crs (R2 = 0.16, p < 0.001, **Panel B**) and PaO2/FiO2(R2 = 0.22, p < 0.001, **Panel C**). Vascular recruitability, measured as CO/PAC, was different in the two models (p < 0.001 of the angular coefficient, **Panel D**). This was a function of the end-inspiratory transpulmonary pressure (R2 = 0.31, p < 0.001), but not of the end-expiratory one (p = 0.43).
Conclusions: PAC was an early indicator of pulmonary vascular dysfunction, closely tracking the decline in lung mechanics and gas exchange. In our model, the loss of vascular recruitability appears more linked to overdistension than atelectasis.

Introduction: Assessment of left ventricular function is crucial for ICU patient management, aiding in risk stratification and therapeutic decisions. Echocardiography, especially the measurement of left ventricular ejection fraction (LVEF), is an essential tool but can be challenging in emergency settings due to time constraints and image quality limitations. In this setting, mitral annular plane systolic excursion (MAPSE) measurement emerges as a practical alternative. MAPSE is a sensitive marker of ventricular function, showing a strong correlation with LVEF, and is useful in emergencies due to its rapid acquisition and technical simplicity. It can be performed at the bedside by healthcare providers with limited echocardiographic training, making it particularly valuable in critical care environments.
Objectives: This study aims to evaluate the correlation between MAPSE-derived LVEF, performed at the bedside by ICU residents, and LVEF measured by the gold-standard Simpson's method by experienced echocardiographers. In addition, it aims to explore the relationship between MAPSE-derived LVEF and clinical outcomes.
Methods: This study includes adult ICU patients from a private hospital in southern Brazil who underwent formal echocardiography within 48 h of MAPSE measurement and consented to participate. Data were obtained through bedside echocardiography, with MAPSE measured and LVEF estimated using a validated formula[1]. These were compared with Simpson's method. Correlation with SAPS3 (Simplified Acute Physiology Score 3) and ICU length of stay was also assessed. Statistical analysis used Pearson's correlation coefficient with a desired confidence interval of 20%, 95% confidence level, and expected correlation of 0.594. A sample size of 184 patients was calculated allowing for 10% of losses. Data corresponding to 40% of the expected sample size have been gathered.
Results: In this interim analysis, 73 (40% of the expected sample size) patients were evaluated. Mean age was 72 years (± 16 years), and 43.84% were female. 59 patients (80%) had an LVEF > 40%. Correlation between MAPSE and Simpson's method was moderate at $r = 0.62$ for septal MAPSE (sMAPSE), $r = 0.58$ for lateral MAPSE (lMAPSE), and r = 0.56 for mean MAPSE (mMAPSE). The correlation between the mMAPSE-derived LVEF and the official LVEF was $r = 0.61$. Regarding clinical outcomes, Pearson's correlation with SAPS3 was weak: $r = -0.28$ for sMAPSE, $r = -0.24$ for lMAPSE and $r = -0.10$ for mMAPSE. Correlation with ICU length of stay was also weak: $r = 0.08$ for sMAPSE, $r = 0.03$ for lMAPSE, $r = 0.06$ for mMAPSE, and $r = 0.06$ for MAPSE-derived LVEF.
Conclusions: Preliminary data show a moderate correlation between bedside MAPSE-derived LVEF and formal LVEF assessment in ICU patients. However, the association with relevant clinical outcomes is weak. Further analysis is needed to assess MAPSE's clinical utility in critical care.

Intensive Care Medicine Experimental 2025,* 13(1)*:001447

Introduction: Cervical necrotizing fasciitis (CNF) is a rare but life-threatening condition that may complicate tonsilitis. To date, literature on CNF is very scarce, in particular no study evaluated host and pathogen factors associated with CNF as compared to peritonsillar abscess. In this perspective, we sought to investigate risk factors for the development of CNF, with the aim of improving early diagnosis and management.
Methods: We conducted a retrospective monocentric study in Lariboisière Hospital, Paris, France, between January 1st, 2017 and December 31st, 2024. All adult patients hospitalized for tonsillar disease requiring surgical intervention were included. Patients were excluded if their hospital stay was shorter than 48 h. Patients with uncomplicated peritonsillar abscess were compared to patients with tonsil-related CNF. Our primary objective was to identify risk factors associated with CNF. Secondary objectives included description of CNF population, microbiology and outcomes, and the identification of underlying conditions that could predispose patients to CNF.
Results: 169 patients were included in our analyses. Among them, 84 patients suffered from tonsil-related CNF, while 85 suffered from peritonsillar abscess. Patients suffering from CNF were significantly older ($p < 0.0001$) had more history of alcohol use disorder ($p = 0.005$), and prior use of non-steroidal anti-inflammatory drugs (NSAIDs) ($p < 0.0001$) or steroid use ($p = 0.03$). Patients with CNF showed significantly lower diastolic blood pressure ($p < 0.001$) on admission, higher oxygen requirement as demonstrated by lower PaO_2/FiO_2 ratio ($p < 0.001$). Biologically, those patients demonstrated higher neutrophil count ($p = 0.037$), lymphopenia ($p < 0.001$), and more elevated C-reactive protein (CRP) ($p < 0.001$). Microbiological analyses revealed a higher prevalence of *Staphylococcus* spp., *fusobacterium* spp., and Gram-negative bacilli in CNF cases, whereas Epstein–Barr virus (EBV) was more commonly associated with uncomplicated phlegmons. After adjustment for cofounding variables, factors independently associated with the development of CNF were age, male sex, history of NSAIDs use (aOR 8.45), and Steroid use (aOR 3.42). Interestingly, among patients admitted for CNF with no history of immunosuppressive comorbid condition, systematic screening revealed that 42% of patients had previously unrecognized diseases, such as diabetes, solid and hematological malignancies, or chronic viral infections (HIV or C hepatitis).
Conclusions: This study identifies several independent risk factors strongly associated with CNF: older age, alcohol use disorder, and use of NSAIDs and steroids prior to admission. In addition to outlining the clinical and biological profile of this under-studied population, our findings highlight a high prevalence of underlying disease, suggesting that systematic screening should be considered in CNF patients.

Introducing vasopressin in a general ICU: clinical impact in high-dose norepinephrine septic shock

B. Soares Nunes[1]; P. Batarda Sena[1]; F. Côrte-Real[1]; M. Drumond[1]; G. Faro Silva[1]; JJ. Nóbrega[1]
[1]Intensive Care Medicine, Hospital Dr. Nélio Mendonça, Funchal, Portugal
Correspondence: B. Soares Nunes
Intensive Care Medicine Experimental 2025,* 13(1)*:001448

Introduction: Septic shock requiring high-dose norepinephrine (NE) remains a clinical challenge, often associated with high mortality and prolonged vasopressor dependency. Vasopressin is recommended as an adjunct vasopressor in cases of refractory shock, yet its impact remains variable, especially in units, where vasopressin is not consistently available.
Objectives: This study aims to evaluate the clinical impact of introducing vasopressin in the management of septic shock with high-dose NE, based on a structured ICU protocol, comparing patients treated before and after its implementation.
Methods: This retrospective observational study was conducted in a medical–surgical ICU and included patients admitted with a diagnosis of septic shock requiring norepinephrine (NE) > 1 mcg/kg/min. The group without vasopressin comprised patients treated in 2023 when vasopressin was not available. The vasopressin group included patients treated in 2024, following the implementation of an ICU protocol guiding the initiation and titration of vasopressin as part of vasopressor management. Collected variables included demographics, ICU length of stay, type of admission (medical vs. surgical), lactate levels, NE dosing, and mortality. In the vasopressin group, NE was recorded at multiple timepoints over 24 h after vasopressin initiation.
Results: The group without vasopressin included 22 patients with a mean age of 63.3 years, while the vasopressin group comprised 26 patients with a mean age of 66.7 years. Although not statistically significant, a higher proportion of surgical patients was observed in the vasopressin group. ICU mortality was 81.8% in the group without vasopressin and 65.4% in the vasopressin group ($p = 0.33$). The use of vasopressin was associated with a significant reduction in norepinephrine dose over the first 24 h ($p < 0.00001$), indicating improved hemodynamic control. However, no significant differences were observed in initial ($p = 0.99$) or final ($p = 0.11$) lactate levels between groups.
Conclusions: The protocolized introduction of vasopressin in a general ICU was associated with a significant reduction in norepinephrine requirements during the first 24 h of septic shock. However, this hemodynamic benefit did not translate into improved lactate kinetics or correlate with ICU mortality. These findings highlight the complexity of septic shock and support further prospective evaluation of vasopressin's role in perfusion-targeted strategies.

Vitamin-K-dependent matrix Gla protein and pulmonary damage during severe COVID-19

J. Walk[1]
[1]Intensive Care Medicine, Radboud univeristy medical center, Nijmegen, Netherlands
Correspondence: J. Walk
Intensive Care Medicine Experimental 2025,* 13(1)*:001449

Introduction: Activated matrix Gla protein (MGP) is required to protect against pulmonary and vascular elastic fibre degradation. Activation is vitamin K-dependent and vitamin K deficiency leads to the accumulation of inactive MGP (dp-ucMGP). In observational studies, patients with severe COVID-19 had high levels of inactive MGP, which was associated with increased levels of biomarkers associated with inflammation and elastic fibre damage, and poorer clinical outcome [1]. This warrants further investigation as we recently demonstrated in an RCT that vitamin K administration improves MGP activation in COVID-19 patients in a safe and feasible manner [2].
Objectives: To further examine the role of Matrix Gla Protein in protection against pulmonary damage in severe COVID-19 using functional respiratory imaging and lung histology, and the effects of vitamin K supplementation on these parameters.
Methods: Observational cohort: A total of 60 patients with severe COVID-19 (invasive ventilation and/or death) were compared to 75 hospitalized COVID-19 patients that did not need invasive ventilation and 184 controls. Intervention study: In a single-centre, double-blind,

randomized, placebo-controlled trial, 40 hospitalized COVID-19 patients were randomly assigned in a 1:1 ratio to receive 999 mcg of vitamin K2—menaquinone-7 (MK-7)—or a placebo daily. In both the observational cohort and the clinical trial, we determined levels of inactive MGP, and markers of inflammation and elastic fibre degradation. We also performed pulmonary CT scans at admission (observational cohort and intervention study) and 5 days after admission (intervention study only). We used functional respiratory imaging coupled with automated algorithms to map airways and pulmonary vasculature on the CT scans. Finally, we studied MGP in lung biopsies from deceased COVID-19 patients.
Results: Lung biopsies from COVID-19 patients showed a marked loss of active MGP in areas of inflammation and damage. CT scans demonstrated that patients with severe COVID-19 had decreased blood volume in small pulmonary vessels with a diameter of < 5 mm ($p < 0.01$). In contrast, airway volume appears relatively spared. Higher levels of inactivated MGP were associated with more severe CT scan defects ($p < 0.01$). Final results from the intervention study are currently being analyzed.
Conclusions: Loss of active MGP and accumulation of inactive MGP are associated with increased pulmonary and vascular damage, and poor outcome in patients severe COVID-19. It may be modified by increased vitamin K supplementation. These findings warrant further study to determine whether this improves clinical outcomes and—perhaps more importantly—whether this is relevant for patients with other severe lung infections and ARDS.

Intensive Care Medicine Experimental 2025, **13(1)**:*001451*

Introduction: Pendelluft, the movement of gas from non-dependent to dependent lung regions, is present in active breathing patients of ARDS. However, pendelluft during spontaneous breathing trial (SBT) is not well-known and whether it is associated with post-extubation outcomes has not been investigated.
Objectives: We investigated the occurrence of pendelluft during SBT in patients who succeeded SBT and whether the pendelluft during SBT can predict reintubation.
Methods: This study was a prospective observational study in a single center in Japan. All patients over 18 years who were mechanically ventilated and passed SBT using a mode of pressure support (PS) ventilation (PS 5 cmH2O, PEEP 5 cmH2O) were included. After enrollment, patients were monitored with an EIT system. We recorded in the last 3 min of SBT and pendelluft was measured. We defined pendelluft volume as the sum of the volumes of gas inspired from the dependent lung region during expiration and the volume of gas expired from the non-dependent lung during inspiration. The primary outcome of this study was reintubation.
Results: A total of 102 mechanically ventilated patients were included. Twelve patients had reintubation within 72 h. Pendelluft tended to be greater in patients who were reintubated than in those who were not, but the difference was not significant (6.6 vs. 4.6 ml, $p = 0.11$). The area under the receiver operating characteristic curve (AUC) for the pendelluft during SBT to predict reintubation was 0.643.
Conclusions: Pendelluft can be measured in patients who succeeded SBT, but its volume was small. Pendelluft during SBT is not a potential predictor of reintubation.

Topic: Acute respiratory failure and mechanical ventilation.

Implementation of sustainability initiatives in ICUs in the netherlands: a survey of the green ICU

J. Zeeman[1]; E. van Raaij[2]; N. Hunfeld[3]
[1]Intensive care, Erasmus MC, Rotterdam, Netherlands; [2]Erasmus School of Health Policy & Management, Erasmus University Rotterdam, Rotterdam, Netherlands; [3]Intensive care and Pharmacy, Erasmus MC, Rotterdam, Netherlands
Correspondence: J. Zeeman
Intensive Care Medicine Experimental 2025, **13(1)**:*001452*

Introduction: ESICM aims to reduce the impact of ICU activities [1]. This goal is reflected in the Netherlands, where 'The Green ICU' was established in 2022 as a collaborative network of ICUs. The Green ICU network collects and shares sustainability initiatives and best practices enabling ICUs in making their ICUs more sustainable [2]. Still, while sharing green initiatives is valuable, it does not necessarily translate into implementation or environmental improvements. On a nation level, monitoring, encouraging effective action, and identifying which green ICU initiatives have been implemented—and where—is crucial in the development of the Green ICU network and in decreasing the ICU's footprints.
Objectives: To investigate which sustainability initiatives of The Green ICU have been implemented in Dutch ICUs from 2022 to 2024.
Methods: A questionnaire was sent to 72 ICUs in the Netherlands in May 2024 and contained 24 questions encompassing all sustainability initiatives of the Green ICU. The initiatives were divided into seven themes: general, waste management, metal reuse, isolation gowns, mats (absorption pads), medication, and other. The number of beds of the participating ICU was also queried to determine the size of the ICU. The data analysis included frequency counts to evaluate how often each sustainability initiative was implemented, and mean scores were calculated per thematic category to identify overall implementation trends. Participants had the opportunity to provide an explanation or an alternative answer through open text space, which was analyzed qualitatively.
Results: In total, 46 ICUs (64%) have opened the questionnaire, of whom 28 ICUs (response rate 39%) rated all sustainability initiatives. Based on the questionnaire, we have detailed information on the implementation frequency of 50 + sustainability initiatives. Some of the widely implemented initiatives were: 'The establishment of a Green Team' (implemented by 100% of responding ICUs), 'Not routinely replacing the CVL, only if there is suspicion of infection' (93%), and 'Using ultrasound for line insertion' (89%). Some of the less commonly implemented initiatives were: 'Using NaCl for the ultrasound instead of gel' (0%), 'Measure vancomycin sustainably via blood gas analysis' (4%), and 'Use a sleeve to cover the blade of a video laryngoscope' (14%). Figure 1 provides an overview of several widely implemented sustainability initiatives across Dutch ICUs. Figure 2 provides an overview of several sustainability initiatives that are less commonly implemented by Dutch ICUs.
Conclusions: Our questionnaire concerning ICU sustainability initiatives facilitates the identification of implemented actions and focus areas in Dutch ICUs. The results also provided insight into the differences between ICUs. This can serve as a starting point for further research into aspects contributing to successes and obstacles of the implementation of sustainability initiatives.

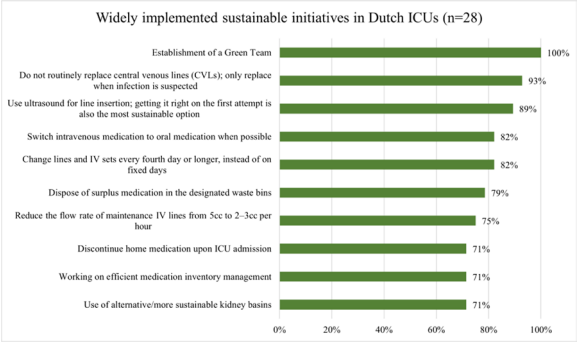

Figure 1 Overview of widely implemented sustainability initiatives in Dutch ICUs
(100% indicates that all responding ICUs have implemented the respective initiative).

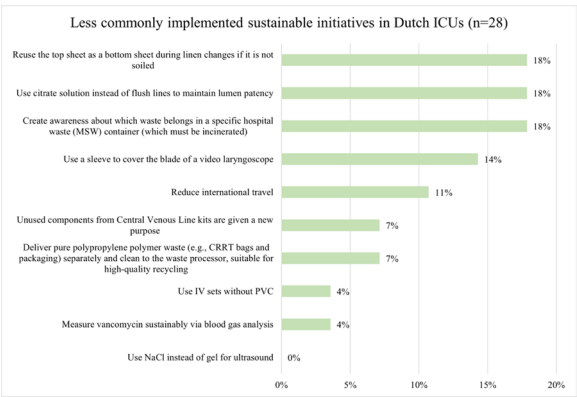

Figure 2 Overview of less commonly implemented sustainability initiatives in Dutch ICUs
(0% indicates that none of the responding ICUs have implemented the respective initiative).

Intensive Care Medicine Experimental 2025,* 13(1)*:001454

Introduction: Hospitalization in intensive care units (ICU) is associated with the development of long-term sequelae that have a negative impact on functionality, cognition, family and social participation, and quality of life, known in the literature as PICS (post-intensive care syndrome). Although the epidemiological results of PICS are scarce, it is estimated that half of survivors will suffer from one of its components. Given these implications, predicting the development of disability on discharge from the ICU using machine learning tools, can alow programming early interventions capable of mitigate the development of sequelae. Simultaneously, even though an optimal model of outpatient ICU follow-up care remains uncertain, models of post-icu care witthout in-person attendence at the hospital have potential to higher recruitment, intervention delivery succes, and participants retention. Therefore, the incorporation of new/emerging technologies such use of "apps" could be considered adjunct therapies to improve patient recovery.
The SelfCare@home project aims to develop new models for providing care to critically ill patients, to integrate new technologies, to develop predictive models that make possible to anticipate healthcare needs, and to develop applications that make easier for patients to participate in their recovery process.
To achieve these goals, we began collecting data from critically ill patients to train prediction models using machine learning algorithms and develop an app that allows patients to follow a therapeutic regimen and interact with healthcare professionals.
The results of the follow-up of the first 40 patients are presented, as the project is currently undergoing.
Methods: A longitudinal study was carried out, collecting and analyzing data consecutively from 40 patients on admission and discharge from the ICU and 1, 3, and 6 months after discharge.
This study was approved by the board of directors, the local ethics committee, the service director, and the nurse manager. Informed consent was obtained from the participants.
Results: The average age of the participants was 57.8 years (41–83 years), 24 men and 16 women. The mean SAPSII score was 31.85 (SD 13.89), and the mean SOFA score was 4.15 (SD 2.74). The average number of days of sedation was 6.25 (SD 12.72), and delirium was diagnosed in 27.5% of the patients. The average number of days under invasive mechanical ventilation was 7.53 (SD 14.85). On average, patients spent 7.53 days (SD 16.29) and 28.53 (SD 26.44) in hospital.
On discharge from the ICU: 25% of participants needed help with self-care activities (hygiene, dressing/undressing, grooming, transferring, and walking), 25% needed help taking medication, 40% had respiratory problems, 7.5% had urinary incontinence, 85% had reduced strength, 27.5% reported pain, and 17.5% had swallowing problems.
Some patients recovered over time and 6 months after discharge: 7.5% of participants needed help with self-care activities, 17.5% needed help with medication, 27.5% continued to have respiratory problems (1 patient still needed CPAP), 5% continued to have urinary incontinence, 30% continued to have reduced strength, 2.5% continued to report pain, and 1% continued to have swallowing problems. There were also three patients who remained in rehabilitation programs.
Conclusions: On discharge from the ICU, several patients had disabilities that affected their autonomy and recovery. Six months after discharge, although some patients had recovered, others remained disabled in terms of self-care, strength, and breathing, indicating the need for further support and rehabilitation care. As more data are collected and analyzed, relationships between problems at ICU discharge and their long-term prevalence can be clarified. The use of new technologies can help to improve the continuity of care.

Effectiveness of basal cisternostomy in treating intracranial hypertension: a case series

P. Oliveira[1]; C. Cerca[1]; S. Dias[1]; M. Bruno[1]; L. Bento[1]
[1]Intensive Care Unit, ULS São José, Lisboa, Portugal
Correspondence: P. Oliveira
Intensive Care Medicine Experimental 2025,* 13(1)*:001457

Introduction: Intracranial hypertension [ICH—when intracranial pressure (ICP) exceeds 20–22 mmHg] complicates common causes of acute brain injury, such as traumatic brain injury (TBI) or spanteneous intracranial hemorrage (ICH). The pathophysiology of secondary brain injury is complex and multifactorial but increased ICP, not only is part of the problem, but is a potentially treated complication. A stepwise approach for increased ICP is recommended, with decompressive craniectomy and thiopental perfusion being reserved for the most refractory cases. Both these treatments have high rates of complication. Recently, basal cisternostomy has been proposed as an alternative strategy to control ICP. This technique consists of drainage of cerebrospinal fluid from the basal cisterns, by introducing a catheter in this location.
Objectives: Report of a case series of use of cisternotomy to treat increased ICP refractory to medical treatment.
Methods: Description of a series of cases of cisternotomy in increased ICP and identification of demographics, etiology, complications, length of ICU stay, intrahospital mortality, and functional disability at-discharge [defined as a modified Rankin Scale (mRS) score].
Results: Four patients were submitted to cisternotomy, all male, with a mean age of 29 years (range 19–60). Three patients were admitted in the ICU for severe TBI and 1 for spontaneous acute subdural hematoma. Initial Glasgow Coma Scale (GCS) was between 4 and 7. Patients became refractory to medical treatment between the second and fourth days, and all started thiopental perfusion. Two TBI patients underwent frontal contusectomy in addition to basal cisternostomy. ICP control with cisternotomy was achieved in three patients, with the other patient requiring further decompressive craniectomy. It was possible to progressively reduce thiopental, with its suspension between the first and second post-surgical day and the suspension of sedation between the second and fifth post-surgical day (on average on the 3.25th day). All patients survived, and a median period of ICU stay was 21 days. Only one patient had a mRS score higher than 4 at 3 months.
Conclusions: Basal cisternostomy is a promising treatment for refractory increased ICP in acute brain injury, allowing patients to avoid more aggressive treatments like descompressive craniectomy.

Intensive Care Medicine Experimental 2025,* 13(1)*:001458

Introduction: Orthotopic liver transplantation (OLT) greatly improves survival in end-stage liver disease, yet it is frequently complicated by neurological issues, especially metabolic encephalopathy. Despite advancements in surgical techniques and immunosuppressive therapy, these complications persist as a significant challenge. Mental status changes affect up to 70% of liver transplant recipients in the early postoperative period, resulting in prolonged hospitalizations and higher mortality rates. Early identification of risk factors and preoperative neurological assessments is essential for recognizing high-risk patients and optimizing outcomes. (1)(2).
Objectives: To assess the incidence of metabolic encephalopathy in our cohort of liver transplanted patients, focusing on the etiology of neurological signs and syndromes.
Methods: Pre-operative, intraoperative, and post-operative factors were analyzed, with outcomes, including hospital/ICU stay, complications, rehabilitation needs, and mortality. Ethical approval and informed consent were obtained, and descriptive statistical analysis was performed.
Results: Delirium and metabolic encephalopathy occurred in up to 53 ($p = 0.6053$) patients, especially in the males subgroup (69%).
Among the preoperative factors, the incidence of episodes of PSE (portosystemic encephalopathy) was found in almost half of the subjects.
Moreover, an higher prevalence of chronic renal impairment ($p = 0.0147$), smoking ($p = 0.9611$), and severe ascites before transplant ($p = 0.0564$) were highlighted. On the other hand, possible risk factors such as HCV and HBV etiology were correlated with a lower probability to develop NC, with an incidence inferior of 28% ($p = 0.0427$; OR = 0.6) and 11% ($p = 0.5662$) in both cases.
Between the peri-operative variables, it appears that 46% of the patients had higher sodium plasma concentrations (3), with immediate acute renal impairment in 45.6% ($p < 0.0001$; OR = 3.74) of the cases and continuous renal replacement therapy (CRRT) in 65.8% ($p < 0.0001$; OR = 7.1), respectively.(4) (5).
Moreover, patients with metabolic encephalopathy have shown longer in-hospital length of stay (36% of the cases, $p < 0.0001$; OR = 1.04), with higher incidence of readmissions in ICU (53%, $p < 0.0001$; OR = 6.65), while the necessity of rehab after discharge emerged only in a third of the population considered.
Conclusions: Identifying the risk factors and managing them appropriately in the preoperative and perioperative phase represents a key strategy for reducing postoperative risk. This approach could serve as the focus of future prospective studies.

Pre-operative Risk Factors	Peri-operative Risk Factors	Post-operative Scenario
Severe **ascites** (p<0.05)	Peri-operative renal impairment (p<0.0001)	Longer **in-hospital stay** (p<0.001)
Pre-transplant **K+ concentration** (p<0.05)	Continuous renal replacement therapy - **CRRT** (p<0.001)	Longer ICU stay (p<0.01)
Chronic renal insufficiency - CRI (p<0.05)	**Post-operative infections** (p<0.001)	Higher likelihood of **ICU readmission** (p<0.0001)
Portosystemic encephalopathy - **PSE** (p<0.0005)	**Graft rejection** (p=0.001)	Need for **rehabilitation** after discharge (p<0.05)
Critical condition before transplant (p=0.001)	>3 post-operative complications (p<0.0001)	
Higher **MELD** score (p<0.01)		
Higher **Na+** concentration at POD2		

Summary of relevant risk factors in developing metabolic encephalopathy and related consequences.

Is admission lactate a predictor of outcome in trauma patients admitted to the intensive care unit?

T. Guimaraes[1]; P. Pestana[2]; G. Cabral-Campello[2]
[1]Critical Care Medicina, ULSTS, Penafiel, Portugal; [2]Intensive Care Medicine, Centro Hospitalar Tâmega e Sousa, Penafiel, Portugal
Correspondence: T. Guimaraes
Intensive Care Medicine Experimental 2025,* 13(1)*:001459

Introduction: Early identification of trauma severity is critical to guide timely and appropriate clinical interventions. Serum lactate levels are an important biomarker in trauma, reflecting the severity of the injury and predicting the outcome of treatment. Elevated lactate levels are associated with increased mortality and organ failure.
Objectives: This study aimed to evaluate the predictive value of lactate levels upon admission to the emergency room (ER) for key clinical outcomes, including mortality and lengh of stay (LOS), in a cohort of adult trauma patients.
Methods: This retrospective cohort study was conducted at a secondary care hospital. The study included all trauma patients who were admitted to the Intensive Care Unit (UCI) between October 1st and December 31st, 2024. However, patients under the age of 18 were excluded from the study. Data were collected by reviewing individual electronic medical records. The initial lactate values were obtained from arterial blood gas analyses that were performed in the emergency room. The variables were analyzed using the statistical software R and the significance level was 0.05.
Results: The study included 36 patients, of whom 25 had an Injury Severity Score (ISS) $\geq$ 9. The baseline characteristics are described in Table 1.

Characteristic	
Male, *n* (%)	28 (78)
Age (years, mean ± SD)	55 ± 17
Clinical Frailty Score > 2	6 (17)
Length of stay in ICU (days, mean ± SD)	7 ± 12
Total hospital length of stay (days, mean ± SD)	30 ± 20
ISS (mean ± SD)	15 ± 8
SAPS II (mean ± SD)	26 ± 15
ICU mortality	2 (6)
In-hospital mortality	4 (11)

In a linear regression model evaluating the association between admission lactate levels and ICU length of stay, no statistically significant relationship was found: F (1, 6) = 0.302, p = 0.602. Admission lactate explained only a small proportion of the variance in ICU length of stay (R^2 = 0.048), indicating that it is not a relevant predictor in this cohort. The standardized beta coefficient was 0.219, indicating a small effect size. A logistic regression model was performed to evaluate whether lactate levels at ER admission predicted hospital mortality. The model was not statistically significant (χ^2 = 0.613, p = 0.432) and explained only 4.1% of the variance in outcomes (Nagelkerke R^2 = 0.041). The Hosmer–Lemeshow test suggested adequate model fit (p = 0.557), but the model failed to correctly predict mortality cases (0%).
Conclusions: In this small cohort of critically ill trauma patients, serum lactate levels at admission to the ER did not show a statistically significant correlation with ICU LOS or in-hospital mortality. Although lactate is a biologically plausible marker of injury severity, its prognostic value may be limited when used as a standalone indicator in this population. Further research involving larger sample sizes and additional clinical variables is necessary to fully understand lactate's role in early risk stratification of trauma patients.

Measuring satisfaction levels of healthcare staff and families in a post-pandemic open ICU setting

Cl. Loudet[1]; J. Vilca Becerra[1]; F. Ceschini[1]; E. Del Coco[1]; S. Albornoz[1]; MS. Rios[1]
[1]Intensive care unit, H.I.G.A. SAN MARTIN LA PLATA, La Plata, Argentina
Correspondence: C.I. Loudet
Intensive Care Medicine Experimental 2025,* 13(1)*:001460

Introduction: Meeting the needs of patients' families is a key responsibility for ICU physicians and nurses, aiming to alleviate their distress. Equally, staff satisfaction is vital for delivering quality care and maintaining a harmonious work environment.
Our ICU has upheld an open visitation policy for over a decade. However, post-pandemic restructuring, while maintaining this policy, has led to staff discomfort. This study aims to assess current satisfaction levels among family members and ICU staff.
Objectives: 1. To evaluate family member satisfaction using the Critical Care Family Needs Inventory (CCFNI).
2. To assess job satisfaction among general practitioners (GPs), nurses, and non-physician staff using the Safety Attitudes Questionnaire (SAQ) and the Warr–Cook–Wall (WCW) Job Satisfaction Scale.
Methods: Cross-sectional study conducted over 6 months in a medical-surgical ICU. Family satisfaction was assessed using the short version of the Critical Care Family Needs Inventory (CCFNI), comprising 11

items rated on a four-point Likert scale yielding total scores ranging from 11 to 44. Responses were analyzed both globally and by individual item. Questionnaires were distributed to family members upon patient discharge, provided that the patient had been admitted for more than 2 days.
Job satisfaction among physicians, nurses, and non-physician staff was evaluated using the 15-item Warr-Cook-Wall (WCW) Job Satisfaction Scale, which employs seven-point Likert responses. In addition, the short version of the Safety Attitudes Questionnaire (SAQ) was used to assess Teamwork Climate and Safety Climate domains, using a five-point Likert scale. SAQ scores were transformed to a 0–100% scale, with < 50% indicating poor, 50–79% average, and ≥ 80% excellent perceptions.
We compared job satisfaction across professional groups using both instruments. Data are presented as N (%), mean ± SD, or median (25th–75th percentile). Differences among staff categories were evaluated using one-way ANOVA with Bonferroni correction; a p-value < 0.05 was considered statistically significant.
Results: Out of 233 surveys distributed to families, 97 were completed (42% response rate). The respondents' relationships to the patients were: spouses (23, 24%), children (29, 30%), parents (17, 18%), siblings (13, 13%), and friends/others (15, 15%). The majority of respondents were female (75, 77%), with a mean age of 44 ± 13 years. Patients mean age 50 ± 21 years; 42 (44%) were female.
The mean score on the Critical Care Family Needs Inventory (CCFNI) was 34 ± 4, with a median item score of 3 [interquartile range: 3–4], indicating a high level of family satisfaction.
Among the 160 healthcare staff members surveyed, 146 responded (91% response rate), with 34 physicians, 81 nurses, and 31 non-physician staff members, including physical therapists, occupational therapists, and speech-language pathologists. The SAQ revealed: Teamwork Climate scores: overall staff 71 ± 17, physicians 77 ± 13, nurses 65 ± 18*, and non-physician staff 80 ± 9 (*p < 0.01). For the Safety Climate domain, the mean scores were: overall 65 ± 20, physicians 64 ± 24, nurses 62 ± 19, and non-physician staff 76 ± 12* (*p < 0.01). Figure 1 illustrates the Warr–Cook–Wall (WCW) Job Satisfaction Scale.
Conclusions: Among families, there was a high level of satisfaction, indicating strong approval of the open ICU policy and the overall care received.
- Among staff members, while an acceptable level of job satisfaction was observed across the evaluated SAQ domains, opportunities for improvement were identified in the safety climate domain. Significant differences were noted in both the teamwork and safety climate domains for nursing staff and in the safety climate domain for physicians.
- Based on the findings from the Warr–Cook–Wall (WCW) Job Satisfaction Scale, several items exhibited low performance, highlighting the need to continue with existing policies while seeking strategies to enhance staff satisfaction. This is particularly crucial given the current health crisis affecting the region and specialty, which requires urgent attention.

WCW item	Physicians N 34	Nurses N 81	Non-physicians N 31	p value
1.Physical working condition	3 ±1.8	4.7 ±1.6	5.5 ± 0.8	< 0.01

Early diastolic blood pressure and outcome in hemodynamically unstable trauma patient

FJ. Moran Gallego[1]; P. Moreno Ciudad[1]; C. García Ortiz[1]; I. Lopez De Toro[1]; E. Alonso Ciria[1]; J. Romeu Prieto[1]; M. Sanchez Casado[1]; P. Leal Sanz[1]; G. Morales Varas[1]
[1]Intensive Care Department, Hospital General Universitario de Toledo, Toledo, Spain

Intensive Care Medicine Experimental 2025,* 13(1):*001461

Introduction: The assessment of hemodynamic status is essential in the management of patients with severe trauma. The value of early diastolic blood pressure (DBP) has been little studied, and its utility in hemodynamically unstable patients remains unknown.
Objectives: To evaluate the impact of diastolic blood pressure (DBP) on clinical outcomes and resource utilization in hemodynamically unstable patients with severe trauma.
Methods: A prospective cohort study including patients consecutively admitted to a Trauma and Neurocritical Care Unit between June 2023 and December 2024. We analyzed patients with severe trauma and initial hemodynamic unstability, defined as a shock index (SI) > 0.9. The cohort was stratified into three groups according to DBP at the start of initial management: < 60 mmHg, 61–80 mmHg, and > 80 mmHg. Demographic variables, trauma severity, resource use, and complications were analyzed. The primary outcome was ICU mortality. Secondary outcomes included red blood cell (RBC) transfusion, activation of the massive transfusion protocol (MTP), hospital mortality, and length of stay in both ICU and hospital. Categorical variables were expressed as counts and percentages and compared using the χ^2 test or Fisher's exact test. Continuous variables were reported as median and interquartile range (IQR) and compared using the Kruskal–Wallis test or ANOVA, as appropriate. A two-sided p value < 0.05 was considered statistically significant. Statistical analysis was performed using STATA version 13® (StataCorp LLC).
Results: A total of 83 patients were included, with a median age of 47 years (IQR 26–63); 69.8% were male (n = 58), and the most common cause of trauma was traffic accidents (48.19%, n = 40), with no significant differences between groups.
The group with a DBP < 60 mmHg showed lower Revised Trauma Score (RTS) values (6.2 [3.5–7.1] vs. 7.8 [6.4–7.8]; p = 0.007), as well as other parameters reflecting hemodynamic status (lower systolic and mean arterial pressures, reduced Diastolic Pressure Time Index values, and higher shock indices) (Table 1). However, no significant differences were observed in ICU or hospital mortality, length of stay, need for red blood cell transfusions, norepinephrine requirement, or activation of the massive transfusion protocol. Nevertheless, patients with lower DBP did exhibit a higher incidence of trauma-associated coagulopathy (TIC) within the first 24 h (Table 2).
Conclusions: In patients with severe trauma and hemodynamic instability, lower diastolic blood pressure (DBP) was not associated with increased mortality or greater resource utilization. As expected, other hemodynamic parameters indicative of instability were also altered, suggesting that DBP may provide limited prognostic information in this context, beyond its potential utility as an early indicator of trauma-associated coagulopathy (TIC).

Table 1 Hemodynamic status at initial assessment

Parameter	DBP < 60 mmHg (n=47)	DBP 60–80 mmHg (n=25)	DBP > 80 mmHg (n=11)	Total (n=83)	p-value
Shock Index, median (IQR)	1.32 (1.06-1.62)	1.05 (0.98-1.25)	1 (0.93-1.23)	1.2 (1-1.4)	< 0.001
Systolic BP (SBP), mmHg, median (IQR)	87 (78-95)	109 (100-105)	111 (108-126)	98 (85-110)	< 0.001
Diastolic BP (DBP), mmHg, median (IQR)	50 (44-56)	69 (66-75)	86 (83-90)	60 (50-70)	< 0.001
Mean Arterial Pressure (MAP), mmHg, median (IQR)	63 (47-68)	83 (79-87)	97 (93-102)	72 (60-86)	< 0.001
Diastolic Pressure Time Index (DPTI), points, median (IQR)	15.1 (11.8-21.5)	21 (16.1-22.8)	25.5 (23.9-32.13)	18.2 (14-24)	<0.001
DPTI/SPTI > 1, n (%)	34	44	72.7	42.2	0.063

Table 2 Outcomes and resource utilization

Parameter	DBP < 60 mmHg (n=47)	DBP 60–80 mmHg (n=25	DBP > 80 mmHg (n=11)	Total (n=83)	p-value
Resource Use					
Norepinephrine use during initial management, %	59,1	40	3,3	48,8	0,349
Lowest Hb within 24h, g/dL, median (IQR)	8,85 (8,7-9)	14,3 (14,3-14,3)	11,3 (10,1-12,8)	10,7 (9-12,8)	0,117

Acute alpha-chloralose poisoning: clinical aspects, management, complications and outcome in a Tunisian medical intensive care unit

R. Ben Dabebiss[1]; H. Zouari[1]; A. Chihaoui[1]; H. Hmouda[1]
[1]medical Intensive care unit, Sahloul Hospital, Sousse, Tunisia
Correspondence: H. Hmouda
Intensive Care Medicine Experimental 2025,* 13(1)*:001462

Introduction: In Tunisia, suicide attempts using alpha-chloralose remain a major concern due to the widespread availability of the toxic substance to the general population, and the lack of an appropriate surveillance system. In European countries, chloralose poisoning is mainly encountered in animals (1, 2, 3).
Objectives: The aim of the study was to describe the epidemiological characteristics, clinical aspects, biological features, management, and outcome of patients admitted to the Medical Intensive Care Unit of a Tunisian University hospital for acute alpha-chloralose self-poisoning.
Methods: This was a descriptive, observational, single-center, retrospective study conducted in a Tunisian Medical Intensive Care Unit, from January 1, 2011, to December 31, 2016. Data collection was conducted retrospectively, including social and demographic characteristics, previous medical history, clinical, biological, radiological, toxicological data, severity scores, ICU management, and outcome.
Results: The population included 74 patients with a mean age of 27 ± 9 years, with a female predominance: 57 women (77%) and 17 men (23%), 10 of whom (13.5%) had a history of psychiatric disorders. Only 15 patients were from an urban area, and 59 were from a rural area. The presumed ingested dose averaged 3.36 ± 1.3 g. The time from ingestion to the first medical examination averaged 118 ± 65 min. Medical transport was ensured in 25 patients (33.8%). In the ICU, the severity scores were: APACHE II at 14 ± 2 and SAPS II at 37 ± 6. On examination, all patients were unconscious (GCS less than 8), 31 patients (41.9%) had bilateral mydriasis, myoclonus was present in all patients, and 11 patients had acute circulatory failure. Almost all patients (95.96%) required the use of invasive mechanical ventilation with a mean duration of 22.81 ± 10.54 h. The biological abnormalities encountered included hyperleukocytosis in 25% of patients, hypokalemia in 26% of patients, hyponatremia in 4.1%, relative hypoglycemia in 70.3% of patients, and acute rhabdomyolysis in 27.1% of patients. The main arterial blood gas abnormalities included low bicarbonate level in 39.72% of cases and hypoxemia (PaO2/FiO2 < 300) in 23.28% of patients. Aspiration pneumonia was found in 57 patients (77%). The poisoning was confirmed in all cases by toxicological analyses which showed the presence of alpha-chloralose in gastric content and urine. The median length of stay in ICU was 50 h (20–144 h). The outcome was favorable, and all patients were discharged from the ICU without sequelae.
Conclusions: Acute alpha-chloralose self-poisoning is a common condition in Tunisian intensive care units, affecting a young population. Despite the severity of the initial clinical presentation, the outcome was favorable in all cases. Psychiatric care was provided for all patients.

Percutaneous dilatational tracheostomy in intensive care: a decade-long review in a tertiary single center

B. Queiroz; T. Petrucci; P. Mota; H. Bento; I. Moniz; JM. Ribeiro
Correspondence: B. Queiroz
Intensive Care Medicine Experimental 2025,* 13(1)*:001464

Introduction: Percutaneous dilatational tracheostomy (PDT) has become the preferred alternative to traditional surgical tracheostomy (ST) in intensive care units (ICU) due to lower complication rates and operational efficiency. PDT has been associated with a lower incidence of wound infections. PDT is classically indicated to facilitate weaning

of mechanical ventilation, to protect airways in patients at risk of aspiration, and to minimize sedation requirement.
Objectives: This retrospective study aims to provide valuable insights into the treatment strategies and complications of PDT, to enhance patient care, and to refine therapeutic approaches. Evaluating the safety of PDT in critically ill patients, discussing its indications and complications, and reviewing PDT techniques are among the main objectives.
Methods: Retrospective data were collected from our Intensive Care Department over a period of 10 years. Five hundred thirty-four patients were included. Demographic data, indications for the PDT, techniques used, duration of mechanical ventilation, ventilatory parameters, and associated complications were determined.
Results: Most patients were male (63.5%), with a mean age of 57 years (range 18–94 years). Indications for tracheostomy were airway protection (54.5%) and prolonged mechanical ventilation (41.2%). The main diagnoses identified were traumatic brain injury (19.7%), acute respiratory failure (13.8%), non-traumatic central nervous system hemorrhage (13.5%), and ischemic stroke (10.3%). Other diagnoses leading to the indication for the procedure included critical illness myopathy, anoxic encephalopathy, non-convulsive status epilepticus, and polytrauma patients. The Ciaglia technique was the most commonly employed (91.4%), followed by the Griggs technique (8.4%), both performed electively. The mean duration of invasive ventilation was 14 days (range: 0–46 days). Bronchoscopic guidance was used in 85.6% of cases and ultrasound assistance was applied in 91.6%, reflecting a minimally invasive and guided approach. Immediate complications had a low incidence of 7.0%, with hemorrhage being the most prevalent. No cases of pneumothorax or pneumomediastinum were reported.
Conclusions: Percutaneous tracheostomy has proven to be a safe and effective procedure for critically ill patients, with a low rate of severe complications. Proper patient selection and the adoption of auxiliary techniques, such as bronchoscopy and ultrasound, significantly contribute to procedural success. The optimal technique should be chosen based on individual expertise. The literature supports that standardized tracheostomy care protocols and a structured decannulation process are crucial aspects of patient management, contributing to reduced hospital stays. Further prospective studies are recommended to evaluate the long-term impact of these approaches on clinical outcomes.

Enhancing pediatric burn management: critical care strategies and severity assessment tools

V. Rajagopalan[1]
[1]Anaesthesiology, Pain Medicine & Critical Care, All India Institute of Medical Sciences, New Dlehi, New Delhi India
Correspondence: V. Rajagopalan
Intensive Care Medicine Experimental 2025,* 13(1)*:001467

Introduction: Background: Effective critical care management of pediatric burn patients in a burns center requires a thorough understanding of specific parameters and the utilization of severity assessment tools. Incorporating scores such as PRISM III (Pediatric Risk of Mortality III) and PELOD II (Pediatric Logistic Organ Dysfunction II) aids in risk stratification and optimizing care delivery.

Objectives:
To evaluate the critical care management strategies employed in pediatric burn patients admitted to a specialized burns ICU, focusing on fluid resuscitation, infection control, pain management, respiratory support, and nutritional care.
To assess the utility of PRISM III and PELOD-II scoring systems in the early identification of illness severity and risk stratification in pediatric burn patients.
To analyze the relationship between organ dysfunction scores, complication rates (including sepsis, MODS, and AKI), and patient outcomes such as ICU length of stay and mortality.
To determine whether the integration of illness severity scores can inform clinical decision-making and contribute to the standardization and optimization of pediatric burn critical care protocols.
Methods: A retrospective analysis was conducted on pediatric patients admitted to the burns intensive care unit (ICU) of a burns center between April 2022 and March 2025. A detailed analysis of fluid resuscitation, pain management, infection control, nutritional support, and respiratory care insights into illness severity score (PRISM III) and pediatric logistic organ dysfunction (PELOD-II) on day 1 subsequently.
Results: The study included 574 pediatric patients with burn injuries admitted to the burns ICU. Inhalation injuries were present in 8.78 of cases, necessitating intubation and mechanical ventilation. A total of 22.86% of patients developed complications the leading causes being infections/sepsis (62.65%), multi-organ dysfunction syndrome (MODS) (27.71%), and acute kidney injury (AKI) requiring renal replacement therapy (RRT) (4,0.82%). The complication rates were higher in patients with higher PRISM III and PELOD II scores. The utilization of severity assessment tools such as PRISM III and PELOD II scores facilitates risk stratification and informs treatment decisions, enhancing patient care and prognostication.
Conclusions: Higher resuscitation requirements with higher organ dysfunction scores may predict mortality in pediatric burns warranting further study for standardization of care.
Applicability in clinical practice: In a burns center setting, the integration of critical care parameters and severity assessment tools is integral to optimize outcomes for pediatric burn patients. Continuous refinement of critical care protocols and utilization of appropriate severity assessment tools contribute to improved patient outcomes and resource utilization.

Antibiotic utilization patterns in a burns center: a retrospective analysis

V. Rajagopalan[1]; S. Singh[1]; S. Gupta[1]; R. Ramkumar[1]
[1]Anaesthesiology, Pain Medicine & Critical Care, All India Institute of Medical Sciences, New Dlehi, New Delhi India
Correspondence: V. Rajagopalan
Intensive Care Medicine Experimental 2025,* 13(1)*:001468

Introduction: Antibiotic therapy is pivotal in managing burn patients due to their high risk for infections and sepsis. However, inappropriate antibiotic use may contribute to antimicrobial resistance. Analyzing utilization patterns can inform stewardship strategies tailored to burn-specific clinical scenarios.

Objectives:
To analyze the patterns of antibiotic prescribing in patients admitted to a specialized burns intensive care unit (ICU), including the selection, timing, and duration of therapy.
To identify the most commonly isolated pathogens in culture-positive burn patients and evaluate the appropriateness of antibiotic selection based on sensitivity profiles.
To assess the level of adherence to institutional antibiotic stewardship guidelines and examine reasons for deviations from recommended protocols.
To evaluate the impact of clinical factors such as burn severity, inhalation injury, and immunosuppression on antibiotic use and treatment outcomes.
To provide evidence for the development and implementation of antimicrobial stewardship initiatives specifically tailored to the needs of burn patients.
Methods: A retrospective observational study was conducted at a tertiary burns ICU from November 2022 to March 2025. Patient records were reviewed for demographics, indications for antibiotic initiation, choice and duration of therapy, culture results, and adherence to institutional antibiotic prescribing guidelines. Empirical and targeted therapy approaches were compared.
Results: Of 1754 burn patients admitted during the study period, 300 (17.1%) received systemic antibiotic therapy. Broad-spectrum antibiotics, including cefoperazone–sulbactam and piperacillin–tazobactam, were the most commonly used agents, primarily for prophylactic purposes. Of the 250 patients with positive cultures, *Pseudomonas aeruginosa* was the most frequently isolated pathogen, followed by *Acinetobacter baumannii* and *Klebsiella pneumoniae*. Antibiotic regimens were adjusted based on culture and sensitivity in 83% of cases. Therapy duration was influenced by burn severity, presence of inhalation injury, and immunocompromised status. Adherence to institutional guidelines was noted in the majority of cases, with deviations typically occurring during empiric treatment prior to microbiological confirmation.
Conclusions: Antibiotic use in burn patients requires a delicate balance between timely prophylaxis and targeted treatment. Culture-guided therapy and standardized protocols enhance therapeutic efficacy while reducing the risk of resistance. The development and implementation of antimicrobial stewardship programs specifically adapted to the burn population are essential.

Relevance to Clinical Practice
Burns ICUs present unique challenges for antibiotic stewardship due to high infection risk and complex microbial profiles. Multidisciplinary stewardship models—integrating burn surgeons, intensivists, infectious disease specialists, and clinical pharmacists—are key to optimizing antimicrobial use, preventing resistance, and improving outcomes in burn patients.

Antibiotic utilization patterns in a burns center: a retrospective analysis

Intensive Care Medicine Experimental 2025,* 13(1)*:001469

Introduction: The assessment of potential organ donors is crucial for optimizing transplant outcomes. Among the various tools employed, the Kidney Donor Profile Index (KDPI) and the Donor Risk Index (DRI) stand out as significant prognostic scores. These indices integrate a range of donor characteristics to predict graft survival and recipient outcomes following kidney and liver transplantation, respectively. By quantifying donor risk, KDPI and DRI aid in informed decision-making during organ allocation. This allows transplant centers to balance the risks and benefits for individual recipients, ultimately aiming to improve patient survival and graft function. Their broad implementation reflects the growing recognition of standardized risk assessment as a cornerstone of effective organ transplantation practices.
Objectives: While KDPI and DRI are not routinely calculated for every potential donor, the Simplified Acute Physiology Score II (SAPS II) is a standard assessment performed upon admission to the Intensive Care Unit (ICU). Given the availability of SAPS II data, the objective of this data analysis is to evaluate whether a statistically significant correlation exists between SAPS II scores and the KDPI and DRI values in potential organ donors.
Methods: This study, authorized by local Ethic Committee, involved a retrospective analysis of patients who underwent brain death determination according to clinical criteria. Patients were enrolled from those admitted to the Intensive Care Unit (ICU) of Gaetano Martino University Hospital of Messina, between January 2019 and March 2024. 65 patients underwent in brain death diagnosis criteria were enrolled. We excluded: 18 patients because of lack some of clinical or laboratory parameters and 7 patients, because were included in some other clinical studies. The mean ICU length of stay is 7.14 days. Causes of brain death, including: traumatic brain injury (18 patients, 27.69%); sub-arachnoid hemorrhage (9 patients, 13.85%); ischemic stroke (11 patients, 16.92%); hemorrhagic stroke (18 patients, 27.69%); post-anoxic encephalopathy (2 patients, 3.08%); and brain tumor (6 patients, 9.23%). We calculated the SAPS II score on the day of the patient's admission to the ICU and on the day of brain death diagnosis. These values were then correlated with the corresponding KDPI and DRI values using Pearson's correlation coefficient, implemented with the SciPy library in the open-source programming language Python.
Results: The results of our analysis revealed the following Pearson correlation coefficients: SAPS II Score at ICU admission showed a weak positive correlation with KDPI ($r = 0.428$, $p < 0.001$) and a weak positive correlation with DRI ($r = 0.412$, $p = 0.001$). The SAPS II score at the time of brain death diagnosis demonstrated a moderate positive correlation with KDPI ($r = 0.658$, $p < 0.001$) and a strong positive correlation with DRI ($r = 0.709$, $p < 0.001$).
Conclusions: Our analysis shows a association between the SAPS II score and the KDPI and DRI, suggesting that the SAPS II score, due to its straightforward and routine calculation in ICU settings, could potentially serve as a predictor for KDPI/DRI values. It is important to acknowledge that the current sample size is a limitation, and future studies with larger and more diverse cohorts are essential to validate these preliminary findings and explore their clinical implications.

Intensive Care Medicine Experimental 2025,* 13(1)*:001471

Introduction: Acute liver failure (ALF) is a rapidly progressive condition with high mortality, requiring urgent liver transplantation (LT) in up to 50% of cases. This accounts for approximately 8% of all liver transplants. Factors that have been associated with higher mortality include non-paracetamol etiologies; organ failure with the need for mechanical ventilation, renal replacement therapy (RRT) or vasopressors, and donor factors.
Objectives: This study aims to explore the outcomes of LT in patients with ALF, focusing on the impact of their clinical status on hospital mortality.
Methods: We conducted a retrospective analysis of LT motivated by ALF, including patients submitted to LT in this context between 2020 and 2023. Data were extracted from hospital records, and statistical analysis was performed using SPSS v27 with a significance level of 0.05.
Results: Of the 312 LTs conducted between 2020 and 2023, 24 were due to ALF (7.7%) and, therefore, included. Patients had a mean age of 42.5 years (SD 12.877), 54.2% were female, and 45.8% had blood group O. Concerning the subclasses of ALF, 45.8% were hyperacute, 37.5% were acute, and 16.7% were subacute. The most prevalent cause was toxicity (33.3%), which was due to a variety of agents (only one paracetamol-related ALF). Other causes included post-procedural ALF (20.8%), mainly after high-risk abdominal surgery or TIPS. The mean SOFA score was 8.8 (SD 4.70) at admission and 13.1 (SD 5.09) at LT, with an average delta-SOFA of 4.3 (SD 3.97). The mean donor age was 57.05 (SD 18.365), with no live donors and only one with circulatory death. Three (12.5%) were ultimately submitted to retransplant. Survival to discharge was 79.2%, and 1-year survival was 70.8%. Factors that significantly impacted hospital mortality (p value < 0.05) included donor age > 75, hepatic encephalopathy grade (West-Haven), need for vasopressor or RRT, total bilirubin before LT, SOFA score at LT, units of packed red blood cells during LT, and length of hospital stay. There was also a tendency for statistical significance (p value < 0.10) for active infection and the number of fresh frozen plasma units during LT. We built a logistic regression model using the most significant variables, which showed that for each one-point increase in SOFA at LT, the mortality increased by 69%. Of the 17 1-year survivors, 15 had registries about their current performance status, which was mostly good, with half of them specifying that they had returned to work.
Conclusions: Our results build upon the existing evidence that pre-LT organ dysfunction and advanced donor age are critical determinants of post-transplant outcomes in ALF. Therefore, strategies to mitigate these risks, such as prompt referral and timely transplantation, are crucial. Optimizing donor selection, potentially prioritizing younger donors when feasible, and aggressively managing multiorgan failure may further improve survival in this challenging patient population.

Intensive Care Medicine Experimental 2025,* 13(1)*:001474

Introduction: Electrical injury, especially involving high-voltage currents, can cause life-threatening complications due to severe metabolic disorders.
Objectives: The aim of this study was to identify metabolic disorders following electrical injuries and their impact on prognosis of these patients.
Methods: A retrospective descriptive study was conducted in the intensive burn care department in Tunisia over a period of 5 years, from January 1st 2018 to December 31st 2022. Electrical burned patients required hospitalization was included. Biological data were collected.
Results: During the study period, 223 patients were victims of electrical burns (10.5%). The average age was 35 ± 15 years with a male predominance (96.4%). It was mainly a high voltage electrical injury (83.9%). Rhabdomyolysis was frequently observed (n = 169; 75.8%), particularly in cases of high-voltage electrical injuries (n = 154, 69%). The median levels of creatinine phosphokinase (CPK) and lactic dehydrogenase (LDH) were 7670 [3586–30121] UI/l and 658 [432–1351] UI/L, respectively. Hemoconcentration was also common (n = 106; 47.5%) with an average hemoglobin level of 16.6 ± 1.33 g/dl and an average hematocrit of 47.9 ± 4%. Acute renal failure (ARF) was noted in 40 patients: on admission in 30 cases (13.5%), especially following high-voltage electrical injuries (n = 29; 96.7%), and during hospitalization at day 3 in 10 cases (4.5%). The average urea and creatinine levels were 10.2 ± 0.8 mg/l and 153.4 ± 20.1 µmol/l, respectively. ARF was functional in 25 cases (62.5%) and organic in 15 cases (37.5%). Renal replacement therapy (RRT) was required in nine cases (22.5%). Metabolic acidosis was observed in ¼ of patients (n = 50, 22.4%). The mean pH was 7.32 ± 0.09 [6.90–7.35]. Hyperlactatemia was observed in 13.5% of cases (n = 30). Hepatic cytolysis was observed in 1/3 of patients (n = 65; 29.1%). All metabolic disorders were significantly associated with mortality except for hepatic cytolysis (Table 1). In multivariate analysis, lactatemia higher than 3 mmol/l was predictive of mortality (p = 0.000 AUC = 0.75, Se = 72%, Sp = 72.7%, and CI 95% = 0.635–0.871).
Conclusions: Metabolic disorders following electrical injury are common and severe. Early management and close monitoring of these disorders are crucial to limit their complications and improve prognosis of patients.

Table 1 Metabolic disorders associated with mortality in electrical injuries

Metabolic disorders	Groupe 1 (Survivors) (n=187)	Groupe2 (Dead patients) (n=36)	P
Hemoconcentration (n, %)	79 (42,2)	27 (75)	**0,000**
Metabolicacidosis (n, %)	29 (15,5)	21 (58,3)	**0,000**
Lactatemia (mmol/L) Mean, standard deviation	1,4±0,6	3,7±2,3	**0,000**
Rhabdomyolysis (n, %)	138 (73,8)	31 (86,1)	**0,03**
Maximum CPK (UI/L) Median, interquartile range	7 735 (1070-24729,2)	11 325 (3409-38769,5)	**0,000**
Maximum LDH (UI/L) Median, interquartile range	500 (324,1046)	979 (561,5-2076,5)	**0,000**
Acute renal failure: n (%)	16 (8,6)	24 (66,7)	**0,000**

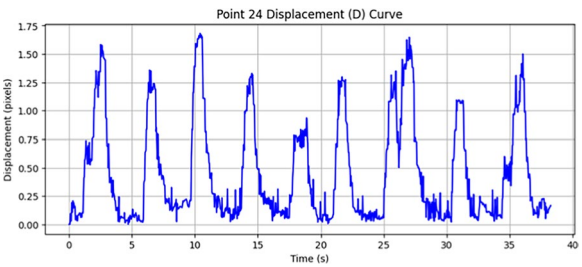
Detection of patient–ventilator asynchrony in the ICU using computer vision

M. Zhang[1]; M. Hendrickson[2]; J. Sahajwani[3]; D. Mercado[4]; M. Franklin[4]; B. Taati[1]; A. Bhattacharyya[3]
[1]Department of Computer Science and the Institute of Biomedical Engineering, University of Toronto, Toronto, Canada; [2]Respiratory Care, Mayo Clinic, Jacksonville, United States of America; [3]Critical Care, Mayo Clinic, Jacksonville, United States of America; [4]Department of Simulation, Mayo Clinic, Jacksonville, United States of America
Correspondence: A. Bhattacharyya
Intensive Care Medicine Experimental 2025,* 13(1)*:001475



Introduction: Patient–ventilator asynchrony occurs when a patient's breathing efforts are not properly synchronized with the mechanical ventilator, potentially leading to discomfort, impaired gas exchange, and prolonged ICU stays. Detecting this asynchrony is especially important in the ICU, where timely intervention can significantly improve patient outcomes. Non-invasive monitoring of respiratory patterns offers the potential for real-time detection of ventilation abnormalities.
Objectives: This project aims to develop and evaluate a computer vision system that analyzes motion signals from ICU video footage to automatically detect patient–ventilator asynchrony. The objective is to assess the utility of this contactless approach for detecting patient–ventilator asynchrony episodes and improving real-time respiratory monitoring in critical care settings.
Methods: Two 4-h ICU simulation videos of a mannequin connected to a ventilator were analyzed. Each breath was manually annotated as normal, abnormal (asynchrony), or unsure. Feature point detection and optical flow algorithms were applied to track motion in the chest region. From the resulting displacement time series, two respiratory signals were derived: Flow, indicating the rate of chest movement, reflecting breathing dynamics, and volume, calculated by integrating flow over time, approximating lung inflation and deflation. The time-series data were segmented using a sliding window of 256 frames (~ 8.5 s at 30 frames per second). Each window was labeled according to the presence of normal or abnormal breathing events, with windows containing uncertain labels excluded from the training set. For classification, each segment was transformed into the frequency domain using the fast Fourier transform (FFT), and the magnitude spectrum was used as input features. These features were then input into a multi-layer perceptron (MLP) classifier trained to distinguish between normal and abnormal breathing patterns.
Results: The accuracy of the extracted flow and volume signals was validated by overlaying the derived volume curve onto the original video footage and visually confirming its close agreement with ventilator-provided waveforms. For model evaluation, the data set was divided into training (first 60% of each 4-h video), validation (next 20%), and test (final 20%) sets. On the test set, the MLP classifier achieved an accuracy of 98.3%, demonstrating its effectiveness in detecting abnormal respiratory events directly from ICU video data.
Conclusions: This study demonstrates that a video-based, AI-powered system can accurately and non-invasively detect respiratory abnormalities, offering a promising supplementary tool for ICU monitoring, especially in settings, where contactless methods are preferred. Further validation in human subjects is needed to confirm its clinical utility.

A wearable, ocular ultrasound-based system for non-invasive diagnosis and monitoring of intracranial pressure (ICP)

I. Emeruwa[1]; G. Herrnstadt[2]; G. Oland[3]; N. Parikh[4]; P. Vespa[5]
[1]Medicine, University of California, Los Angeles, Los Angeles, United States of America; [2]Operations, CranioView, Inc., Vancouver, Canada; [3]Surgery, Mount Sinai, New York, United States of America; [4]Healthcare, HealthQuest Capital, San Antonio, United States of America; [5]Neurosurgery, University of California, Los Angeles, Los Angeles, United States of America
Correspondence: I. Emeruwa
Intensive Care Medicine Experimental 2025,* 13(1)*:001476

Introduction: Elevated intracranial pressure (ICP) can threaten lives in traumatic brain injury patients. Ventriculostomy is the standard method for monitoring and managing ICP. Due to risks of infections and bleeding, extraventricular drain (EVD) placement occurs in about 3% of patients at risk for elevated ICP post-injury. There is a need for innovative, non-invasive technology to enhance ICP monitoring access, reduce complications, and improve outcomes. Ocular ultrasound, measuring the optic nerve sheath diameter (ONSD), shows strong potential in detecting elevated ICP. However, its application varies among providers and cannot currently estimate absolute ICP quantitatively.
Objectives: To develop and validate a machine learning (ML) algorithm for automatic segmentation and interpretation of ultrasound images of the optic nerve sheath and surrounding structures while standardizing the image acquisition technique for high-quality input data.
Methods: In this study, healthy individuals were recruited to obtain ultrasound images of the eye. Examinations were conducted in a simulation and procedure training lab at UCLA.
Blood pressure and heart rate were measured and recorded in addition to demographic data. A faculty ophthalmologist completed a visual examination, which covered visual acuity, visual field confrontation, extraocular muscle activity, and pupillary response. The investigator conducted this examination before and after ultrasound imaging collection.
The operator performed one sweep of the eye from top to bottom using a custom 3D-printed headframe placed on the patient's face (Fig. 1). A clean dressing and ultrasound gel were applied to each eye for imaging. The probe was positioned for optimal ONSD measurement, continuously imaging for 15 s, generating a "cine" file of images with measured heart rate. These data were analyzed for quality, as described by Padayachy et al. This was done in four positions: upright, semi-recumbent at 30 degrees, supine, and 15 degrees Trendelenburg, with heart rate measurements repeated for each position.
The continuous, steady insonation in the optimal plane was phase-synchronized to the patient's heart rate by employing temporal (resampling and peak detection) and spectral (Fourier transform) techniques to identify temporal trends related to arterial pulsations within the eye.
Results: 128 distinct images were collected for 12 subjects. CranioView's ML auto-segmentation algorithm measured ONSD with an accuracy of up to 97% compared to expert measurements. CranioView also demonstrated a decrease in motion artifacts with the wearable device and the accurate identification of dynamic brain tissue motions.
Conclusions: The CranioView wearable device enhances image stability during prolonged insonation. Paired with CranioView's processing method, it accurately detects dynamic signals in ultrasound videos. CranioView is advancing ML techniques for auto-segmentation and hands-free extraction of variables from structures surrounding the optic nerve.

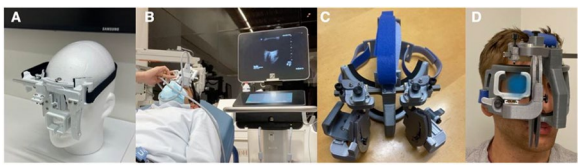

Figure 1 *Custom headframe was developed to stabilize the ultrasound probe for optic nerve sheath diameter (ONSD) measurement. The headframe consists of a head brace and probe holder with passive hinges to allow probe positioning. (**a**) Version 1 prototype headframe, (**b**) optic nerve during active data collection with version 1 prototype, (**c**) assembled headframe prototype version 2 for bilateral probes, and (**d**) version 2 prototype donned.*

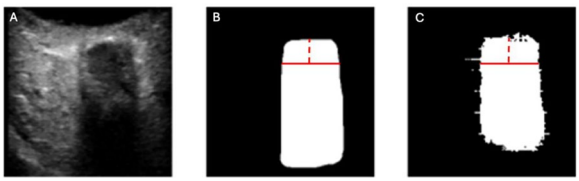

Figure 2 *(**a**) Real-time ultrasonography of a subject's eye and optic nerve sheath [indicated by arrow]; (**b**) "ground truth" identification of optic nerve sheath [white] and diameter [solid red] as measured 3 mm behind the eye [dashed red]; (**c**) mask image of optic nerve sheath as predicted by CranioView ML auto-segmentation algorithm.*

Intensive Care Medicine Experimental 2025,* 13(1):*001477

Introduction: Optimizing antibiotic therapy in sepsis is crucial to improving clinical outcomes. Clinical pharmacists can play a significant role in antibiotic stewardship, potentially enhancing patient outcomes. However, existing evidence on the impact of pharmacist interventions in critical care settings is inconsistent. This study focuses on semicritical units, hypothesizing that antibiotic interventions may play a more central role in patients with less severe illness.
Objectives: To evaluate whether clinical pharmacist intervention improves optimal antibiotic therapy at day 4 and clinical response at day 7 in septic patients treated in semicritical units.
Methods: A randomized controlled trial was conducted, including 200 adult septic patients (100 per arm), randomized into pharmacist intervention, or standard care groups. Data on demographic, clinical, and therapeutic variables were collected. Primary outcomes included optimal antibiotic therapy at day 4 (defined by coverage, dosage, frequency, route, and duration adjustments) and favorable clinical response at day 7. Descriptive statistics, chi-square tests, and logistic regression analyses were performed to evaluate group differences and outcome predictors.
Results: Groups were comparable in age (mean 62.9 ± 19.0 vs. 61.7 ± 20.5 years), gender (44% vs. 53% male), BMI, comorbidities, and previous hospitalizations. Pharmacist intervention significantly increased optimal antibiotic therapy at day 4 ($p = 0.003$) and clinical response at day 7 ($p = 0.018$). Logistic regression showed pharmacist intervention independently predicted optimal antibiotic therapy at day 4 (OR = 2.94, 95% CI 1.50–5.75, $p = 0.002$). Optimal antibiotic therapy at day 4 strongly predicted favorable clinical outcomes at day 7 (OR = 15.16, 95% CI 5.00–45.97, $p < 0.001$).
Conclusions: Clinical pharmacist involvement significantly improves antibiotic optimization by day 4 and subsequently enhances clinical outcomes by day 7 in septic patients treated in semicritical units. This underscores the importance of pharmacist-led interventions, particularly in less critically ill populations, to enhance antibiotic stewardship and patient outcomes.

Table 1 Patient's characteristics

Variable	Control (mean±SD or %)	Intervention (mean±SD or %)	p-value
Age	62.91 ± 18.95	61.70 ± 20.49	0.681
BMI	27.16 ± 5.64	25.18 ± 5.50	**0.018**
Number of Comorbidities	2.27±1.36	2.22±1.48	0.615
SOFA score Day 1	1.20 ± 1.67	0.86 ± 1.25	0.119
SOFA score Day 7	0.81 ± 1.49	0.66 ± 1.22	0.445
Delta SOFA	-0.39 ± 1.16	-0.20 ± 0.95	0.233
Male gender	44.4%	53.3%	0.297
Antibiotic allergies	12.2%	3.3%	0.051
Transferred patients	36.7%	35.6%	1
Previous hospitalization	57.8%	64.4%	0.445
Previous cultures	90.0%	95.6%	0.249

Intensive Care Medicine Experimental 2025,* 13(1):*001478

Introduction: Nutritional problems, including malnutrition, are an important issue in intensive care units. The rate of malnutrition ranges from 8.1% to 71.7% in critically ill children. Early detection and prevention of malnutrition are crucial in reducing morbidity and mortality. Most societies recommend using a rapid and simple screening tool after the first 24 h to identify patients at risk for malnutrition.
Objectives: To evaluate the relationship between nutritional screening tools and critically ill children's morbidity and mortality.
Methods: We used a database generated from the electronic health records of patients aged 2–16 who were admitted to our 18-bed tertiary care Pediatric Intensive Care Unit (PICU) between February 2023 and January 2024. Demographical data and calculated values of Pediatric Nutritional Risk Score (PNRS), Pediatric Yorkhill Malnutrition Score (PYMS), Screening Tools for Risk of Nutritional Status and Growth (STRONGkids), Screening Tool for the Assessment of Malnutrition in Pediatrics (STAMP), Pediatric Risk of Mortality 3 (PRISM-3), Pediatric Logistic Organ Dysfunction-2 (PELOD-2), Pediatric Index of Mortality (PIM2), and Pediatric Sequential Organ Failure Assessment (pSOFA) after 24 h of admission were recorded. The prognostic nutritional index (PNI), computed as albumin level (g/L) + 0.005 × lymphocyte count (μL), assesses nutritional and immunological status concerning morbidity and mortality.
Results: A total of 415 children were admitted to the PICU during the study period, and 169 children (69 girls, 100 boys, median 87 months; IQR 24–192 months) were included. 37.8% ($n = 64$) were previously healthy children. The reason for admission to the PICU was medical (81.6%; $n = 138$). Lower respiratory tract infections (26.6%) are the most common diagnosis at admission, followed by neurological diseases (17.7%). The median length of stay in PICU was 3 days (IQR, 1–188 d). Malnutrition was detected in 16.5% ($n = 28$) of the patients, and 11.2% ($n = 19$) had chronic malnutrition. Overall, the PICU mortality rate was 10%. All nutritional screening tools and PICU prognosis scores were correlated with mortality, PICU LOS, and the number of days on mechanical ventilation. A statistically significant difference was detected when all nutritional screening tools, and PICU prognosis scores of non-survivors were compared with those who survived ($p < 0.001$ for all). With logistic regression analysis, the highest correlation was found with PYMS ($p < 0.001$). ROC analysis revealed that mortality and all nutritional screening tools had low sensitivity but high specificity. PYMS has the highest prediction accuracy among the scores. Mortality risk was higher in patients who began enteral feeding later or were not fed at all. The PNI values were statistically significantly lower in non-survivors than in the survivors (median 36.5; IQR 20.3–54.7 vs. median 50.2; IQR 26.7–93.2; $p = 0.001$).
Conclusions: This study is the first pediatric study to demonstrate the relationship between nutritional screening tools and the PRISM

3, PELOD-2, PIM2, and pSOFA scores, which are commonly used in the PICU to predict mortality risk, especially for PYMS. PNI is also a valuable biomarker for assessing mortality risk in PICU patients.

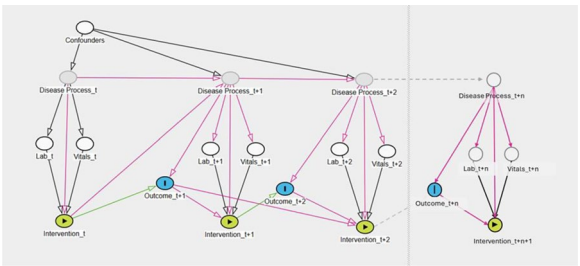
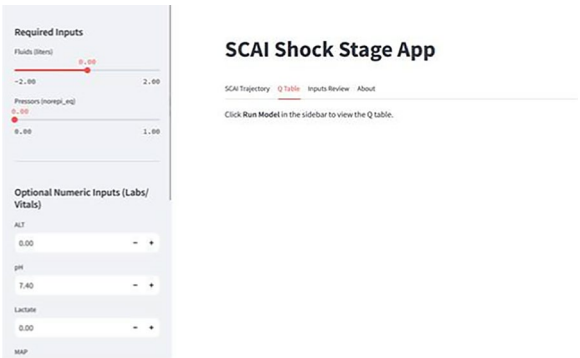
Intensive Care Medicine Experimental 2025,* 13(1)*:001479



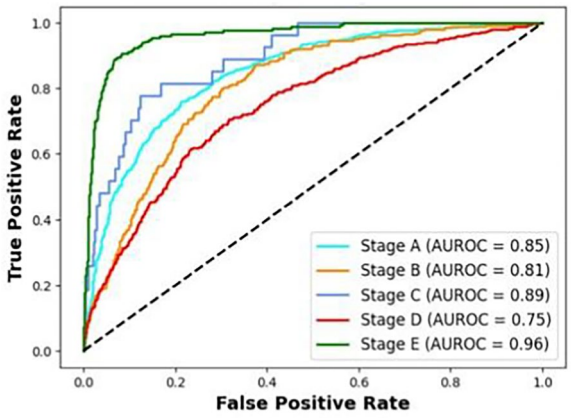
Introduction: Shock is a life-threatening syndrome characterized by inadequate tissue perfusion, necessitating precise hemodynamic monitoring and patient-specific therapeutic adjustments to prevent irreversible organ damage and mortality. Considerable heterogeneity remains in fluid resuscitation and vasopressor titration practices across ICUs. Current fixed treatment algorithms fail to adequately address the dynamic alterations in cardiac output, vascular resistance, and microcirculation observed in shock progression. This mismatch highlights the critical need for responsive, physiology-driven treatment strategies capable of rapidly adapting to evolving clinical states and preventing multiorgan failure.

Objectives: To develop and evaluate a predictive and prescriptive digital twin utilizing deep learning and reinforcement learning to optimize personalized fluid and vasopressor therapy in shock management.



Methods: This study utilized electronic medical record (EMR) data—including demographics, comorbidities, hourly vitals, and laboratory values—to build a digital twin-based decision support system. Patients were categorized into five clinical states: hypotension without shock (SCAI A/B), shock (SCAI C/D), refractory shock (SCAI E), discharge, and death. A long–short-term memory (LSTM) model was developed for real-time prediction of shock state transitions within a 2-h prediction window. A directed acyclic graph (DAG) modeled causal relationships between fluid and vasopressor interventions and shock progression. A Q-learning reinforcement learning model was employed to optimize fluid and vasopressor strategies for each clinical state, with interventions adaptively adjusted based on patient responses. An interactive simulator was created, enabling visualization and manipulation of interventions and observing consequent *Q* value changes.

Results: In this retrospective study, data from 2061 ICU patients admitted to Amsterdam University Medical Center were analyzed; patients with EMR data under 24 h were excluded. The digital twin LSTM model showed strong predictive performance, with AUROC values highest for refractory shock (Stage E, AUROC = 0.96) and lower for Stages A (0.85), B (0.81), C (0.82), and D (0.75). Q-learning analysis highlighted that optimal interventions varied according to shock severity and patient subgroup. In general shock states, neutral fluid balance combined with low-dose vasopressors consistently provided optimal outcomes across most cohorts. In refractory shock (extremis shock), cohort-specific strategies emerged; neutral fluid balance with low-dose vasopressors was optimal for cardiac and cardiothoracic surgery patients, while negative fluid balance combined with high-dose vasopressors proved most effective in surgical patients.



Conclusions: This study establishes the feasibility and potential clinical value of a digital twin system integrating deep and reinforcement learning for real-time shock trajectory prediction and optimization of fluid and vasopressor management. Future studies will validate this approach across broader patient cohorts and explore advanced reinforcement learning techniques to enhance personalized ICU care.

Causal directed acyclic graph representing the evolving disease process and clinical decision-making in an ICU setting.

A dynamic graphical user interface for real-time clinical decision support, allowing the clinician to modify treatment interventions and observe their predicted effects on key physiological variables over time.

Hiding in plain sight: how baseline kidney function may hold the key to hydrocortisone efficacy in septic shock–post hoc analysis of VANISH trial

DB. Antcliffe[1]; F. Uhle[2]; AC. Gordon[1]; L. Forni[3]
[1]Division of Anaesthetics, Pain Medicine and Intensive Care, Department of Surgery and Cancer, Imperial College London, London, United Kingdom; [2]Medical, Sphingotec GmbH, Hennigsdorf, Germany; [3]Royal Surrey County Hospital NHS Foundation Trust, Department of Clinical and Experimental Medicine, Faculty of Health Sciences, Guildford, United Kingdom
Correspondence: F. Uhle
Intensive Care Medicine Experimental 2025,* 13(1)*:001480

Introduction: Hydrocortisone has been studied for decades as an adjunctive therapy in septic shock, yet large scale RCTs have yielded ambiguous and often conflicting results [1]. Heterogeneity of treatment effect (HTE) has been proposed as a key driver, arising from the syndromic nature of sepsis itself, highlighting the need for trial enrichment strategies to identify the responsive critical ill patients while minimizing harmful side effects. Until now, patient stratification based on renal function has not been explored. Given the kidney's pivotal role in sepsis pathophysiology and corticosteroid metabolism, we hypothesize that baseline renal function, assessed using the novel kidney function biomarker Proenkephalin A in plasma, may determine hydrocortisone efficacy.
Objectives: To evaluate whether baseline kidney function modifies the efficacy of hydrocortisone in patients with septic shock, with a focus on survival and renal failure.
Methods: We conducted a post-hoc analysis of a subgroup of patients (n = 173) enrolled in the VANISH trial [2], for whom plasma was available for the measurement of Proenkephalin A (penKid) at baseline. VANISH was an NIHR-funded RCT using a two-factorial design (first stratum: noradrenaline vs. vasopressin, second stratum: placebo vs. low-dose hydrocortisone) in 409 patients with septic shock. The additional penKid measurements were performed using an IVD-certified chemiluminometric immunoassay (sphingotest penKid, SphingoTec GmbH, Germany) in an experimenter-blinded manner. Biomarker results were analysed together with other characteristics of renal function and severity of illness [e.g., serum creatinine (sCr), lactate, and APACHE II score] and associated with the primary endpoint 28-day mortality in this study as well as renal-failure free days (within 28 days) the primary outcome of the trial. For penKid, a concentration of 89 pmol/L was set as a cutoff to define abnormal kidney function at higher levels. For sCr, gender-specific cutoffs of 84 mmol/L in females and 104 mmol/L in males was used. Analysis was performed using logistic regression models and the aligned rank transform test.
Results: A total of 173 patients were available for this post-hoc analysis, with no major imbalances compared to the full study. Proenkephalin A independently predicted 28-day mortality, even after adjusting for serum creatinine, renal failure (according to AKIN stage 3), lactate, and APACHE II, which all remained significant. Patients with elevated penKid at baseline had a 28-day mortality of 39% vs. 16% in those with low levels.
The penKid–treatment interaction (n = 111) was not significant (p = 0.14), possibly due to sample size, but a trend emerged: patients with impaired kidney function had higher mortality with hydrocortisone vs. placebo (50% vs. 32%), while those without kidney dysfunction showed a reversed trend (14% vs. 24%, HC vs. placebo).
A significant interaction existed for renal failure-free days (p = 0.008), with 11 (0–26) vs. 26 (15–28) days in elevated penKid patients treated with HC or placebo, respectively. Serum creatinine as a grouping variable did not yield a significant interaction (p = 0.2), with 20 (0–28) vs. 26 (14–28) days in patients with elevated sCr and HC or placebo, respectively.
Conclusions: This post-hoc analysis highlights penKid as a promising biomarker for patient enrichment in septic shock. Our findings suggest that kidney function may serve as a key determinant for individualized adjunctive treatment, warranting further research to refine precision medicine in sepsis.

Hypocalcemia as a predictor of mortality and vasopressor requirement in trauma patients: a retrospective analysis

S. Costa[1]; J. Gameiro[2]; S. Mexia[1]; M. Magno[1]; E. Gisca[1]; C. Cunha[1]; C. Santos[1]; A. Araujo[1]; L. Pereira[1]

Intensive Care Medicine Experimental 2025,* 13(1)*:001481

Introduction: Trauma remains one of the leading causes of potentially preventable death in adults, despite the implementation of trauma protocols [1, 2]. In trauma patients, calcium plays a significant role in platelet aggregation, the coagulation cascade, cardiac contractility and vasoconstrictive capacity, the latter of which contributes to worsening acidosis [2, 3]. Over half of trauma patients are hypocalcemic upon arrival at the emergency department, even before receiving any blood products [2, 4]. Although there is no current consensus on the optimal timing or degree of calcium repletion in trauma care, clinicians should be aware of the associated morbidity and mortality and be prepared to treat hypocalcemia.
Objectives: To compare overall in-hospital mortality between trauma patients presenting with hypocalcemia ($Ca^{2+} < 1.2$ mmol/L) and those with normocalcemia ($Ca^{2+} \geq 1.2$ mmol/L) upon emergency department admission.
Methods: We performed a retrospective comparative analysis including trauma patients admitted to the emergency department over a 6-month period. Two groups were created: Group 1 (G1) with $Ca^{2+} < 1.2$ mmol/L and Group 2 (G2) with $Ca^{2+} \geq 1.2$ mmol/L. Serum calcium levels were measured upon admission using routine blood analysis. Patients without documented calcium levels at admission were excluded. Levene's test was used to assess group homogeneity. The chi-square test and ANOVA were used for group comparisons.
Results: We included 27 patients (G1: n = 12, 83% male, median age 66.7 ± 19, average Charlson score 3.17 ± 2.16; G2: n = 15, 66.7% male, median age 62.5 ± 20.5, and average Charlson score 2.80 ± 2.5). The majority of injuries were due to blunt trauma (88.9%), mostly from traffic accidents (40.7%) and high-energy falls (29.6%). The most common trauma type was thoracic (44.4%), with pulmonary contusion being the most prevalent (25.9%). Traumatic brain injury (TBI) occurred in 25.9%, with subdural hematoma (SDH) being the most frequent (22.2%). Mechanical ventilation was required in 40.7%, and 33.3% required vasopressor support and surgery. ICU admissions accounted for 37% (n = 10), with a median ICU length of stay of 14.67 ± 15.2 days (range: 2–43). A total of 44.4% of patients were transferred to a tertiary hospital. The overall median in-hospital length of stay was 19.63 ± 20.6 days (range: 1–68). Trauma scores were compared between G1 (RTS: 2.68 ± 1.47, range: 2.63–7.84; ISS: 23 ± 17.50, range: 9–61; TRISS survival: 77.4 ± 27.9%, range: 4.40–99.4%) and G2 (RTS: 6.99 ± 1.23, range: 4.09–7.84; ISS: 14 ± 11.3, range: 1–41; TRISS survival: 87.3 ± 22.3%, range: 22.2–99.8%). Hypocalcemia was significantly associated with increased vasopressor support (G1: 58.3% vs. G2: 13.3%; $\chi^2 = 6.075$, $p = 0.014$) and in-hospital mortality (G1: 50% vs. G2: 6.7%; $\chi^2 = 6.51$, $p = 0.011$).
Conclusions: In this sample, hypocalcemia (serum $Ca^{2}+ < 1.20$ mmol/L) was associated with increased need for vasopressor support and higher in-hospital mortality. Such associations were not observed in patients with higher calcium levels, highlighting the potential prognostic value of early calcium assessment and correction in trauma care.

Intensive Care Medicine Experimental 2025,* 13(1)*:001482

Introduction: Artificial intelligence (AI) presents transformative opportunities to address the global healthcare challenges, particularly in data-intensive environments like intensive care units (ICUs). A systematic review published in 2021 revealed that less than 5% of AI applications in the ICU had reached clinical operationalization [1]. Since then, there has been growing interest in leveraging AI for healthcare. Continued monitoring of AI's transition from development to implementation is essential to monitor its progress and impact.
Objectives: To systematically evaluate AI system's operationalization in the ICU, focusing on the AI field's progress over time, technical maturity, and risk of bias.
Methods: This systematic review used the PRISMA guideline and was registered in the PROSPERO database (CRD4202341913). We continued a previous search [1], transforming this in an AI-ICU living systematic review. The search was continued in five databases (Embase, MEDLINE ALL, Web of Science Core Collection, Cochrane Central Register of Controlled Trials, and Google Scholar) from July 28, 2020 to June 10, 2024. Eligible studies focused on AI applications intended for the use within adult ICUs (≥ 16 years) and utilized data collected during ICU stays. Two reviewers independently assessed eligibility of all titles and abstracts. Disagreements were resolved by a third reviewer. Data extraction included AI application aims, type of data set, Technology Readiness Level (TRL) classification [2], and the use of reporting standards. Risk of bias was assessed using the PROBAST method [3].
Results: Out of 17,401 screened records, 1263 studies met the inclusion criteria. The majority of studies (74%) were classified as early-stage development or initial validation (TRL 4 or below). Among these, 37% utilized internal data sets, 46% used MIMIC (Medical Information Mart for Intensive Care) data sets, and 6% used the open-source eICU Collaborative Research Database (eICU-CRD). 24% of the studies achieved external validation (TRL 5). Only 2% progressed to clinical integration (TRL ≥ 6), with no studies realizing full implementation (TRL 9). Similar findings were described in 2021 (Fig. 1) [1]. In addition, only 16% of studies referred to the use of reporting standards, with reference modestly increasing from 14% in 2021 to 23% in 2024. In 53% of the studies, a high risk of bias was identified, primarily explained by methodological issues in the PROBAST analysis domain.
Conclusions: Despite the steep growth in AI research within intensive care in recent years, the growth continues to be largely driven by retrospective studies and the progress toward clinical operationalization

remains limited with little progress over time. These findings emphasize the urgent need for a paradigm shift in the ICU AI literature, one that moves beyond retrospective validation toward the operationalization and prospective testing.

Intensive Care Medicine Experimental 2025,* 13(1)*:001483

Introduction: Coma is a frequent yet under-reported condition in intensive care, particularly in resource-limited regions. We aimed to characterize its prevalence, etiologies, management, and short-term outcomes across Latin American critical care units.
Objectives: To describe the burden of coma across adult intensive care units in Latin America and identify factors associated with short-term outcomes.
Methods: A multinational, cross-sectional point prevalence study was conducted on May 28, 2024, involving adult patients in 392 hospitals across 19 Latin American countries. Inclusion was based on the COME-TOGETHER consensus definition of coma. Data were collected through a standardized electronic questionnaire and included demographics, etiology, resource availability, complications, and 14-day outcomes. Multivariate logistic regression and random forest models were applied to assess predictors of mortality and care limitations.
Results: Out of 8385 critically ill patients, 1170 met coma criteria (13.9%), with national prevalence ranging from 6% to 25%. The most frequent individual cause was traumatic brain injury (24.9%), followed by hypoxic–anoxic injury (14.6%) and intracerebral hemorrhage (13.5%). Cardiovascular-related causes, as a group, were predominant (48.6%). The median age was 55 years; 64.1% were male. Short-term mortality at 14 days (available for 50% of the cohort) was 29.2%, and 32.3% of survivors remained comatose. Higher coma case volume per center and cardiovascular comorbidities were associated with increased mortality in random forest analysis. Staffing ratios were independently associated with decisions to limit life-sustaining therapies.
Conclusions: Coma represents a significant portion of critical care occupancy in Latin America, with wide etiological diversity and variable outcomes. Findings highlight the need for prevention strategies and the development of specialized neurocritical care resources. Institutional experience and staffing appear to influence patient outcomes, underscoring potential benefits from system-level interventions in coma care.

Reduction of greenhouse gas emissions through inhaled sedation with sevoflurane for 48 h instead of isoflurane (Sevo-48)

C. Arlt[1]; K. Scheffler[1]; T. Volk[2]; A. Meiser[2]; F. Albrecht[1]

Intensive Care Medicine Experimental 2025,* 13(1)*:001484

Introduction: Volatile anesthetics are potent greenhouse gases (GHG). Sevoflurane is less harmful to the climate than isoflurane and has been recommended for long-term sedation up to 72 h [1]. Some studies have shown an impairment of renal integrity with long-term use of sevoflurane. [2].
Objectives: The aim was to quantify reductions in GHG emission by replacing isoflurane with sevoflurane for 48 h. We also assessed if sevoflurane is non-inferior to isoflurane in long-term sedation regarding renal integrity.

Methods: After introducing a new sedation protocol, patients with an indication for inhaled sedation received sevoflurane for 48 h followed by isoflurane as long as needed (Sevo-48). For administration, the Sedaconda® system (Sedana Medical, Danderyd, Sweden) was used. In a retrospective analysis, we compared these patients with those who only had received isoflurane (Iso-only). GHG emissions of both drugs were assessed according to their global warming potential over 20 years (1 g sevoflurane/isoflurane equivalent to 440/1800 g CO2). Renal integrity was assessed by comparing daily plasma creatinine, sodium, urea, urine output, fluid balance, AKIN stages, and requirement for renal replacement therapy (RRT) over 10 days from start of inhaled sedation. Patients on RRT were not considered for plasma levels, urine output, and fluid balance.
Results: During 1 year of observation (AUG 23–JUL 24), 111 patients had received inhaled sedation. Characteristics of patients in group Sevo-48 (n = 94) and Iso-only (protocol violators, n = 17) were comparable (Table 1). The mean hourly infusion rates of sevoflurane were 7.0 mL compared to 4.6 mL isoflurane (Fig. 1A). Total GHG-emissions during this year amounted to 137 t CO2. If all patients had received isoflurane, only this would have been 169 t CO2. Thus, a reduction of 32t or 19% could be realized (Fig. 1B). Within the 10-day observation period, we did not find significant group differences in AKIN stages (Fig. 2), creatinine and urea levels. On individual days, we found short-lived statistically significant differences in plasma sodium, urine output, and fluid balance without clinical relevance (Fig. 3).
Conclusions: By implementation of the new sedation protocol, we could realize a reduction in GHG emissions equivalent to a car journey of 141.000 km [4] [5] or 3.5 times surrounding the world. We did not find evidence for impaired renal integrity with sevoflurane sedation up to 48 h compared to isoflurane only. Therefore, we support the recommendation of the S1 guideline on sustainability in intensive care and emergency medicine [1] to use sevoflurane instead of isoflurane during the first days of inhaled sedation.

Table 1 Patient biometrics. Data as mean ± SD or quantity (percentage)

	Sevo (n = 94)	Iso only (n = 17)
Age [years]	62 ± 14	67 ± 13
Height [cm]	174 ± 9	173 ± 8
Weight [kg]	87 ± 27	91 ± 25
Female	25 (26.6%)	6 (35.3%)

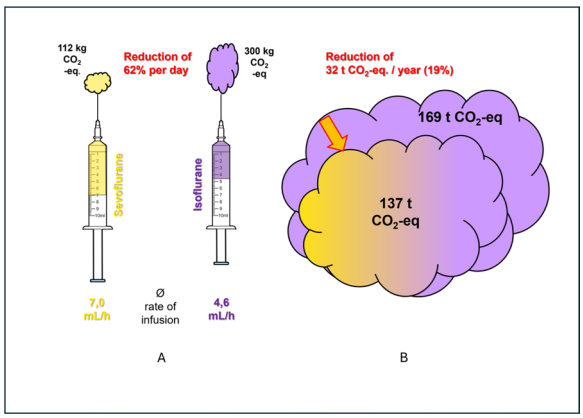

Figure 1 Green house gas emissions per 1 day of inhaled sedation (A) and during the observation year (B) calculated with *GWP-20.* **CO2 eq = CO2 equivalents**

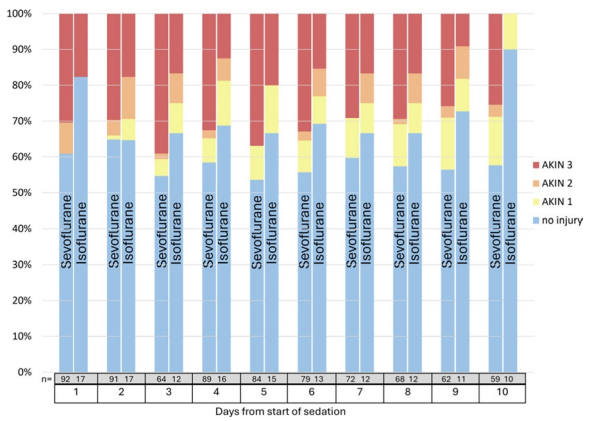

Figure 2 *Renal injury classified as AKIN stages.*
There were no significant differences (chi-square test) on individual days.

Critical care resource availability for coma management in Latin America: insights from a multinational observational study

A. Giglio[1]; M. Pino[2]; A. Ferre[3]; A. Reccius[1]
[1]Programa de Medicina Intensiva, Universidad Finis Terrae - Postgrado, Providencia, Chile; [2]Centro de Paciente Crítico, Clinica Las Condes, Las Condes, Chile; [3]Critical Care Department, Universidad Finis Terrae - Postgrado, Providencia, Chile

Intensive Care Medicine Experimental 2025,* 13(1)*:001485

Introduction: Effective management of coma requires multidisciplinary teams and access to specialized monitoring and therapeutic resources. However, in low- and middle-income regions, data on the availability and variability of such resources remain scarce.
Objectives: To assess the availability of human and technological resources for coma care across Latin American critical care units and explore associations with patient outcomes and institutional practices.
Methods: As part of a broader multinational point prevalence study of coma conducted on May 28, 2024, we analyzed data from 392 hospitals in 19 Latin American countries. Participating units reported availability of neuromonitoring modalities, critical care staffing ratios, and rehabilitation services using a standardized electronic questionnaire. We explored associations between resource availability, coma prevalence, and 14-day mortality using descriptive statistics and machine learning approaches.
Results: Most centers (98.9%) reported the availability of at least one neuromonitoring modality beyond clinical examination. The most frequently available tools were optic nerve ultrasound (69.3%) and intracranial pressure monitoring (60.5%), while advanced techniques such as brain tissue oxygenation (17%) and NIRS (10.6%) were limited. Only 37.1% of centers had dedicated neurocritical care nursing. The median nurse-to-patient ratio was 1:2; the physician-to-patient ratio was 1:6. Allied rehabilitation services were inconsistently available, with physical and respiratory therapy present in 57.2% and 51.7% of centers, respectively.
Centers with higher coma volumes tended to have better neuromonitoring capacity and lower 14-day mortality. Random forest analysis identified center coma volume and resource availability as key determinants of survival. Logistic regression showed that lower physician staffing was independently associated with higher likelihood of limitations in life-sustaining therapies (OR 0.84, 95% CI 0.74–0.96).
Conclusions: Substantial heterogeneity exists in the availability of critical care resources for coma management in Latin America. While basic neuromonitoring tools are widespread, access to advanced monitoring and specialized personnel remains limited. These disparities likely influence outcomes and care practices. Investment in training, equipment, and neurocritical infrastructure is urgently needed to improve equity and effectiveness in coma care across the region.

Intensive Care Medicine Experimental 2025,* 13(1)*:001486

Introduction: Bladder cancer is one of the most common tumors in the world, with a growing prevalence worldwide. This patient population has certain common characteristics, such as smoking or exposure to common risk factors for the development of bladder cancer, such as aniline dyes and solvents. These substances are also associated with the development of neurodegeneration and oxidative stress. Circulating indicators of inflammation, including S100B, NSE, IL-4, and IL-6, may be correlated with the clinical frailty score (CFS) and the patient's cognitive status.
Objectives: An aim of this preliminary study is to evaluate correlations of CFS, cognitive status and inflammatory markers in the perioperative course in the urologic patients.
Methods: After an Ethical Committee approval was obtained, 28 adult patients of both sexes have signed written informed consent and were included in the prospective observational study (> 18–80 years). Biomarkers analyzed were S100B, NSE, "IL-6, IL-4, CBC, HbA1c, preoperatively, and 24 h after surgery. The assessment of the patients' health condition was done using ASA, CFS scale, hand grip test, mini-mental score examination (MMSE), and Montreal cognitive Assessment (MoCA) tests preoperatively and 24 h after surgery.
Results: A statistically significant correlation was observed between CFS and MoCa in all measurements ($r = -0.619$, $P = 0.001$), IL-6 after 24 h ($r = 0.432$; $P = 0.028$), and erythrocyte values ($r = -0.411$; $P = 0.33$). A negative correlation was observed between CFS and handgrip strength in all measurements ($P < 0.05$). No statistically significant association was confirmed between preoperative CFS and MMSE, s100b, cholinesterase, CRP, urea, creatinine, and other laboratory markers. Body mass index was also positively correlated with MoCA ($R = 0.432$; $P = 0.024$), with frail patients showing worse results on cognitive assessments.
Conclusions: This study has confirmed that preoperative clinical frailty score is a risk factors for the development of clinically measurable impairment in patients' cognitive functions and increase in the IL-6 levels after transurethral resection of the urinary bladder. In a bigger study, these data may serve as a starting point for research into possible interventions that can reduce the increase in inflammatory markers and new cognitive deficits.

Intensive Care Medicine Experimental 2025,* 13(1)*:001487

Introduction: Leukopenia in surgical patients in the intensive care unit (ICU) may be associated with drug use, viral and bacterial infections, or other comorbid conditions. Leukopenic patients are often immunocompromised and have been reported to have poorer treatment outcomes.
Objectives: The aim of this study was to examine the incidence of leukopenia in surgical patients in the ICU, to compare their comorbidity, mechanical ventilation (MV), and length of stay in the ICU with a control population of surgical patients. Their early recognition and diagnostics could improve their treatment outcomes.
Methods: After an Ethical Committee approval was obtained, a retrospective analysis of an electronic database of laboratory findings over a 2.5-year period. Leukopenia was defined as a white blood cell count < 4 × 10 9/L in blood samples taken during treatment in the ICU. Comorbidity, prior chemoradiotherapy, duration of mechanical ventilation, and length of ICU stay were analyzed in patients with leukopenia ($N = 78$, total 3.2% of ICU patients), and the results were compared with a control group ($N = 262$) of consecutive surgical patients treated in the ICU. Data were compared using the Mann–Whitney U test or the $\chi 2$ test.
Results: The mean age of leukopenic patients was 66 [58–73.75] vs. 69 [60–77 years], ($P = 0.041$), and 83% of leukopenic patients vs. 47% of controls were emergency patients. There was no difference in the incidence of cardiovascular, renal, neurological, or metabolic diseases between leukopenic patients and controls. Leukopenic patients significantly more often had previous respiratory diseases (38:18%, $P < 0.001$), gastrointestinal (74:52%, $P = 0.003$), chemoradiotherapy (21:10%, $P = 0.038$), sepsis (41:15%, $P < 0.001$), and pneumonia (33:17%, $P = 0.008$) compared to controls. In the group of leukopenic patients, 48% were reoperated vs. 15% in the control group. The average length of MV was 47 [8.25–96]: 9 [2–47.25] h, and the length of ICU was 6 [3–14] vs. 3 [2–5 days] in the group of leukopenic and control, respectively.
Conclusions: Risk categories of patients for the development of leukopenia are patients with chronic lung diseases, patients with endocrine diseases, previous chemoradiotherapy, and the elderly with abdominal sepsis and pneumonia upon admission. Due to the high frequency of infections, these patients require prompt microbiological diagnosis and isolation.

Topic: Perioperative care.

Introduction: Out-of-hospital cardiac arrest (OHCA) is a global leading cause of death, challenging public health policies. The difficulty lies in obtaining comprehensive epidemiological data on OHCA patients, with literature varying widely in terms of incidence, patient characteristics, and outcomes.
Objectives: Characterize the population and outcomes of OHCA.
Methods: Retrospective, observational, single-center study on patients admitted to an ICU unit of a tertiary hospital following OHCA between 2017 and 2019. Data were collected from clinical registries. Follow-up was obtained by contacting the surviving patients or families.
Results: Out of the 78 patients included in the study, 32.9% were female, exhibiting an average age of 59.3 ± 15.1. Only two patients had a history of family sudden death.
The most common arrest sites were at home (39.2%) and at the street (20.3%). A significant proportion of OHCA was observed by witnesses (84.8%), and basic life support was provided in 72.2% of instances. Notably, only 25.3% of these interventions incorporated the use of an automated external defibrillator. Mean no-flow time was 4.1 ± 3.1 min, and low-flow-time was 22.7 ± 12.3 min. 51.9% had a shockable rhythm. Arrest rhythm is displayed in Ch@art 1 and cause of OHCA in Table 1. Out of the patients with a cardiac cause, 50.9% were due to acute coronary syndrome. Mean left ventricle ejection fraction at 48 h was 38.9 ± 14.2%.
A total of 59 patients (74.7%) died during follow-up (FUP). Mean FUP time in surviving patients was 3.9 years. The majority of the patients died in the ICU (57%) and 67.1% during hospital stay. The main cause of death was anoxic encephalopathy (55.7%).
Neuroprognostication applied to 79.7% revealed: 71.2% considered deceased, 15.2% recovered (Glasgow Coma Score > 9), and 6.3% had unclear prognosis. Of five unclear cases, four died during admission.
Regarding neurological outcomes, the cerebral performance category (CPC) was calculated. At discharge from ICU, the median CPC was 2 and 1 at discharge from hospital. Median CPC at follow-up was 1, and median ECOG performance status was 2. Two patients had a CPC score of 4 at FUP.
Conclusions: This study reveals that our survival rate aligns with previously documented rates in the literature. Our results emphasize that the prognosis for these patients is established early in the hospital admission process. Those who survive until discharge exhibit a positive prognosis, often without significant neurological impairment.

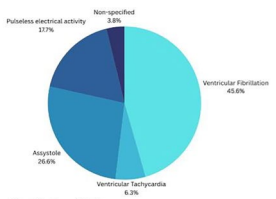

Chart 1: Arrest Rythm

Presumed cause of OHCA	N
Cardiac	53 (67.9%)

The added value of unstructured data in sepsis detection: a subanalysis from the bialert sepsis model

A. Giglio[1]; M. Aranda[2]; A. Socias[3]; A. Del Castillo[4]; M. Borges[3]
[1]Intensive Care Department, Universidad Finis Terrae - Postgrado, Providencia, Chile; [2]Icu. hospital son llatzer, Multidisciplinary Sepsis Unit, Palma, Spain; [3]Multidisciplinary sepsis unit, ICU. Hospital Son Llatzer, Palma, Spain; [4]Icu, Multidisciplinary Sepsis Unit, Palma, Spain
Correspondence: A. Giglio
Intensive Care Medicine Experimental 2025,* 13(1)*:001489

Introduction: Sepsis is a time-sensitive, heterogeneous syndrome, where early detection is critical to improve patient outcomes. While machine learning (ML) models are increasingly used to support early identification, they often rely solely on structured data, overlooking the rich clinical content embedded in unstructured text.
Objectives: To evaluate the contribution of unstructured clinical data from the 48 h preceding expert-validated diagnoses of sepsis, as part of the development of the BiAlert Sepsis detection model.
Methods: This subanalysis used data from 218,715 hospital episodes (2014–2018) involving patients aged ≥ 14 years. A total of 11,864 sepsis cases were prospectively validated in real time by a dedicated multidisciplinary team using modified Sepsis-2 criteria. From the 48-h window prior to validation, 2829 clinical variables were initially extracted. After feature selection, 229 variables were retained in the final model, of which approximately 167 (73%) came from unstructured sources (e.g., clinical notes, triage summaries, and narrative impressions), processed through Natural Language Processing (NLP). Structured variables were coded and classified according to ICD-9-CM, with those related to clinical symptoms (e.g., fever and hypotension) and anatomical focus (e.g., lung and abdomen) being particularly relevant.
Results: Unstructured variables—such as "clinical deterioration," "early antibiotic escalation," and "unknown source of infection"—often appeared earlier than measurable physiological changes. Structured ICD-9-coded data also contributed, particularly symptom-based and organ-specific entries. The final model, combining both data types, achieved an AUC-ROC of 0.95, with sensitivity of 0.93 and specificity of 0.84.
Conclusions: Prior studies have shown that integrating unstructured data through NLP improves the performance of AI models in sepsis prediction. While this subanalysis does not compare performance with and without unstructured data, the high diagnostic accuracy achieved by the BiAlert model may in part be attributed to the early and systematic incorporation of NLP-extracted variables during model construction. These findings support continued exploration of hybrid data models in the development of clinical decision support tools.

Structured variables beyond conventional scores: a subanalysis of the bialert sepsis model

A. Giglio[1]; M. Aranda[2]; A. Socias[3]; A. Del Castillo[4]; M. Borges[3]
[1]Programa de Medicina Intensiva, Universidad Finis Terrae - Postgrado, Providencia, Chile; [2]Icu. hospital son llatzer, Multidisciplinary Sepsis Unit, Palma, Spain; [3]Multidisciplinary sepsis unit, ICU. Hospital Son Llatzer, Palma, Spain; [4]Icu, Multidisciplinary Sepsis Unit, Palma, Spain
Correspondence: A. Giglio
Intensive Care Medicine Experimental 2025,* 13(1)*:001490

Introduction: Conventional sepsis and ICU scores—such as SIRS, SOFA, and APACHE—use a limited number of structured variables to identify critically ill patients. However, the expansion of electronic health records and machine learning (ML) techniques allows for the incorporation of a broader range of structured data in predictive models. Understanding how these data-driven variables overlap—or diverge—from traditional score components may inform the evolution of early sepsis detection strategies.
Objectives: To analyze the structured variables retained in the BiAlert Sepsis model and compare them with the components of classical sepsis scoring systems.
Methods: This subanalysis is based on the BiAlert Sepsis data set, which includes 218,715 hospital episodes and 11,864 sepsis cases validated in real time by expert clinicians between 2014 and 2018. From 2829 candidate variables, 229 were selected for the final model. We identified the 62 structured variables among them and compared their content with those included in widely used sepsis and ICU scores (SIRS, SOFA, APACHE-II, and SAPS-II). Variables were categorized and analyzed based on clinical function: vital signs, laboratory markers, symptoms, and metabolic indicators.
Results: Of the 229 variables selected for the final BiAlert Sepsis model, 62 were structured variables. Among these, 20 variables (32.3%) were included in at least one conventional scoring system for sepsis or critical illness (e.g., APACHE-II, SOFA, SAPS-II, SIRS, and SEPSIS.2/3). The remaining 42 variables (67.7%) were not present in any of the evaluated clinical scores.
Variables included in conventional scores comprised: temperature, heart rate, systolic blood pressure, diastolic blood pressure, respiratory rate, white blood cell count, creatinine, sodium, potassium, bilirubin, urea, hematocrit, and others.
Structured variables not included in traditional scores but retained in the model included: RDW, eosinophils, basophils, platelecrit, monocytes, neutrophils, lymphocytes, calcium, chloride, CRP, ALT, AST, alkaline phosphatase, and fibrinogen.
All 62 variables were present in over 60% of sepsis-confirmed episodes, with 39 variables (62.9%) present in more than 90% of episodes.
Conclusions: This subanalysis demonstrates that modern ML-based sepsis detection models can identify structured variables of clinical importance that extend beyond the scope of traditional scoring systems. Incorporating these variables into future models may enhance sensitivity and clinical applicability, supporting a transition from expert-defined scores to data-driven detection frameworks.

Intensive Care Medicine Experimental 2025,* 13(1)*:001491

Introduction: Driving resumption remains a largely unexplored component of recovery after critical illness.1, 2 Unlike other health conditions, there is no mandated formal testing of driving ability following critical illness. Furthermore, relevant guidance from regulatory bodies such as the Driver and Vehicle Licensing Agency (DVLA) in the United Kingdom is lacking.1
Objectives: Our primary objective was to determine the frequency and type of driving-related impairments in adults recovering from critical illness, via a comprehensive driving assessment conducted 2 months after hospital discharge. Our secondary objectives were to measure patient reported time to driving resumption, to identify factors associated with driving outcome, and to assess participant acceptability of the comprehensive driving assessment.
Methods: We conducted a UK multi-centre prospective cohort study recruiting participants from six hospitals. We included adult ICU survivors who had (i) received mechanical ventilation and/or extracorporeal membrane oxygenation (ECMO) for $\geq$ 72 h; (ii) held a UK driving licence and driven a car in the 12 months preceding admission, (iii) intended to resume or already resumed driving; and (iv) were able and willing to travel to the driving assessment centre. Participants completed a comprehensive assessment of driving ability at 2 months following hospital discharge including physical review, cognitive battery, evaluation of driving ability on a simulator, in-car assessment on a private track, and in-car on-road assessment. Acceptability was assessed with bespoke questionnaires.
Results: We recruited 40 participants with 33 participants completing the driving assessment, median age 53 years, 68% ($n = 27$) male. The proportion of participants with driving-related impairments at 2 months was 18% ($n = 6$) with 50% ($n = 3$) experiencing physical impairments and 50% ($n = 3$) cognitive/psychological impairments. The proportion of participants who had not resumed driving at 2, 3, 6 and 12 months after hospital discharge was 55% ($n = 18$), 38% ($n = 13$), 18% ($n = 6$) and 9% ($n = 3$), respectively. Time to resumption ranged from 7 to 274 days following hospital discharge. Reasons for not resuming driving at the 2-month assessment included physical/mobility concerns (67%, $n = 12$), no need to drive (50%, $n = 9$), reduced confidence (33%, $n = 6$), anxiety (28%, $n = 5$), and family member concerns (17%, $n = 3$), and not being aware driving resumption was an option (17%, $n = 3$). The acceptability of the driving assessment was high, with all participants rating as very good or excellent.
Conclusions: In this cohort of adults recovering from critical illness, despite only a fifth having driving related impairments on formal assessment, more than half had not resumed driving 2 months after hospital discharge. Driving resumption rates increased over the 12-month time-period in line with predicted recovery after critical illness.

Intensive Care Medicine Experimental 2025,* 13(1)*:001494

Introduction: Dynamic parameters used for predicting fluid responsiveness require special equipment and are minimally invasive. Interest in the use of artery peak velocity variation (ΔVpeak) measured by ultrasound has grown. We performed this systematic review and meta-analysis to assess the ability of ΔVpeak to predict fluid responsiveness in critically ill patients.
Methods: We conducted a systematic review and meta-analysis of studies published until Jan 2025, using MEDLINE, Embase, SinoMed, and Cochrane databases. Studies were included if they assessed ΔVpeak in critically ill adult patients and reported its ability to predict fluid responsiveness. Data were extracted and analyzed using a bivariate random-effects model to calculate pooled sensitivity, specificity, and area under the summary receiver operating characteristic curve (AUSROC). Subgroup analyses were performed to explore factors influencing ΔVpeak accuracy.
Results: In total, 26 studies involving 1385 patients were included. The pooled sensitivity and specificity of ΔVpeak for predicting fluid responsiveness were 79% (95%CI 75%-82%) and 82% (95%CI 76%-86%), respectively, with an AUSROC of 0.84 (95%CI 0.80–0.87). Subgroup analysis revealed good diagnostic accuracy in studies using ΔVpeak during the passive leg raising (PLR) test (AUSROC = 0.91, 95%CI 0.88–0.93); in mechanically ventilated patients (AUSROC = 0.86, 95%CI 0.83–0.89) compared to spontaneously breathing patients (AUSROC = 0.81, 95%CI 0.77–0.84) ($p = 0.034$). No significant difference in accuracy was observed between carotid and femoral artery measurements ($p > 0.05$). Diagnostic accuracy was lower in ICU settings (AUSROC = 0.78) compared to the OR (AUSROC = 0.88, $p < 0.001$). Studies using stringent criteria for fluid responsiveness ($\geq$ 15% increase in stroke volume or cardiac output after 500 mL crystalloid infusion) demonstrated higher accuracy (AUSROC = 0.90 vs. 0.84, $p < 0.001$).
Conclusions: The ΔVpeak is a moderately accurate predictor of fluid responsiveness in critically ill patients, with higher diagnostic accuracy in mechanically ventilated patients and those undergoing the PLR test. However, its performance varies across clinical settings and patient populations, emphasizing the need for further validation.

Intensive Care Medicine Experimental 2025,* 13(1)*:001496

Introduction: Venous return (VR) is determined by three principal factors: mean systemic filling pressure (Pmsf), central venous pressure (CVP), and resistance to venous return (RVR). The driving pressure for VR is defined by the gradient between Pmsf and CVP, while RVR modulates the flow through this pressure gradient. This study aimed to investigate the fluid-induced changes in the Pmsf − CVP gradient and in RVR in patients identified as fluid responders or non-responders following volume expansion (VE).
Methods: This was a pooled retrospective analysis of 24 individual studies conducted across multiple centers between 2012 and 2024, involving patients with acute circulatory failure who received VE (500-mL fluid bolus of crystalloids). Pmsf was estimated mathematically using Perkin's formula. RVR was estimated from Pmsf, CVP and cardiac output. Fluid responsiveness was defined as an increase in cardiac index (CI) ≥ 15% following VE.
Results: Of 1156 patients screened, 750 were excluded due to CVP data unavailable. The remaining 406 patients (age 63 ± 13 y.o, 71% with septic shock, 82% receiving norepinephrine, and 93% under mechanical ventilation) were eligible for assessment and were subsequently included in the final analysis. Following VE, 209 patients (51%) were identified as fluid responders (FR +). Before VE, CVP, Pmsf, and the Pmsf − CVP gradient were significantly lower in FR + compared to FR −. During VE, Pmsf increased to a similar extent in FR + and FR- patients (FR + : 15.7 ± 4.4–18.7 ± 4.6 mmHg (+ 3.0 ± 2.5 mmHg), FR − : 17.3 ± 4.7–19.9 ± 5.0 mmHg (+ 2.6 ± 2.3 mmHg), $p = 0.08$). However, CVP increased less in FR + than in FR- patients (FR + : + 1.3 ± 2.3, FR-: + 2.4 ± 2.2 mmHg, $p < 0.01$). As a result, during VE, the Pmsf-CVP gradient increased to a large extent in FR + than in FR- patients (FR + : + 1.7 ± 0.9, FR-: 0.2 ± 0.6 mmHg, $p < 0.01$). RVR changed neither in FR + nor in FR- patients during VE.
Conclusions: In fluid responders, the VE-induced increase in VR was primarily attributed to a substantial elevation in the Pmsf–CVP gradient. The difference between fluid responders and non-responders is mainly driven by a smaller increase in CVP in responders than in non-responders.

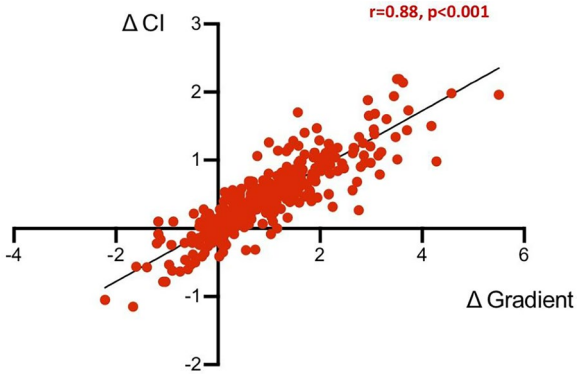

Figure 1 Correlation between the changes in cardiac index (CI) and changes in (Pmsf − CVP) gradient after 500 mL of volume expansion. ($r = 0.88$, $p < 0.001$)

Intensive Care Medicine Experimental 2025,* 13(1)*:001497

Introduction: Fluid responsiveness assessment is essential for optimizing fluid resuscitation in circulatory failure, while the prevention of venous congestion has gained increasing attention to avoid potential adverse effects of fluid therapy. However, their relationship during fluid resuscitation remains poorly explored. This study aimed to delineate the dynamic behaviour of fluid responsiveness and venous congestion during a fluid challenge.
Methods: This multicentre, observational study was conducted in three medical–surgical intensive care units (ICUs) and enrolled patients with acute circulatory failure for whom fluid expansion was deemed necessary by attending clinicians. In patients who received a 500-mL fluid challenge over 15 min as a part of current care, in whom cardiac index (CI) was measured by calibrated pulse contour analysis (PiCCO2) and in whom VExUS had been measured before and after the fluid challenge, we retrospectively collected the change (Δ) in CI, central venous pressure (CVP), venous excess ultrasound (VExUS), and global end-diastolic volume index (GEDVI) induced by the fluid challenge. Fluid responsiveness was defined as a ≥ 15% increase in CI following fluid expansion. VExUS was quantified by grades and by the total number of points recorded at each site (IVC < 2 cm: 0, ≥ 2 cm: 1 point, other sites: normal: 0, mildly abnormal: 1 points, and severely abnormal: 2 points). The fluid-induced ΔCI/ΔGEDVI and ΔVExUS/ΔGEDVI ratios were calculated.
Results: We enrolled 64 patients, of whom 42 were fluid responders (FR +), while 22 were non-responders (FR −). Before the fluid challenge, VExUS grades and VExUS points were comparable between groups (Grade 0: 62% vs. 55%, $p = 0.82$; congestion points: 1.0 [0.0, 2.3] vs. 2.0 [1.0, 3.0], $p = 0.05$). Following fluid administration, VExUS grade deterioration ≥ 1 grade occurred in 5% of FR + vs. 73% of FR − patients ($p < 0.01$). Post-fluid, abnormal VExUS grades were significantly more prevalent in FR − than in FR + (91% vs. 43%, $p < 0.01$), and VExUS points were higher (4.0 [3.0, 5.0] vs. 1.5 [1.0, 3.0], $p < 0.01$). The fluid-induced ΔCI/ΔGEDVI slope was steeper in FR + than in FR − (0.77 [0.39, 1.0] vs. 0.08 [− 0.63, 0.33], $p = 0.01$). Conversely, FR + had flatter slopes for ΔVExUS/ΔGEDVI (0 [0, 0.2] vs. 4.7 [1.7, 9.0], $p < 0.01$) and ΔCVP/ΔGEDVI (1.6 [0.5, 2.7] vs. 4.2 [1.5, 17.8], $p < 0.01$).
Conclusions: In patients with acute circulatory failure, venous congestion was prevalent among FR + and FR- patients, with no significant baseline differences. However, following a 500-mL fluid challenge, FR + patients exhibited better fluid tolerance, as reflected by a lower worsening of venous congestion. In contrast, FR- patients were more vulnerable to a deterioration in venous congestion.

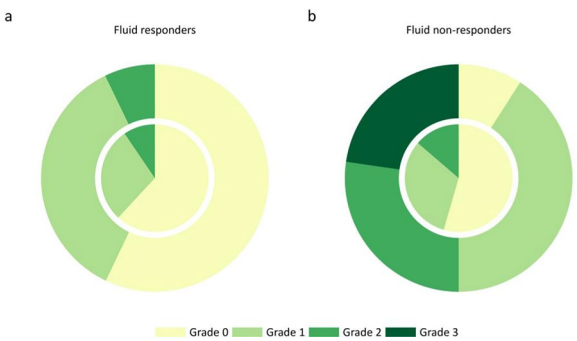

Figure 1 Comparison of VExUS grading and its dynamic changes following a fluid challenge in FR + (**a**) and FR- (**b**) patients. The inner circle represents pre-fluid challenge VExUS grade, and the outer circle represents post-fluid challenge grade. (**a**) FR + : pre- vs. post-, $p = 0.758$; (**b**) FR-: pre- vs. post-, $p = 0.003$. Inner circle: FR + vs. FR-, $p = 0.82$; outer circle: FR + vs. FR-, $p < 0.001$

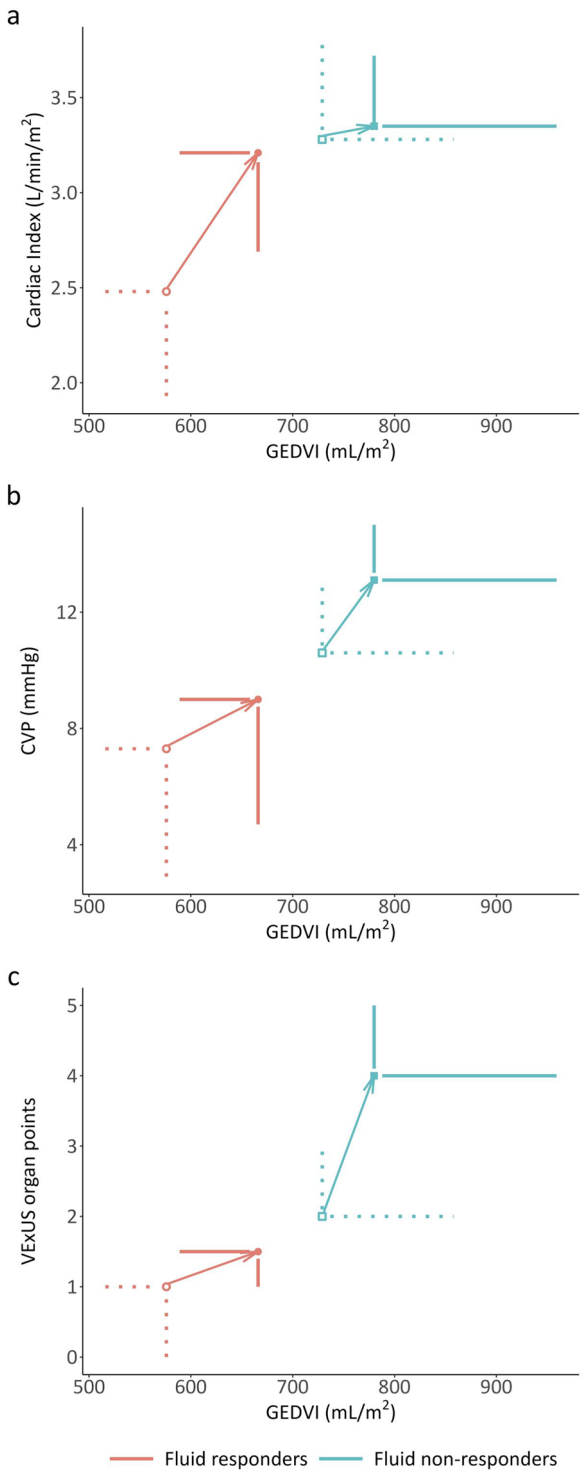

Figure 2 Relationship between fluid responsiveness and fluid tolerance during volume expansion. (**a**) Response slope of ΔCI to ΔGEDVI in FR + and FR − , (**b**) response slope of ΔCVP to ΔGEDVI in FR + and FR − , (**c**) response slope of Δ VExUS to ΔGEDVI in FR + and FR − .

Intensive Care Medicine Experimental 2025,* 13(1)*:001498

Introduction: Although methylene blue (MB) has been increasingly studied as a potential therapy for adult patients with septic shock, it remains unclear whether the current evidence is strong enough to support its routine use in clinical practice. One major limitation of existing reviews is the lack of attention to the variability in MB dosing strategies, which likely contributes to the inconsistent findings across trials.
Objectives: This study aimed to evaluate the impact of methylene blue on clinical outcomes in adult patients with septic shock by synthesizing an updated meta-analysis from randomized controlled trials. We performed trial sequential analysis (TSA) to assess the strength and conclusiveness of the evidence and conducted subgroup analyses based on methylene blue dosing strategies to identify potential sources of heterogeneity and determine optimal therapeutic approaches.
Methods: We conducted a systematic review and meta-analysis of RCTs on methylene blue in adult septic shock, following PRISMA 2020 and PROSPERO registration. Searches were conducted in MEDLINE, Embase, Cochrane CENTRAL, and grey literature through January 2024. Eligible studies compared intravenous MB with placebo or standard care.
Two reviewers independently screened and extracted data, resolving discrepancies with a third reviewer. Outcomes included short-term mortality, MAP, vasopressor duration, ventilation days, and ICU/hospital stay. Meta-analysis was performed using a random-effects model; heterogeneity was assessed by I^2.
TSA was apllied assessed evidence sufficiency by RTSA package in R. Subgroup analyses examined MB initiation timing, total dose, duration, bolus use, and risk of bias. Publication bias was evaluated using funnel plots and Egger's test.
Results: From 3728 records, 12 randomized controlled trials met the inclusion criteria, and 10 were included in the meta-analysis (n = 608). MB significantly reduced short-term mortality compared to control (RR: 0.71; 95% CI 0.56–0.88; I^2 = 0%). Trial sequential analysis confirmed the conclusiveness of this finding (adjusted RR: 0.69; p = 0.0031), with the required information size achieved and no statistical heterogeneity.
MB also significantly shortened the duration of vasopressor use (MD: − 24.56 h; 95% CI − 37.21 to − 11.90). Non-significant trends toward reduced days on mechanical ventilation (MD: − 0.81; 95% CI − 1.68–0.07), and ICU length of stay was observed (MD: − 2.11; 95% CI − 4.81–0.58). MB administration was associated with increased mean arterial pressure (MAP) at both 24 and 48 h, supporting its vasopressor-sparing effect.
Subgroup analyses showed greater benefits with a trend in early MB administration (within 24 h of septic shock onset) in short-term mortality, 24-h MAP, and cumulative doses ≥ 5 mg/kg in shorter hospital stay (interaction p value < 0.05). Sensitivity analyses excluding studies at high risk of bias yielded consistent findings. Funnel plot symmetry and Egger's test indicated low risk of publication bias.
Conclusions: Methylene blue administration in adult septic shock appears to reduce short-term mortality and improve key clinical outcomes, including vasopressor duration and ventilator days. The TSA demonstrates that this mortality benefit is both statistically and sequentially significant, with low heterogeneity, indicating robust and conclusive evidence.

Intensive Care Medicine Experimental 2025,* 13(1)*:001499

Introduction: Tracheotomy is essential in intensive care unit (ICU) for patients requiring prolonged mechanical ventilation due to respiratory failure, neurological conditions, or upper airway obstruction. It helps manage secretions and supports ventilation weaning. Postoperative care is crucial to monitor respiratory, functional, and nutritional status to avoid long-term complications. However, follow-up data for tracheotomized patients in Tunisia are limited.
Objectives: Assess the follow-up of tracheostomized patients.
Methods: A descriptive, single-center analysis conducted at ICU of Zaghouan's regional hospital, focusing on patients who underwent tracheotomy between January 2018 and December 2023. Inclusion criteria comprised patients discharged with a tracheostomy tube and complete medical records. Exclusion criteria involved patients with pre-existing tracheostomies, incomplete records, or those decannulated during their ICU stay. The primary endpoint was the success of decannulation. Data were collected retrospectively from archived medical records using a standardized study form.
Results: A total of 28 patients were included, with a median age of 41 years. Gender ratio was 3:1. The most common comorbidities were chronic renal failure (6 patients), COPD (5), and diabetes mellitus (3). The primary reasons for hospitalization were acute brain injury (10 patients), polytrauma (11 patients), and acute respiratory failure (7 patients).
Tracheotomy was performed for failure of spontaneous ventilation and delayed awakening in 14 patients each. The procedure was done surgically, with 5 patients receiving early tracheotomy (< 10 days) and 23 patients undergoing late tracheotomy (> 10 days). Post-tracheostomy complications included tracheal granulomas and stenosis were identified in two patients.
The median ICU stay was 38 days, with no significant difference between early and late tracheotomy groups. The median post-tracheostomy stay was 26 days. Twelve patients were discharged under oxygen therapy at home and three required mechanical ventilation at home. Five patients needed nasogastric tube at discharge due to swallowing difficulties. Regarding mobility, 16 patients were able to walk at discharge, while 12 had reduced mobility.
Median time to the first outpatient consultation after ICU discharge was 18.5 days [14–28].
Fourteen patients underwent decannulation, with a median decannulation time of 110 days [63.15–280.70]. All patients underwent a predecannulation evaluation and were referred to a physiotherapist and speech therapist. No complications occurred post-decannulation.
Conclusions: This study provides valuable insights into the clinical course and outcomes of tracheotomized patients in a Tunisian ICU setting. The results emphasize the importance of timely tracheotomy and comprehensive post-operative management, including rehabilitation, to ensure successful weaning and decannulation.

Intensive Care Medicine Experimental 2025,* 13(1)*:001503

Introduction: Critically ill patients are highly susceptible to complications resulting from prolonged immobilization, including ICU-acquired weakness, respiratory dysfunction, and cognitive impairment. Early physiotherapy interventions have been shown to reduce the incidence and severity of post-intensive care syndrome [1].
Objectives: This study aimed to explore current physiotherapy practices, intervention modalities, and their frequency in Italian ICUs. A secondary objective was to identify the training needs of physiotherapy staff working in high-intensity care settings.
Methods: This post-hoc observational study was based on a survey designed by a group of healthcare professionals and disseminated across European ICUs via e-mail and social media. The questionnaire was translated into Italian by two independent translators and reviewed by three native speakers. It remained open for 5 months, allowing one response per ICU.
Results: Responses were collected from 33 Italian ICUs, including 16 physiotherapists and 17 intensivists. A majority (54.5%) were university-affiliated hospitals treating adult patients. Most ICUs were mixed medical-surgical (42.4%) or multidisciplinary (27.3%).
Physiotherapists were present in 93.9% of ICUs, but only 16.1% worked exclusively or mostly within ICU settings. In 22.6%, general physiotherapists intervened as needed. In 64.5% of ICUs, physiotherapy interventions required a formal referral, most commonly from intensivists (81.8%) or other physicians (63.6%).
Positioning to optimize ventilation/perfusion (V/Q) was performed regularly in 31.4%, with 7.7% nurse-led. Percussions (84.6%), airway suctioning (92.3%), and manual hyperinflation (84.6%) were regularly performed.
Tracheostomy management was regularly performed in 76.9% of ICUs, while endotracheal tube removal was reported as routine in 61.5%.
Regarding mobility, a passive in-bed range of motion exercises was regularly performed in 30.8%, active in 23.1%, and not performed in 61.5%. Passive/active cycling was regularly implemented in 38.5%, passive verticalization in 71.4%, and transfer to rehab chairs in 57.1%. Mechanical lift transfers were regularly used in 28.6%. Neuromuscular electrical stimulation (NMES) was applied regularly in 28.6% and occasionally in 42.9%.
Assistance with sitting on the bed's edge was regular in 12.1%, standing in 15.2%, sit-to-stand transitions in 3.0%, and assisted walking in 24.2%. Results are shown in Table 2.
Conclusions: The findings highlight a significant variability in physiotherapy interventions and protocols across Italian ICUs. This heterogeneity underscores the need for standardized, evidence-based practices and targeted training to ensure consistent, effective care for critically ill patients in line with current guidelines and scientific literature.

Table 1 Characteristics of physiotherapists in Italy

Category	Details	Count	Percentage
Current Titles	Physiotherapists	14	42.4%

Anticoagulation after hemorrhagic transformation in acute cardioembolic ischemic stroke

H. Kim[1]; BS. Seo[1]; JT. Kim[1]
[1]Department of Neurology, Chonnam National University Hospital, Gwangju, Republic of Korea
Correspondence: H. Kim
Intensive Care Medicine Experimental 2025,* 13(1)*:001504

Introduction: To evaluate the safety and efficacy of anticoagulation in patients with cardioembolic acute ischemic stroke (CES) who develop hemorrhagic transformation (HT), assessing its impact on neuroimaging and functional outcomes.
Methods: This retrospective study enrolled patients presenting with cardioembolic AIS within 48 h at a tertiary stroke center between January 2011 and August 2023. Patients who developed HT during hospitalization and underwent follow-up imaging within 1 week were included, focusing on those with hemorrhagic infarction or parenchymal hematoma type 1. Primary outcomes were HT exacerbation on follow-up imaging and 3-month modified Rankin Scale (mRS) distribution shift, comparing anticoagulation therapy (AC), antiplatelet therapy (APT), and drug discontinuation (NM). The safety outcome was symptomatic intracerebral hemorrhage (sICH) occurrence.
Results: Among 763 patients with HT (age 74.6 ± 8.9 years, 48.1% male), AC was associated with a higher incidence of HT exacerbation compared to APT (adjusted OR 0.48, 95% CI 0.29–0.80, p value = 0.005). AC demonstrated improved 3-month mRS vs. APT (adjusted OR 0.63, 95% CI 0.43–0.92, p value = 0.017) and NM (adjusted OR 0.38, 95% CI 0.26–0.55, p value < 0.001). sICH occurred in 5%, with rates of 1.5%, 2.1%, and 11.7% in the AC, APT, and NM groups, respectively (adjusted OR for NM vs. AC: 3.93, 95% CI 1.18–13.16, p value = 0.026).
Conclusions: In CES patients with HT, anticoagulation may lead to radiological exacerbation without increasing sICH risk while potentially improving functional outcomes. These findings suggest that the presence of HT should not necessarily preclude the use of anticoagulation therapy in this patient population.

Topic: Neurointensive care.

Exploring experiences of physiotherapists accredited in lung ultrasound within the United Kingdom: a national survey

S. Hayward[1]; D. McWilliams[2]; C. Kendrick[1]; E. Porter[1]
[1]Physiotherapy, Blackpool Teaching Hospitals, Blackpool, United Kingdom; [2]Centre for Care Excellence, University Hospitals Coventry and Warwickshire, Coventry, United Kingdom
Correspondence: S. Hayward
Intensive Care Medicine Experimental 2025,* 13(1)*:001505

Introduction: Physiotherapists in the United Kingdom (U.K.) are increasingly adopting lung ultrasound (LUS). However, the background, training, and utilization experiences of the 200 + LUS accredited physiotherapists remains unknown. The aims of this study were to establish their clinical background, explore their training experiences, and understand how LUS is being used.
Methods: This study adopted a closed cross-sectional survey design on U.K. physiotherapists accredited in LUS with ethical approval from Coventry University (P176673). The survey was designed, piloted, and administered using the JISC online survey system and was open for a 4 weeks in January 2025. Known eligible participants received an email invitation and gave consent prior to completion. Questions covered participant demographics, training, and utilization experiences. Analysis was completed using content coding with results presented descriptively.

Results: Of the 223 invitations, 168 were returned (75% response rate). Respondents were typically in a static (87%), Band 7 (61%) role at the time of accreditation and mainly worked in a "hyper-acute" (intensive care) area (64%), primarily covering respiratory (83%), medical (57%), or surgical (49%) specialities (Fig. 1).
Almost all (99%) gained accreditation through the Intensive Care Society's training programmes, with 52% completing it within 12 months. Fifty-six (33%) have become approved mentors.
Most (60%) reported performing 1–2 scans per week, with reported indications being; increased oxygen requirement, an unclear chest radiograph (CXR) or complications during mechanical ventilation (MV). Frequently identified pathologies were consolidation (pneumonia), consolidation (atelectasis), and transudative pleural effusion (Fig. 2).
Conclusions: Only anecdotal evidence existed on which physiotherapists learnt LUS or how they trained. We now have a stronger understanding of the LUS accredited physiotherapy workforce.
One training provider was favoured by most physiotherapists wanting to gain LUS accreditation. However, as the LUS training pathway is heavily dependent on mentorship, having a third of respondents as approved mentors supports the future growth of LUS.
With 1–2 scans being performed per week, most respondents do not scan daily. Indications including signs of patient deterioration (increased oxygen), suboptimal assessments (CXR), and to monitor interventions (MV) could all be explained by the presence of the most frequently reported pathologies, consolidation (pneumonia or atelectasis), and pleural effusion (transudative). The indications and pathologies being reported here hint at the wide range of possible uses of LUS at multiple points within a patient's clinical pathway.
This survey shows the typical background of those that have gained their LUS accreditation alongside how often they scan, why they scan and what they find. This information will allow more informed decisions about LUS service design from managerial, logistical, and clinical perspectives.

Correspondence: G.F. Lehner
Intensive Care Medicine Experimental 2025,* 13(1)*:001506

Introduction: Restoring and maintaining adequate tissue perfusion is paramount in septic shock. However, the selection and titration of vasopressors require careful consideration of individual patient factors, including hemodynamic parameters, comorbidities and potential adverse effects. Current evidence suggests that a subgroup of patients, i.e., those with high renin levels, might particularly benefit from treatment strategies (1) that include angiotensin II (2) and probably also fludrocortisone (3).
Objectives: As renin levels are usually not readily available in standard routine laboratories, understanding typical patient characteristics associated with hyperreninemic hypoaldosteronism becomes crucial for identifying appropriate patients for these targeted therapies. Therefore, the aim of this study was to investigate typical patient characteristics associated with high renin levels in patients with septic shock.
Methods: In this post-hoc analysis, data from two prospective studies were evaluated, comprising 29 healthy controls (HC) and 89 patients with septic shock admitted to a tertiary ICU. Renin concentrations were measured by ELISA on ICU days 1 through 5 and related to SOFA scores, parameters of organ dysfunctions, disease severity and mortality using generalized estimation equations (GEE) models, Spearman's rank-order test, Kruskal–Wallis, and Mann–Whitney *U* tests. Quantitative data are presented as median and 25th–75th quartiles.
Results: Renin levels were significantly higher in patients with septic shock compared to HC (1979 [1105–3464] vs. 475 [376–594] pg/ml, $p < 0.001$) on day 1. High renin levels were particularly related to high SOFA scores ($b = 1.92$ [1.1–2.6], $p < 0.001$), lactate levels ($b = 0.293$ [0.2–0.4], $p < 0.001$), and vasopressor inotropic scores (VIS) ($b = 0.424$, $p < 0.001$) in patients with septic shock. Patients with acute kidney injury (AKI) stage 3 had significantly higher renin levels on day 1 compared to patients with AKI stage 0 (2453 [1682–6660] vs. 1356 [835–2394] pg/ml, $p = 0.04$). Particularly, patients who received renal replacement therapy (RRT) during the study period had higher peak levels of renin compared to patients without RRT (3505 [1706–12989] vs. 2140 [1350–3578] pg/ml, $p = 0.007$). Furthermore, elevated renin concentrations were strongly associated with higher bilirubin levels ($b = 0.375$ [0.20–0.50], $p < 0.001$), a relationship that was already evident on ICU day 1 ($r = 0.30$, $p = 0.004$).
Conclusions: This is the first study to systematically investigate the relationship between renin levels and organ dysfunctions in patients with septic shock. We show that AKI stage 3, requirement for RRT, high vasopressor dose, and liver dysfunction are associated with high renin levels in septic shock patients. These findings highlight the potential of renin as a biomarker for identifying individuals at risk of adverse outcomes and organ dysfunction. Moreover, our data reveal a pattern of organ dysfunctions that might help to identify the subset of patients with hyperreninemic hypoaldosteronism, which is the subset that might benefit from targeted treatment strategies such as angiotensin II or fludrocortisone in septic shock.

Intensive Care Medicine Experimental 2025,* 13(1)*:001507

Introduction: In intensive care medicine, therapeutic drug monitoring (TDM) of β-lactam antibiotics is receiving much attention for the treatment of patients suffering from severe infections. In clinical practice, β-lactam concentrations are determined by in-house developed assays based on chromatographic methods such as liquid chromatography coupled with tandem mass spectrometry (LC–MS/MS). These assays involve drug specific setups and batch measurements limiting availability. Quantitative nuclear magnetic resonance spectroscopy (qNMR) is becoming an emerging technique in clinical sciences. Due to recent improvements in technology, such as sensitivity gains, optimized automatic analysis algorithms and sample handling, qNMR is suited for random access without the need for sample specific isotopically labeled reference substances. qNMR allows for the simultaneous identification and quantification of selected substances in their native environment with preservation of the sample for further studies.
Here, we demonstrate the applicability of qNMR for TDM of β-lactam antibiotics in patients in critical care. As a proof of principle, we developed a qNMR assay to determine the concentration of piperacillin (PIP) in deproteinized human plasma. We further gained plasma samples from critical care patients treated with PIP and determined the concentration of PIP using the newly developed qNMR method and, as reference, an established LC–MS/MS assay.
Methods: This study was approved by the Institutional Review Board (IRB) of the University of Regensburg (23-3311_3-101). Since no personal data of subjects was recorded, informed consent was waived by the IRB. Validation of the qNMR assay was performed on plasma samples collected from healthy volunteers and spiked with PIP according to the guideline of the European Medicines Agency. Leftover material from routine blood sampling from patients who received PIP at the surgical intensive care unit of the University Hospital Regensburg between January 2024 and May 2024 were used. Blood samples were centrifuged and stored at − 80 °C until analysis. PIP was quantified in each sample by qNMR and LC–MS/MS without repeat measurements of the same sample. For qNMR, blood samples were deproteinized and diluted with a buffer solution containing deuterated methanol and pyrazine as internal standard. Final qNMR samples were measured on a 600 MHz Bruker Avance NEO® NMR spectrometer. PIP was quantified within the range of 10–350 mg/L using the triplet resonances at 1.22 ppm with the proprietary "Therapeutic Drug Profiler" software by Lifespin GmbH, Regensburg. For LC–MS/MS, blood samples were deproteinized and diluted with an internal standard solution containing d5-PIP. PIP was quantified within the range of 1.75–100 mg/L as described previously. Results were compared by concordance correlation, Bland–Altman analysis, and Passing-Bablok regression.
Results: A total of 117 specimen were collected from 8 patients at timepoints determined by clinical needs and unrelated to the administration of the antibiotic. Samples outside of the respective limits of quantification for either LC–MS/MS or qNMR were excluded from analysis (n = 67), resulting in an effective range of 10 mg/L LLOQ to 100 mg/L ULOQ.
Results of PIP quantification were higher by LC–MS/MS (median 38.65, IQR 25.73–46.71 mg/L than by qNMR (median 34.09, IQR 18.53–45.70 mg/L). The concordance correlation coefficient was 0.926 (95%-CI 0.895–0.948). Passing-Bablok regression yielded a slope of 1.13 (95%-CI 0.99–1.28) and an intercept of -5.81 (95%-CI − 0.44 to − 12.53) mg/L (Fig. 1). Bland–Altman analysis showed a mean bias of + 1.90 mg/L with limits of agreement from -14.17 mg/L to + 17.97 mg/L (Fig. 2).
Conclusions: This study demonstrates the potential of qNMR as a viable alternative to LC–MS for TDM, with levels of agreement that support further validation across broader patient cohorts.
While liquid chromatography-based methods remain industry standards—e.g., due to their superior sensitivity, commercial kit availability, and established ring trials—qNMR presents several potential advantages. These include minimal sample preparation, random-access analysis, and inherent multi-analyte detection capabilities.
These features support further investigation of its clinical utility in TDM and potentially other applications.

Intensive Care Medicine Experimental 2025,* 13(1)*:001508

Introduction: Refractory shock is a severe systemic condition characterized by persistent hypotension, inadequate tissue perfusion, and organ dysfunction, despite appropriate fluid resuscitation (1–3) The surviving sepsis campaign currently recommends the use of vasopressin (AVP) as an adjunct to catecholamines; however, angiotensin II (Ang-II) has also emerged as a promising alternative vasopressor. The effects of such drugs on microcirculatory function warrant further investigation (5).

Objectives: To assess changes in microcirculatory function before and after the administration of AVP or Ang-II in patients with refractory shock.

Methods: Patients aged > 18 years, admitted to the ICU of the HUB (Brussels, Belgium) between May 2024 and April 2025 with a diagnosis of refractory shock, and enrolled in an ongoing registry study (SEVERE Registry), were included in the analysis. Microcirculatory data, including laser Doppler measurements, capillary refill time (CRT), and near-infrared spectroscopy (NIRS), were recorded prior to the initiation of the second vasopressor and at 24 h following its administration.

Results: We enrolled 18 patients, 9 received AVP, and 9 Ang-II. The groups were homogeneous in terms of baseline characteristics (Table 1). At baseline, NIRS values were similar between the AVP and Ang-II groups (56.5 [50–62] vs. 61.5 [56.5–69.25]), while it results significantly increased in the Ang-II group at 24 h (57 [49–68] vs. 67 [60–74]—p 0.02 Fig. 1). At baseline, 3 patients in the AVP group and 2 in the Ang-II group had CRT < 3 s, while at 24 h, no patient in the AVP group but 5 in the Ang-II group had CRT < 3 s; the improvement in the Ang-II group results significant with p: 0.016 (Figs. 2, 3 and 4). At baseline, SBF was lower in the Ang-II group compared to the AVP group, (20.7 [10.38–37.27] vs. 72.07 [27.15–94.96]); however, at 24 h, SBF was higher in the Ang-II group (152.65 [12.65–373.69]) compared to AVP (96.42 [22.37–234.17]—Figs. 5–9). Velocity blood flow was higher in the AVP group at T0 (273.86 [95.10–408.40] vs. 113.51 [63.4–154.46]) but increased more in the Ang-II group by T24h (363.25 [80.87–604.60] vs. 301.86 [105.19–454.14]) (Figs. 5–9).

Conclusions: This study demonstrates significant improvements in NIRS and CRT with Angiotensin II; whereas, SBF and VBF show trends of enhancement without reaching statistical significance. These findings suggest Ang-II potential benefits, further studies with larger cohorts are needed to confirm these findings and evaluate its role in refractory septic shock.

Intensive Care Medicine Experimental 2025,* 13(1)*:001509

Introduction: Disseminated intravascular coagulopathy (DIC) is associated with worse outcomes in septic patients (1). Different coagulation pathways are implicated in the pathophysiology of DIC, but they are not assessed by commonly used DIC scores.
Objectives: To test if specific coagulation biomarkers can improve prognostication in DIC septic patients.
Methods: In septic patients, we evaluated 11 biomarkers related with 3 relevant pathways in the development of DIC. Tissue factor (TF), von Willebrand factor (Ag vWF), ristocetin cofactor (Risto-Co), soluble P-selectin (sCD62p) regarding platelets and endothelium activation; thrombin–antithrombin complexes (TATc), fibrinogen, tissue factor pathway inhibitor (TFPI) and antithrombin III (AT-3) as pro- and anticoagulant molecules; plasminogen activator inhibitor 1 (PAI-1), tissue plasminogen activator (tPA) and D dimers as biomarkers of the fibrinolysis. We compared the biomarker values considering DIC and survival status. Then, we selected only one biomarker from each pathway able to discriminate both outcomes. For each selected biomarker, we dichotomized values as high or low based on median values for the whole population, and we scored 1 or 0 points when comparing non survivors with survivors, respectively. Finally, we created a new score by adding the points from each specific biomarker. Statistical analysis was performed using SPSS 23.0.
Results: We included 46 patients that were 67 (58–74) years, had a median APACHE II score of 19 (16–27), an SOFA score of 8 (6–10), and a 30-day mortality of 43%. Different biomarkers values are presented in Table 1. The 3 selected biomarkers were: tPA, AT3 and Risto-Co, and mortality tended to be higher with worse biomarkers values (Table 1 and Fig. 1). The mortality was not different when comparing sepsis induced coagulopathy (SIC) or DIC patients, but it was higher with higher values of this new biomarker based score (Fig. 1).

Variable	DIC (−) *n* = 39	DIC (+) *n* = 7	*P*	Survivors *n* = 26	No survivors *n* = 20	*P*
INR	1.4 (1.3–1.6)	2.2 (2.0–2.6)	< 0.001	1.4 (1.3–1.7)	1.5 (1.3–2.1)	0.282
Platelets (10^3/µL)	187 (105–312)	138 (49–257)	0.306	170 (84–252)	193 (108–261)	0.658
Tissue Factor (pg/mL)	57.4 (38.8–78.0)	89.9 (58.4–95.8)	0.108	55.6 (44.0–78.0)	66.4 (43.8–86.1)	0.375
Ag vWF (%)	546.0 (437.0–696.0)	818.0 (697.0–1039.0)	0.023	562.5 (413.0–756.0)	657.5 (477.0–913.5)	0.400
Risto-Co (%)	469.0 (375.0–546.0)	571.0 (531.0–585.0)	0.009	473.1 (375.0–531.0)	518.5 (435.5–568.5)	0.173
sCD62P (ng/mL)	56.4 (44.8–80.1)	77.3 (60.5–127.2)	0.049	59.0 (43.6–78.2)	58.4 (53.1–90.4)	0.330
TATc (pg/mL)	10.7 (6.2–17.6)	33.4 (21.6–62.8)	0.010	10.2 (6.6–27.8)	13.9 (7.4–19.6)	0.756
Fibrinogen (mg/dL)	499 (386–719)	408 (373–445)	0.056	507 (373–734)	464 (408–545)	0.816
TFPI (pg/mL)	38,400 (28,100–99500)	62,600 (33,800–112000)	0.306	35,100 (26,600–56400)	64,550 (33,100–115500)	0.051
AT-3 (%)	55.0 (44.0–69.0)	32.0 (20.0–43.0)	0.005	55.0 (49.0–67.0)	43.5 (29.5–69.0)	0.431
PAI-1 (ng/mL)	81.0 (60.0–124.5)	161.0 (120.0–205.0)	0.003	83.0 (54.0–144.0)	104.0 (78.0–139.5)	0.245
t-PA (pg/mL)	12,300 (9210–34628)	41,627 (35,901–52459)	0.003	11,300 (9326–21,133)	35,264 (12,500–48577)	0.018
D dimers (ng/mL)	4110 (2211–6989)	20,847 (12,712–33,638)	0.003	5021 (2578–12,712)	3963 (2212–13,438)	0.465

Conclusions: A new biomarker-based score incorporating different coagulation pathways prognosticates better the mortality than SIC and DIC scores in septic patients.

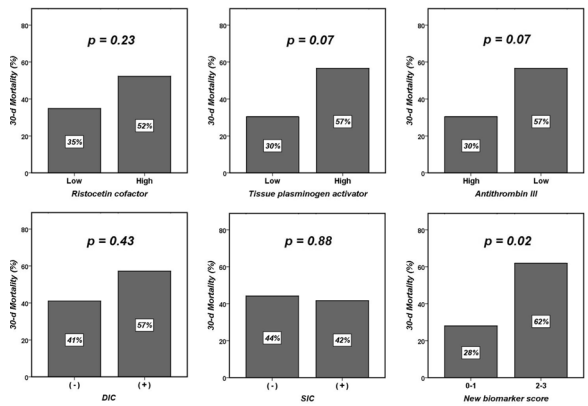

Figure 1 Mortality regarding each selected biomarker and the new proposed score

Plasmapheresis monotherapy vs. adjunctive continuous venovenous hemodiafiltration in acute hepatic failure: a retrospective cohort analysis of efficacy and clinical outcomes

I. ocak[1]

[1]Liver Transplant Intensive Care Unit, Basaksehir Cam Ve Sakura City Hospital, İstanbul, France

Correspondence: I. ocak

Intensive Care Medicine Experimental 2025,* 13(1)*:001510

Introduction: Acute hepatic failure (AHF) is a critical condition marked by rapid decompensation of hepatic function, necessitating prompt intervention to mitigate disease progression. Novel extracorporeal therapies, including therapeutic plasma exchange (TPE) and continuous venovenous hemodiafiltration (CVVHDF), have emerged as potential modalities to enhance toxin clearance and stabilize hepatic hemodynamics. However, the clinical efficacy of TPE as monotherapy vs. its synergistic application with CVVHDF remains a critical area of investigation. This study evaluates the therapeutic outcomes of TPE alone vs. combination therapy with CVVHDF in adult patients with acute or acute-on-chronic liver failure.

Methods: A single-center retrospective cohort study was conducted within a Liver Transplant Intensive Care Unit (ICU), analyzing data from adults aged 39–72 years admitted between January 2022 and March 2025. Eligible patients had confirmed AHF or acute-on-chronic liver failure and received either TPE alone (n = 23, 53.4%) or TPE combined with CVVHDF (n = 20, 46.5%). Primary endpoints included biochemical normalization (INR, ALT, AST) and transplant-free survival. Statistical significance was defined as $P < 0.05$.

Results: The TPE monotherapy cohort demonstrated significant biochemical improvements: median INR decreased from 2.0 (IQR: 1.8–2.8) to 1.3 (1.1–1.8), ALT from 451 U/L (66–1572) to 155 U/L (71–356), and AST from 264 U/L (132–1344) to 81 U/L (34–159) ($P < 0.05$). The TPE + CVVHDF cohort exhibited comparable reductions: INR declined from 3.1 (2.3–4.4) to 1.6 (1.4–2.5), ALT from 681 U/L (61–2486) to 159 U/L (70–1050), and AST from 921 U/L (138–1918) to 68 U/L (43–511) ($P < 0.05$). Overall, 39.5% (17/43) achieved transplant-free survival, while 18.6% (8/43) underwent liver transplantation.

Conclusions: Both TPE monotherapy and combination therapy with CVVHDF significantly ameliorate hepatic dysfunction in AHF, serving as viable bridging strategies to transplantation. The observed transplant-free survival rate underscores the therapeutic potential of these modalities. However, prospective multicenter trials are imperative to validate these findings, optimize treatment algorithms, and refine patient selection criteria for extracorporeal interventions.

Re-evaluating β-lactam infusion strategies in adult sepsis: an updated meta-analysis of randomized trials

E. jung[1]
[1]emergency medicine, Chonnam national University, Gwangju, Republic of Korea
Correspondence: E. Jung
Intensive Care Medicine Experimental 2025,* 13(1)*:001511

Introduction: Recent randomized controlled trials (RCTs) comparing prolonged vs. intermittent β-lactam antibiotic infusions in sepsis patients have yielded conflicting outcomes, leaving clinical consensus unsettled. This study aimed to systematically evaluate the comparative effectiveness and safety of prolonged vs. intermittent infusion strategies in adult patients with sepsis through a meta-analysis of available RCTs.
Objectives: We performed a systematic search of PubMed, EMBASE, and the Cochrane Library for RCTs assessing β-lactam infusion strategies in septic patients. Primary outcomes included all-cause mortality, clinical response, microbiological response, and adverse events. Data were synthesized using a random-effects model, and results were reported as relative risks (RRs) with 95% confidence intervals (CIs). Subgroup analyses explored potential effect modifiers, such as infection etiology and dosing strategies. The review protocol was registered with PROSPERO (CRD42023463905).
Methods: A total of 16 studies encompassing 2210 participants were included. Compared to intermittent infusion, prolonged infusion was associated with a significant reduction in all-cause mortality (RR 0.79; 95% CI 0.67–0.94; $P = 0.01$) and improved clinical response rates (RR 1.20; 95% CI 1.05–1.37; $P = 0.01$). Microbiological eradication rates showed a favorable trend but were not statistically significant (RR 1.08; 95% CI 0.95–1.22; $P = 0.18$). No meaningful differences were found in adverse event rates between the two infusion methods (RR 0.93; 95% CI 0.66–1.31; $P = 0.68$). Subgroup analyses demonstrated greater mortality benefits in trials enrolling > 25 patients per arm (RR 0.81; 95% CI 0.68–0.96; $P = 0.02$), studies published after 2011 (RR 0.82; 95% CI 0.70–0.97; $P = 0.02$), infections primarily caused by gram-negative pathogens (RR 0.77; 95% CI 0.62–0.94; $P = 0.01$), use of a loading dose (RR 0.82; 95% CI 0.69–0.97; $P = 0.02$), and penicillin-based regimens (RR 0.63; 95% CI 0.40–0.99; $P = 0.045$).
Results: Prolonged infusion of β-lactam antibiotics appears superior to intermittent administration in reducing mortality and enhancing clinical success in septic patients, with no associated increase in adverse events. These findings support the adoption of prolonged infusion strategies, especially in settings involving Gram-negative infections and penicillin use.
Conclusions: These findings support the adoption of prolonged infusion strategies, especially in settings involving Gram-negative infections and penicillin use.

Antibiotic resistance and epidemiology of *Staphylococcus* spp. at ICU of tertiary hospital in Southern Vietnam: a retrospective study

NT. Nguyen[1]; NT. Phan[2]; TP. Truong[3]; THV. Tran[2]
[1]Department of Critical Care – Emergency - Toxicology, University of Medicine & Pharmacy HCMC (UMP), Ho Chi Minh City, Vietnam; [2]Department of Laboratory, University of Medicine & Pharmacy HCMC (UMP), Ho Chi Minh City, Vietnam; [3]Department of Microbiology, Cho Ray Hospital, ho Vietnam
Correspondence: N. Ngoc Tu
Intensive Care Medicine Experimental 2025,* 13(1)*:001512

Introduction: Antibiotic resistance *Staphylococcus* spp. infections are increasingly prevalent in ICU, where critically ill patients with multiple comorbidities face a heightened risk of mortality. Despite itsclinical significance, research on the antibiotic resistance patterns and epidemiology of *Staphylococcus* spp. remains limited.
Objectives: This study aims to bridge this gap by providing clinicians with a comprehensiveoverview of *Staphylococcus* spp. and supporting evidence-based decision-making in antimicrobialtherapy.
Methods: This study collected data from 154 patients with *Staphylococcus* spp. infections between January 2020 and December 2024 in the ICU of Cho Ray Hospital, Vietnam.
Results: The highest infection rate was observed in *S. aureus*, accounting for 64.9% (100/154) of cases, followed by *S. haemolyticus* 14.9% (23/154), *S. epidermidis* 13.6% (21/154), *S. hominis* 4.5% (7/154), *S. capitis* 1.3% (2/154), and *S. lugdunensis* 0.6% (1/154). All cases of *S. haemolyticus*, *S. epidermidis, S. hominis*, and *S. lugdunensis* were resistant to oxacillin and benzylpenicillin. In addition, 72.9% of *S. haemolyticus* infections exhibited resistance to cotrimoxazole, while 100% of *S. lugdunensis* isolates were resistant to fusidic acid and tetracycline. Among the 100 cases of *S. aureus*, 98 (98%) were resistantto benzylpenicillin and 73 (73%) were classified as methicillin-resistant *S. aureus* (MRSA). All cases aresusceptible to vancomycin. Moreover, the mortality rate of patients with MRS is 46.3%.
Conclusions: This study provides insights into the changing patterns of antibiotic susceptibility in *Staphylococcus* spp. over a 5-year period. The findings have significant implications for antibioticselection in the treatment of *Staphylococcus* spp. infections among ICU patients.

Use of the anaconda ® anesthesia preserving device and its effect on dead space in patients with healthy lung under mechanical ventilation in a Level III hospital in Colombia

JA. Velandia[1]; N. Moreno[2]; AT. Sainea[2]; A. Salazar[2]; AJ. Velandia Suárez[2]
[1]Unidad de cuidados intensivos, San Rafael Hospital, Tunja, Colombia; [2]Cundinamarca, San Rafael Hospital, Tunja, Colombia
Correspondence: A. Salazar
Intensive Care Medicine Experimental 2025,* 13(1)*:001515

Introduction: The AnaConDa® AnaConDa® Anaesthesia Conservation Device (ACD) reflects exhaled anaesthetic agents and the literature reports ease of use outside operating theatres; however, evidence shows that exhaled CO_2 is also reflected, resulting in a dead space effect that exceeds the internal volume of the ACD (100 mL). CO_2 reflection from the ACD is attenuated by humidity, and these changes may not have a deleterious clinical impact on ventilated patients.
Objectives: To evaluate the effect of the ACD device on arterial blood gas values and ventilatory mechanics compared to a hygroscopic humidification filter (HMEF).
Methods: Prospective analytical analysis of patients under mechanical ventilation (MIV) attended in a level III hospital with ventilatory parameters and arterial blood gases taken on admission to the ICU with HMEF and after the change to ACD with inhaled sedation with isoflurane, excluding patients with lung parenchymal lesions of infectious, inflammatory or neoplastic origin, diagnosis of COPD, COPD and chest trauma.

Results: 57 patients were evaluated under IMV in ASV (adaptive support ventilation) mode, 57% men with mean age of 51.08 years. Statistically significant differences were found in peak inspiratory pressure ($p = 0.001$), airway resistance ($p = 0.001$), dead space volume ($p = 0.001$) and in the percentage of dead space volume ($p = 0.001$) and in the percentage of dead space volume ($p = 0.001$).
Conclusions: Although ACD causes an increasing effect on dead space, this is attenuated, but not eliminated, with the use of isoflurane. No short or long term changes were found on patients' pH, paO2 or pCO2 values which may indicate that its use is not harmful in terms of the use of ASV ventilatory strategy.

Extracorporeal immune cell therapy (ICE) with purified granulocytes: extended-duration feasibility and immunomodulatory profile

G. Klinkmann[1]; S. Brabandt[1]; DA. Reuter[2]; JC. Schewe[1]; S. Mitzner[3]; J. Altrichter[4]
[1]Department of Anaesthesiology and Intensive Care Medicine, University Medical Center Rostock, Rostock, Germany; [2]Department of anaesthesia and intensive care medicine, University Medical Center Rostock, Rostock, Germany; [3]Department of Internal Medicine, Division of Nephrology, University Medical Center Rostock, Rostock, Germany; [4]Artcline gmbh, Artcline GmbH, Rostock, Germany
Correspondence: G. Klinkmann

Intensive Care Medicine Experimental 2025,* 13(1)*:001516

Introduction: Extracorporeal immune cell therapy (ICE) represents a novel therapeutic strategy, where patient plasma is perfused through purified donor granulocytes to actively modulate the immune response while avoiding the risks of direct granulocyte transfusion. Preliminary clinical investigations have established safety and tolerability; however, specific dosing data and characterization of cytokine release patterns are still lacking [1].
Objectives: To investigate the feasibility, granulocyte integrity, and cytokine release dynamics during extended-duration ICE treatment up to 24 h.
Methods: Standard GC were purified to increase the potential storage time and subsequently used in the extracorporeal immune cell perfusion system (Fig. 1). An ex-vivo closed-loop extracorporeal circuit utilized three plasma filters (PF): PF-BC separated plasma from anticoagulated whole blood, PF-CC1 contained density-gradient purified granulocytes (2.5×10^9 cells, > 95% purity), and PF-CC2 served as a safety filter (Fig. 1). Two durations were studied—10 h (plasma flow 33 mL/min) and 24 h (13.5 mL/min). Granulocytes were stored for 72 h at 4 °C before use. Measurements at 0, 6, 10, and 24 h included viability (trypan-blue exclusion), phagocytosis of FITC-labelled Escherichia coli, oxidative burst (dihydrorhodamine-123), lactate dehydrogenase (LDH), glucose/lactate exchange, and cytokines (multiplex Luminex).
Results: Granulocyte viability remained consistently high (> 90%) in both regimens, with unchanged LDH indicating maintained cellular integrity. Functional assays demonstrated sustained phagocytic activity and oxidative burst (≥ 80% of baseline) throughout 24 h. Cytokine release followed a distinct time-dependent pattern: IL-8 levels peaked early at 6 h (median 8.2 ng/mL), stabilizing thereafter, whereas significant elevations of MCP-1, IL-6, IL-1β, and TNF-α occurred primarily between 10 and 24 h (all $p < 0.001$) (Fig. 3). Metabolic parameters remained stable without clot formation.
Conclusions: ICE demonstrates sustained granulocyte function and cell integrity over an extended treatment period, revealing a unique time-dependent cytokine release profile distinct from conventional extracorporeal techniques. These findings provide a scientifically robust framework for optimizing future ICE dosing strategies aimed at reversing sepsis-induced immunoparalysis.

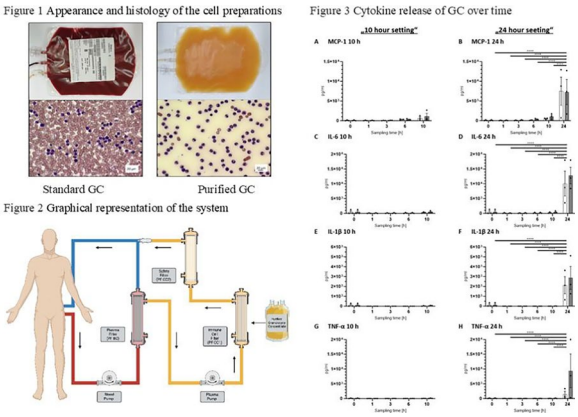

Figure 1. Appearance and histology of the cell preparations.

Excessive oxygen exposure is associated with short-term poor prognosis in critical ill patients after abdominal surgery: a retrospective study

X. Qian[1]; KY. Lui[1]; H. Ma[1]; X. Guan[1]; C. Cai[1]
[1]Department of Critical Care Medicine, the First Affiliated Hospital of Sun Yat-sen University, Guangzhou, China
Correspondence: K.Y. Lui
Intensive Care Medicine Experimental 2025,* 13(1)*:001518

Introduction: Patients after abdominal surgery in the ICU routinely receive adjuvant oxygen therapy to prevent hypoxemia. However, excessive oxygen exposure may pose potential hazards to critically ill patients through mechanisms, such as inducing oxidative stress, vasoconstriction, and atelectasis. At present, the impact of hyperoxia on the prognosis of patients after abdominal surgery in the ICU remains controversial. Therefore, this study aimed to explore the association between oxygen exposure indicators (PaO_2, FiO_2 and oxygen exposure time) and the 30-day mortality of patients after abdominal surgery in the ICU, and to clarify the appropriate range of oxygen therapy for postoperative patients.
Methods: This study was a retrospective cohort study, including patients who were admitted to the ICU for more than 24 h after abdominal surgery at the First Affiliated Hospital of Sun Yat-sen University from January 2018 to June 2022. Extracted all arterial blood gas results of the patients in the first 7 days during their stay in the ICU or before they were transferred out of the ICU (for patients staying in the ICU for less than 7 days), and calculated TWA-PAO_2 and TWA-FiO_2 [time-weighted average (TWA): The ratio of area under the variation-time curve to time] and the proportion of hyperoxia exposure time (the proportion of the duration of $PaO_2 \geq 112.93$ mmHg in the total ICU duration). The Kaplan–Meier curve and log-rank test were used to determine the optimal cutoff values of each indicator. Survival analysis was conducted after controlling the baseline differences using the propensity score matching (1:1) method. Finally, the independent risk factors for 30-day mortality of patients admitted to ICU after abdominal surgery were determined by the multivariate Cox regression model.
Results: A total of 1286 patients after abdominal surgery admitted to ICU who met the inclusion and exclusion criteria were included in this study. Among them, 1067 patients (83%) were in the survival group and 219 patients (17%) were in the non-survival group. The APACHE II score and SOFA score of the non-survival group were significantly higher than those of the survival group (23.00 [19.00, 29.00] vs. 17.00 [13.00, 21.00], $P < 0.001$; [5.00, 8.00] 6.00 vs. 5.00 [3.00, 7.00], $P < 0.001$, respectively), and BMI was significantly lower than that of the survival group (21.64 [19.71, 24.07] vs. 22.68 [20.20, 24.92], $P < 0.001$). Based on the log-rank test, the cutoff values of TWA-PaO_2, TWA-FiO_2, and the proportion of hyperoxia exposure time were determined to be 112.93 mmHg, 48.11% and 18%, respectively. The patients were divided into the hyperoxia and the hypoxia group, respectively, with the cutoff values of the three indicators as the boundaries. After propensity score matching, the baseline characteristics between the groups reached equilibrium. The survival analysis after matching also showed that the 30-day mortality of patients in the TWA-$PaO_2 \geq 112.93$ mmHg group ($P = 0.001$), the TWA-$FiO_2 \geq 48.11\%$ group ($P < 0.001$), and the group with the proportion of hyperoxia exposure time > 18% ($P < 0.001$) were all significantly higher than those in the corresponding hypoxia groups. Further multivariate Cox regression analysis revealed that TWA-FiO_2 (HR = 1.059, 95% CI 1.040–1.074, $P < 0.001$) and the proportion of hyperoxia exposure time (HR = 2.418, 95% CI 1.250–3.683) $P = 0.006$) is an independent risk factor for 30-day mortality in patients after abdominal surgery in the ICU.
Conclusions: High fractional inspired oxygen (TWA-$FiO_2 \geq 48.11\%$) and the proportion of hyperoxia exposure time (> 18%) are significantly associated with the 30-day mortality of patients admitted to ICU after abdominal surgery. The oxygen therapy strategies for patients after abdominal surgery should be carefully evaluated to avoid excessive oxygen therapy.

Topic: Acute respiratory failure and mechanical ventilation.

Exploring nutritional recovery following hospital discharge in adult survivors of critical illness: a scoping review

E. Terblanche[1]; DM. Isa[2]; HA. Majid[1]
[1]School of Health and Rehabilitation Sciences, Health Sciences University, Bournemouth, United Kingdom; [2]Centre for Population Health, University of Malaya, Kuala Lumpur, Malaysia
Correspondence: E. Terblanche
Intensive Care Medicine Experimental 2025,* 13(1)*:001519

Introduction: Survivors of critical illness frequently experience post-intensive care syndrome including muscle wasting and weight loss (1). Malnutrition and inadequate dietary intake are prevalent during hospitalisation, yet post-hospital discharge nutrition interventions remain under-investigated (2).
Objectives: This review aimed to synthesise current evidence available on nutritional recovery in adult survivors of critical illness following hospital discharge and to identify dietetic interventions supporting recovery.
Methods: Using Joanna Briggs Institute methodology, systematic search was conducted in MEDLINE, Embase, CINAHL, Web of Science, and Cochrane databases (2010–2024). Eligible studies reported nutrition intakes, body composition or dietetic interventions in survivors of critical illness after hospital discharge. Data were synthesis using the Social Ecological and Biopsychosocial Models to capture individual and systemic influences on recovery.
Results: Forty-four studies (mostly observational) met inclusion criteria. Nutritional recovery was shaped by complex biological, psychological, and systemic factors. Key barriers included appetite loss, dysphagia, and psychological distress significantly contributing to inadequate dietary intake. Across all times points, protein intake consistently fell below targets, with only 10% of survivors meeting the target of 1.2 g/kg/day after 12-month post-discharge (3). Energy intake remained suboptimal, throughout the first year (3, 4). Malnutrition and weight loss persisted for 12-month post-discharge. Body composition data revealed a dynamic trajectory: initial loss of lean mass followed by increases in fat mass. Two DEXA based studies demonstrated gains in total mass and fat mass between 6 and 12 months, while lean mass was maintained or further declined, indicating a shift toward adiposity rather than muscular recovery (5, 6). Six studies reported on handgrip strength which remained clinically low at 3 months (4) and was a significantly associated with 1-year mortality, particularly amongst malnourished individuals (7). Despite high nutritional risk, only 30% of studies reported explict dietitian involvement with referral rates varying from 9% to 43%. Dietetic interventions such as food fortification, texture modification and oral nutritional supplements were associated with improved nutritional adequacy and weight gain (4).
Conclusions: This review emphasises the complex challenges faced by ICU survivors after hospital discharge and highlights significant gaps in post-discharge nutrition care. Few survivors received adequate dietetic support, with considerable variability in dietary strategies and follow-up. Further research is required to develop effective, nutrition interventions, particularly within the vulnerable first 3-month post-discharge.

Corelation between nt-probnp and procalcitonin in sepsis and septic shock

R. chugg[1]; A. Ajay[2]; H. Malhotra[2]
[1]Internal Medicine, Fortis hospital, Noida, Noida, India; [2]Internal Medicine, Fortis Hospital Noida | Best Hospital in Noida, Noida, India
Correspondence: R. Chugg
Intensive Care Medicine Experimental 2025,* 13(1)*:001521

Introduction: Sepsis and septic shock continue to pose major global health threats, marked by substantial mortality and long-term morbidity. Prognostic tools that combine markers of cardiac dysfunction and systemic inflammation may improve risk stratification. This study investigates the relationship between N-terminal pro-brain natriuretic peptide (NT-proBNP), a marker of myocardial strain, and procalcitonin (PCT), a biomarker of bacterial infection and systemic inflammation, in patients with sepsis and septic shock.
Objectives: To assess the correlation between NT-proBNP and PCT levels in patients with sepsis and septic shock, and evaluate their individual and combined prognostic value with respect to clinical outcomes, including ICU and hospital stay duration and in-hospital mortality.
Methods: A prospective, cross-sectional observational study was conducted over 12 months (April 2023–April 2024) at Fortis Hospital, Noida, India. One hundred adult patients (> 17 years) meeting Sepsis-3 diagnostic criteria for sepsis or septic shock were included. Patients with pre-existing cardiac, renal, or pulmonary disease were excluded. Blood samples were obtained on admission and at 72 h for NT-proBNP (electrochemiluminescence immunoassay) and PCT (fluorescent immunoassay). Clinical data and outcomes were collected. Statistical analyses included Pearson's correlation, independent *t* tests, and ROC curve analysis using SPSS v22.
Results: Demographics: 62% of patients were male, with a mean age of 53.07 ± 13.51 years. Pulmonary infections (45%) were the most frequent source.
Biomarker levels: Non-survivors had significantly higher NT-proBNP (12,483 vs. 6396 pg/mL at admission; 11,877 vs. 502 pg/mL at 72h) and PCT (21 vs. 8 ng/mL at admission; 25 vs. 2 ng/mL at 72h) than survivors ($p < 0.01$ for all comparisons).
Correlation: A moderate positive correlation was observed between NT-proBNP and PCT ($r = 0.48$, $p < 0.01$).
Prognostic performance: NT-proBNP predicted mortality with 80.5% sensitivity and 60.8% specificity; PCT showed 78.4% sensitivity and 63.5% specificity.
Outcomes: The overall mortality rate was 41%. ICU stay was longer in non-survivors (14.96 vs. 9.79 days), though not statistically significant ($p = 0.23$).
Conclusions: NT-proBNP and PCT are significantly elevated in non-survivors of sepsis and demonstrate moderate correlation. Both markers, individually and together, show promise as prognostic tools in sepsis. Further studies are warranted to validate their use in clinical algorithms guiding early risk stratification and therapeutic decisions.

Pleural effusion in patients with heart failure and preserved ejection fraction

O. Maadarani[1]; Z. Bitar[2]
[1]Cardiology, New Ahmadi Hospital, Alahmadi, Kuwait; [2]Critical care unit, New Ahmadi hospital KOC -, Ahmadi, Kuwait
Correspondence: O. Maadarani
Intensive Care Medicine Experimental 2025,* 13(1)*:001523

Introduction: The incidence of pleural effusions (PEs) radiologically in acute decompensated heart failure was estimated by 50%(1).The prevalence of PEs using chest ultrasound in patients with heart failure with preserved ejection fraction (HFpEF) was not studied before.
Objectives: To determine the prevalence and severity of PE using bedside chest ultrasound in patients with HFpEF.
Methods: We prospectively evaluated 85 patients admitted to the coronary care unit with acute pulmonary edema. 27 patients had LVEF below 50% and they were excluded. We used bedside ultrasonography to document the presence of pleural effusions (Fig. 1) and estimate the amount using Goecke 2 formula.
Results: 58 patients were recruited with estimated LVEF above 50% and median age of 73 years. The baseline characteristics of the patients are shown in Table 1. Pleural effusion was detected by chest ultrasound in 54 patients (94%) with 91% being bilateral and of moderate amount. The mean value of E/A and E/E' ratio was 1.92 and 19.9, respectively, where mean deceleration time (DT) was 171 ms; however, these parameters were not related to severity of pleural effusion ($P = 0.52$, 0.99 and 0.7, respectively) (Table 2). The N-terminal pro-brain-type natriuretic peptide (NT-proBNP) was significantly higher in patients with pleural effusion ($P = 0.046$).
Conclusions: PEs are present on chest ultrasound in 94% of patients with HFpEF and mainly bilateral. The severity of PE was moderate and not related to the LV filling pressure parameters.

Elevated left ventricular end diastolic pressure can be detected by the presence of sonographic B lines on chest ultrasound

O. Maadarani[1]; Z. Bitar[2]
[1]Cardiology, New Ahmadi Hospital, Alahmadi, Kuwait; [2]Critical care unit, New Ahmadi hospital KOC -, Ahmadi, Kuwait
Correspondence: O. Maadarani
Intensive Care Medicine Experimental 2025,* 13(1)*:001524

Introduction: Echocardiography and lung ultrasound are important tests for assessing left ventricular function in patients presented to the emergency department with acute pulmonary edema. Chest ultrasound is becoming an important tool in diagnosing acute pulmonary edema.
Objectives: To investigate the relationship between the B profile on ultrasound chest and spectral tissue Doppler echocardiography (E/e' ratio) in patients presented with the suspicion of acute pulmonary edema.
Methods: This paper reports a prospective observational study of 61 consecutive patients, which was presented with symptoms and signs of pulmonary edema and B—profile detected by echocardiography with a 5 MHz curvilinear probe. Critical care physicians trained in ultrasound examination performed echocardiography and chest ultrasounds.
Results: Sixty-one participants were included in the study. Forty-seven of the 61 patients had a B-profile and 14 patients had an A profile. The mean E/e' level in the patients with B-profile was 20.8, compared with the mean level in the patients with an A-profile of 8.2 (CI = 0.33–0.82). The distribution in the two groups differed significantly (p = 0.003). Based on the value of E/e', the sensitivity and specificity were determined; the sensitivity of B profile on ultrasound was 92% (95% confidence interval (CI) = 0.812–0.968), and the specificity was 91% (CI = 0.623–0.98). The positive predictive value of the B-profile was 97% (CI = 0.889–0.996), and the negative predictive value was 71% (CI = 0.454–0.883). The systolic function in the subjects with a B-profile was below 50% in 74.3% of the subjects and normal in 25.7% of the subjects. All the subjects with B profile and systolic function > 50% had elevated ProBNP and E/e' > 15. An A-profile subjects had systolic function > 55%.
Conclusions: Detecting the B-profile in lung ultrasound is highly sensitive and specific for elevated left ventricular diastolic pressures regardless of the systolic function of the left ventricle which may help in diagnosing pulmonary edema.

B lines.

Plasma from septic patients induces neutrophil extracellular trap (NET) release ex vivo: impact of illness severity and modulation by plasma exchange

A. Villa[1]; H. Xue[1]; M. Scully[2]; S. David[3]; D. Brealey[1]; M. Singer[1]; TAC. Snow[1]; N. Arulkumaran[1]
[1]Bloomsbury Institute of Intensive Care Medicine, University College London, London, United Kingdom; [2]Department of Haematology, University College Hospital, London, United Kingdom; [3]Institute of intensive care medicine, University Hospital Zurich, Zurich, Switzerland
Correspondence: A. Villa
Intensive Care Medicine Experimental 2025,* 13(1)*:001525

Introduction: Excessive neutrophil extracellular trap (NET) formation contributes to sepsis-related endothelial injury and thrombo-inflammation. Circulating mediators may drive this dysregulated response. Therapeutic plasma exchange (TPE) has been suggested to modulate this process, but its effect on NET formation remains underexplored.
Objectives: We aimed to assess whether plasma from septic ICU patients induces NET release ex vivo in neutrophils from healthy volunteers (HVs), and whether NET induction is associated with illness severity and mortality. We also investigated the effect of TPE on NET formation in plasma from critically ill COVID-19 patients.
Methods: Neutrophils were isolated from 6 HVs and incubated for 4 h with plasma from 40 ICU patients with sepsis (26 survivors, 14 non-survivors) or plasma from 5 ICU COVID-19 patients before and after TPE. NETs were quantified via fluorescence microscopy following propidium iodide and MPO staining. Neutrophil phenotype was assessed by flow cytometry. Controls included autologous plasma and PMA/ionomycin-stimulated neutrophils.
Results: Neutrophils incubated with plasma from septic patients showed significantly increased NET release compared to autologous plasma ($p < 0.01$), with a greater effect from non-survivors ($p < 0.001$). This was associated with reduced CD14, CD16, and CD64 expression. Plasma from COVID-19 patients before TPE induced marked NET formation ($p < 0.001$), which was significantly reduced post-TPE ($p < 0.05$), though not to baseline levels. Cytokine levels (IL-6, TNF-α) did not differ significantly between survivors and non-survivors and were not reduced by TPE (Figure a, b, c).
Conclusions: Plasma from septic and COVID-19 patients induces NETosis in healthy neutrophils, more so in patients with greater severity or non-survival. TPE partially attenuates this effect in COVID-19, supporting the role of circulating large molecules in driving NETosis. These findings suggest NET-related biomarkers could identify patients for NET-targeted therapies, including TPE.

(a) Representative images of NET release from neutrophils incubated with autologous plasma or plasma isolated from septic ICU survivors, non-survivors, and PMA-I (phorbol myristate acetate with ionomycin as a positive control). Propidium iodide (PI, red) indicates chromatin release, and MPO (myeloperoxidase, green) highlights neutrophil-specific structures. Merged images demonstrate colocalization of MPO and chromatin, indicative of NETs. Scale bars represent 100 µm. Insets magnify individual NET structures.

(b) Compared to incubation with autologous plasma, incubation with plasma from septic ICU survivors ($p < 0.01$) and non-survivors ($p < 0.0001$) is associated with increase in NETs release.
(c) Compared to incubation with autologous plasma, incubation with plasma from COVID-19 patients ($p < 0.0001$) is associated with an increase in NTEs, which is abrogated following TPE ($p < 0.05$).
Bars represent medians. Comparisons between groups are assessed using Mann–Whitney *U* tests and statistical significance is marked with an asterisk (*$p < 0.05$, ** $p < 0.01$, ***$p < 0.001$, ****$p < 0.0001$).

Optimizing fluid resuscitation in burn ICU patients: implementation of a nurse-driven, titratable protocol

M. Albalawi[1]; I. Alamri[2]; T. Alotaibi[1]; G. Alramahi[3]; M. AlFaifi[1]
[1]Pharmaceutical Care Department, King Saud Medical City, Riyadh, Saudi Arabia; [2]Critical Care Department, King Saud Medical City, Riyadh, Saudi Arabia; [3]Department of Trauma Surgery, King Saud Medical City, Riyadh, Saudi Arabia
Correspondence: M. Albalawi
Intensive Care Medicine Experimental 2025,* 13(1)*:001526

Introduction: Burn injuries are among the most critical forms of trauma, often resulting in systemic complications such as burn shock within the first 72 h. Fluid resuscitation is vital, particularly in patients with burns exceeding 20% of total body surface area (TBSA). While the Parkland formula remains widely used, both over- and under-resuscitation have been linked to poor outcomes, including abdominal compartment syndrome. Nurse-driven protocols may enhance precision, but standardized titratable methods are still underutilized.
Objectives: To evaluate the impact of a nurse-driven, titratable fluid resuscitation protocol on clinical outcomes and fluid-related complications in critically ill burn patients.
Methods: A quasi-experimental study was conducted in the Burn ICU of a tertiary hospital between June 2023 and September 2025 (IRB: H1RI-07-May24-01). Nurses completed a pre-intervention survey assessing knowledge of burn resuscitation, followed by targeted

education and post-assessment. A titration-based nurse-driven protocol was then implemented. Patient outcomes using the new protocol were compared to those managed with the standard approach. Primary Outcome mainly reduction in fluid-related complications and improvement in clinical workflow. Secondary Outcomes include ICU complications (e.g., infections, VAP, ARDS, CAUTI, GI ulcers, sepsis, VTE, and delirium), need for renal replacement therapy, incidence of abdominal compartment syndrome, mechanical ventilation duration, and ICU/hospital length of stay.
Results: To be presented upon data analysis.
Conclusions: A nurse-driven, titratable protocol may improve the safety and effectiveness of fluid resuscitation in burn ICU patients.

Determination of critical DO_2 in patients undergoing cardiac surgery

JS. Serrano[1]; D. Manzur Sandoval[1]; N. Queb[1]
[1]Cardiovascular Intensive Care Unit, National Institute of Cardiology Ignacio Chavez, Ciudad de México, Mexico
Correspondence: N. Queb
Intensive Care Medicine Experimental 2025,* 13(1)*:001529

Introduction: Patients undergoing cardiac surgery are exposed to significant physiological stress from tissue injury and cardiopulmonary bypass, often leading to hemodynamic mismatch during the first 24 h postoperatively. Hemodynamic coherence (alignment between macro- and microcirculatory parameters) is frequently disrupted in this context and is associated with poor outcomes. Despite its clinical relevance, the critical threshold of oxygen delivery (DO_2) specific to cardiac surgery patients remains unclear.
Objectives: To determine the critical DO_2 in patients undergoing cardiac surgery and evaluate its association with clinical outcomes and in-hospital mortality, based on lactate levels and the CO_2 gap/Ca-vO_2 ratio.
Methods: A retrospective observational study was conducted, including 508 adult patients admitted to the ICU after cardiac surgery between June 1, 2022, and June 1, 2024. Patients were categorized into three profiles:

- **Profile 1**: Lactate < 2 mmol/L
- **Profile 2**: Lactate ≥ 2 mmol/L and CO_2 gap/Ca-vO_2 ratio > 1
- **Profile 3**: Lactate ≥ 2 mmol/L and CO_2 gap/Ca-vO_2 ratio ≤ 1

Demographic and clinical data were collected. Logistic regression adjusted for age and sex was performed to assess outcomes and mortality.

Results: Of 508 patients, 165 (32.5%) were Profile 1, 295 (58.1%) Profile 2, and 48 (9.4%) Profile 3. The mean age was 57 years, of which 43.9% were women. Comorbidities included hypertension (42.3%), diabetes (22.4%), and hypothyroidism (10%). Common cardiovascular histories included heart failure (27%), atrial fibrillation (18.3%), and prior myocardial infarction (11.6%). Previous cardiac surgery was significantly more frequent in Profile 2 ($p < 0.05$).
Compared to Profile 1 and 3, Profile 2 was associated with higher risks of stroke (OR 4.3; 95% CI 1.23–14.78), hospital-acquired pneumonia (OR 2.0; 95% CI 1.07–3.88), acute kidney injury (OR 1.8; 95% CI 1.21–2.69) and in-hospital mortality (OR 2.2; 95% CI 0.99–5.13).

Table 1 Outcomes according to logistic regression in profile 2

Variable	OR	CI 95%	*p*
Stroke	4.27	1.23–14.78	0.02
Hospital-acquired pneumonia	2.04	1.07–3.88	0.002
Acute kidney injury	1.81	1.21–2.69	0.003
Renal replacement therapy	1.63	0.75–3.52	0.21
Hepatic failure	1.95	0.95–3.99	0.06
In-hospital mortality	2.25	0.99–5.13	0.05

Conclusions: Cardiac surgery patients exhibit a critical DO_2 threshold distinct from other hemodynamic states. A $DO_2 \leq 7.3$ ml/min/kg was associated with increased likelihood of developing Profile 2 and greater in-hospital mortality. Early identification of oxygen delivery imbalance may guide targeted interventions and improve postoperative outcomes.

Introduction: Malignancy associated hemophagocytic lymphohistiocytosis (mal-HLH) poses unique challenges in diagnosis and management. We aimed to evaluate the utility of soluble Interleukin-2 receptor (sIL-2r) and sIL-2r/Ferritin for its diagnosis.
Objectives: To assess the performance of sIL-2R & sIL-2R/Ferritin ratio for the diagnosis of malignancy associated HLH in critically ill patients.
Methods: We retrospectively evaluated 72 patients admitted with suspected HLH, in whom s-IL 2r was measured. We collected relevant data from the our database including demographics, presentation, laboratory findings, outcomes etc.
Results: Using HLH 2004 criteria, 40 (of 72) patients had HLH with malignancy. The sensitivity, specificity, positive predictive and negative predictive value of sIL-2r as a part of HLH-2004 criteria for diagnosis of HLH for entire cohort were 77.5% (95% CI 61.55–89.16), 53.12%(95% CI 34.7–70.91), 67.3% (95% CI 57.96–75.60%) and 65.38% (95% CI 49.38–78.53%) with AUROC of 0.65 (95% CI 0.52–0.78). For sIL-2r/Ferritin ratio, the sensitivity, specificity, positive predictive and negative predictive value for entire cohort were 2.5% (95% CI 0.06–13.16%), 90.62% (95% CI 74.98–98.02%), 25% (95% CI 3.51–75.33%) and 42.65% (95% CI 39.69–45.65%) with AUROC of 0.521 (95% CI 0.38–0.66). Nineteen of 40 (47.5%) mal-HLH patients were discharged alive from ICU, as against 20 of 32 (62.5%) other patients. Mal-HLH patients had a longer Intensive care unit (ICU) and hospital length of stay (LOS) (11.10 ± 12.55 and 25.40 ± 21.39 vs. 7.70 ± 7.39 and 22 ± 11.93) days, respectively.
Conclusions: Performance of sIL-2r and sIL-2r/Ferritin ratio was moderate to poor for diagnosis of mal-HLH. The cutoff values of these variables need revision, with further research in a larger patient cohort.

The effect of therapeutic plasma exchange on the outcome of patients with neurological autoimmune disease treated in the ICU of adam malik general hospital

B. Lubis[1]
[1]Anasthesiology, Universitas Sumatera Utara, Medan, Indonesia
Correspondence: B. Lubis
Intensive Care Medicine Experimental 2025,* 13(1)*:001532

Introduction: Therapeutic plasma exchange (TPE) eliminates circulating pathogenic substances such as autoantibodies from the bloodstream, thereby improving clinical outcomes. Diseases such as Myasthenia Gravis and Guillain–Barre syndrome often cause paralysis that requires intensive care, one of the expected uses is TPE. The purpose of this study was to determine the effect of TPEon the outcome of patients with neurological autoimmunity treated at Adam Malik Hospital.
Objectives: Guillain–Barre syndrome, ICU, Myasthenia Gravis, neurological autoimmune, therapeutic plasma exchange.
Methods: An analytical retrospective study was conducted on patients with neurological autoimmune disorders who underwent TPE and were ventilated at Adam Malik General Hospital. Demographic data, clinical outcomes, duration of ventilator use, and assessment of changes in neurological autoimmune scores using the Myasthenia Composite Scale (MCS) and Guillain Barre Disability Scale (GBDS) before and after TPE (1–2 cycles) were analyzed using descriptive and inferential statistical methods.
Results: We have 22 patients who underwent TPE, 16 people with myasthenia gravis underwent TPEand 9 people with Guillain Barre Syndrome underwent TPE, but no significant difference was foundbetween the two ($p > 0.05$). On the contrary, there was a decrease in MCS values after TPE, a significant difference was found between the two groups ($p < 0.05$).
Conclusions: TPE has been shown to have a positive impact on the outcome of patients with neurological autoimmune in the ICU of Adam Malik General Hospital. Further research is needed to explore the long- term effects and optimization of TPE protocols in this population.

Intensive Care Medicine Experimental 2025,* 13(1)*:001534

Introduction: Acute liver failure (ALF) is a rapidly progressing disease in patients without pre-existing chronic liver diseases caused by severe liver damage. Hepatocyte death during ALF triggers the release of proinflammatory cytokines, fueling systemic inflammation and, consequently, multiorgan failure.(1) Despite recent advances in critical care, survival remains low without liver transplantation (LTx). Various liver-assist devices, all highly complex procedures limited to specialized centers, have been developed to support liver function but failed to show any clinical benefit.(1, 2) Cytosorb is a hemadsorption device that can be easily applied to continuous renal replacement therapy (CRRT), potentially supporting liver function by removing bilirubin and proinflammatory cytokines.(3) However, data on Cytosorb adsorber in ALF patients is scarce.(4).
Objectives: We aimed to assess the effects of Cytosorb on clinical and laboratory parameters in ALF patients. Furthermore, we investigated potential complications associated with Cytosorb use.
Methods: In our retrospective single-center analysis, all patients admitted with ALF to the Intensive Care Unit (ICU) at the Medical University of Vienna who received CRRT from 2012 to 2025 were included and separated into two groups (CRRT + Cytosorb and CRRT) with an observation period set from ICU admission to LTx, ICU discharge, or death.
Results: 28 ALF patients ($n = 14$ CRRT + Cytosorb and $n = 14$ CRRT) were included with a median age of 47.1 years (IQR: 32.5–56.4) and 82.1% female patients. Median SAPS II and SOFA scores were 43

(33.3–50.3) and 11 (5–14), with high rates of invasive mechanical ventilation (n = 24, 85.7%) and vasopressor therapy (n = 23, 82.1%). Of 19 patients (67.9%) listed for LTx, 13 (46.4%) received LTx. ICU and 3-month survival was 60.7% and 50%, respectively. Cytosorb significantly decreased bilirubin (median pre-treatment 20.85 mg/dL to post-treatment 9.46 mg/dL; − 54.6%; $p < 0.001$). A significant platelet drop was detected in both groups. Survival was higher in the Cytosorb group compared to the control group (ICU survival: 71.4% vs. 42.9%, $p = 0.127$; 3-month survival: 71.4% vs. 28.6%, $p = 0.023$). However, patients in the control group were sicker (SAPS II: 45.5 vs. 38.5, p = 0.039), less often listed for LTx (42.9% vs. 92.9%, p = 0.005) and less often transplanted (28.6% vs. 64.3%, p = 0.058). No complications attributed to Cytosorb were observed.

Conclusions: Cytosorb was associated with a significant reduction in bilirubin levels. Survival differences are probably attributed to differences in baseline characteristics and transplant eligibility between groups. No major bleeding complications or other adverse effects directly related to Cytosorb use were detected. Our data support the feasibility, safety, and potential benefits of Cytosorb as an adjunctive therapy in ALF management. Larger prospective studies are warranted to evaluate the impact of Cytosorb treatment in ALF patients.

Intensive Care Medicine Experimental 2025,* 13(1):*001537

Introduction: Multiple Intensive Care Unit (ICU) databases have been publicly released to advance data driven intensive care medicine. However, these public ICU data sets are prone to changes, updates and new releases. Therefore, the goal of this review is to provide clinicians and data scientists with a state-of-the-art overview and guide for choosing the relevant ICU data sets for their respective research questions.

Methods: A systematic search was carried out in PubMed, PhysioNet, Arxiv, MedRxiv, and BioRxiv to identify all publicly available intensive care data sets of adult patients. After data extraction of database characteristics, a qualitative synthesis of results was carried out.

Results: 876 publications were identified. After screening, 7 publicly available ICU databases were included for analysis: AmsterdamUMCdb, eICU Collaborative Research Database (eICU-CRD), HiRID, Medical Information Mart for Intensive Care (MIMIC)-IV, Northwestern ICU (NWICU), Salzburg Intensive Care database (SICdb), and Zigong Fourth People's Hospital (ZFPH) database of patients with infections. A qualitative synthesis showed notable differences in number of patients, usage of organ support, admission types, and frequency of measurements.

Conclusions: Each public ICU datas et differs due to differences in medical practice, information technologies and approach to legal restrictions. This systematic review provides clinicians and data scientists with an overview of available public ICU data sets and their characteristics.

Visual comparison of ICU data set characteristics. ALAT = alanine aminotransferase, CRP = C-reactive protein, FiO2 = fraction of inspired oxygen, PEEP = positive end-expiratory pressure, pO2 = partial pressure of oxygen.

A comparison of efficacy of high-dose magnesium sulphate infusion vs. standard dose magnesium sulfate infusion in moderate-to-severe asthma exacerbation in children

B. Suetrong[1]
[1]Pediatrics, Nopparat Rajathanee Hospital, Bangkok, Thailand
Correspondence: B. Suetrong
Intensive Care Medicine Experimental 2025,* 13(1)*:001538

Introduction: Standard dose magnesium sulfate was recommended in GINA guideline for treatment of severe asthma exacerbation. There have been a few prospective randomized studies assessing the efficacy of high dose compared with standard dose magnesium sulfate for treatment of severe asthma exacerbation in children which demonstrated the better efficacy of high dose magnesium sulfate but there was no a single study evaluate in moderate asthma exacerbation in children. We hypothesized that early administration of high dose magnesium would be benefit in moderate to severe asthma exacerbation in children.
Objectives: To compare the efficacy of a high dose magnesium sulfate infusion vs. standard dose in pediatric patients with moderate to severe asthma exacerbation.
Methods: This was a randomized double blinded controlled trial of 38 children 2–15 years of age who presented with moderate to severe asthma exacerbation. All patients were not completely responded to the standard bronchodilators and systemic steroid in the first hour. They were randomized into 2 groups, 20 for high dose magnesium sulfate (50 mg/kg in 30 min then 50 mg/kg/hour for 4 h) and 18 for standard dose magnesium sulfate (50 mg/kg in 30 min then placebo). Patients were monitored every 1 h. for clinical asthma score (CAS) and cardiopulmonary complications such as hypotension, bradypnea and apnea.
Results: There were no significant difference in ages, gender, past medical history of asthma, personal atopy and initial clinical asthma score between two groups. The mean of clinical asthma score at 6 h was significantly lower in the patients treated with high dose magnesium sulfate compared with the standard dose (2.20 ± 1.66 vs. 3.28 ± 1.54, *P* value = 0.038). Furthermore, there was a trend of higher responder percentage, defined by reduction of CAS 3 or more within 6 h, in high dose group 86.7% vs. 64.3% but the *P* value did not reach the significant level (*P*-value = 0.215). There were no adverse events in both groups.
Conclusions: The early administration of high dose magnesium sulfate infusion in children with moderate-to-severe asthma exacerbation is better than standard dose without any adverse events.

Mean Clinical Asthma Score (CAS) of high-dose vs. standard dose of MgSO4 in moderate-to-severe asthma exacerbation in children.

Short- vs. long-course antibiotic therapy in patients with acute cholangitis

J. Fuss[1]; A. Voloboyeva[2]; V. Polovyj[3]
[1]Department of surgery, Medical Center of St. Paraskeva, L'viv, Ukraine; [2]Icu, Communal Municipal Clinical Hospital 8, L'viv, Ukraine; [3]Department of surgery, Bukovinian State Medical University, Chernivtsi, Ukraine
Correspondence: J. Fuss
Intensive Care Medicine Experimental 2025,* 13(1)*:001539

Introduction: The mortality rates of acute cholangitis (AC) have significantly decreased by comparing patients' data before 1980 and after 2000, from 10–30% to 2.7–10%[1]. Multiple factors, such as the development of modern diagnostic techniques, therapeutic methods for bile duct decompression, and new antibiotics adapted to microbiological studies, have significantly contributed to this improvement in the prognosis of AC.
Objectives: To investigate if shorter-course antibiotic treatments could be similarly effective to long-course treatments in adults with AC.
Methods: Inclusion criteria were as follows: (i) 18 years of age or older, (ii) patients with moderate or severe acute cholangitis according to Tokyo guidelines 2018 (19), and (iii) patients who underwent successful biliary drainage through ERC, EUS-guided drainage, or PTBD.
All patients with moderate or severe cholangitis were planned for emergent biliary drainage (within 48 h of admission). Once successful biliary drainage was achieved, patients were randomized into two groups: conventional duration group (CD group): 10 days of intravenous antibiotic therapy; short duration group (SD group): 5 days of intravenous antibiotic therapy. The choice of antibiotic was as per guideline and institutes bacteriological profile.
Results: A total of 202 consecutive patients with acute moderate or severe cholangitis were screened during the study period. Of them, 130 met the inclusion criteria and were randomized to the CD or SD group.
The mean age of included patients was 63.85 ± 10.74 years and 55% were male. In the study cohort, 101 (77.7%) patients had moderate cholangitis and 29 (22.3%) patients had severe cholangitis. Most of the patients (51.7%) had malignant etiology of cholangitis, while the remaining patients (48.3%) had benign etiology of cholangitis. For biliary drainage, ERC (*n* = 101; 84.2%) was the most commonly used procedure followed by PTBD (*n* = 18;15%). One hundred eleven (92.5%) patients underwent drainage within 48 h of admission (81 patients within 24 h and 30 patients between 24 and 48 h of admission); however, 9 (7.5%) patients underwent drainage after 48 h because of logistic reasons. All 9 patients had moderate cholangitis.
Predrainage intravenous antibiotics were given to all included patients. 115 patients received intravenous piperacillin-tazobactam, and 15 patients received carbapenems. Of 130 patients, bile culture was sent in 85 (65.3%) patients.
Total duration of antibiotics required postintervention till day 30 was 10.32 ± 1.92 and 5.35 ± 3.33 days in the CD and SD groups, respectively (*P*, 0.001). The mean total duration of hospitalization in the CD and SD groups was 2.81 ± 1.48 days and 3.0 ± 1.76 days, respectively (*P* = 0.53).
Conclusions: To conclude, short duration of antibiotics is noninferior to conventional duration of antibiotics in patients with moderate to severe cholangitis in terms of clinical cure, recurrence of cholangitis, and overall mortality.

Intensive Care Medicine Experimental 2025,* 13(1)*:001540

Introduction: Acute cholangitis, the most common hepatobilliary system disease, is an infectious condition caused by partial or complete obstruction of the biliary system and can have life-threatining consequences if not given timely treatment [1, 2]. Fever, abdominal pain, and jaundice are typical clinical manifestations of patients with acute cholangitis and obstruction of the bile duct is the main cause biliary obstruction.
Clinical manifestations and laboratory tests upon admission were reviewed to predict the presence of bacteria in bile when bile drainage was conducted [3, 4].
Methods: This was a retrospective study. Patients with acute cholangitis admitted to a St.Paraskeva medical center, Communal Clinical hospital 8, department of surgery Pustomyty Hospital between January 2018 and December 2023. The diagnostic criteria for acute cholangitis were based on Tokyo Guidelines 18. Data were collected retrospectively by local investigators using electronic case report forms (eCRF) then centralized and anonymized. The following data were collected: age, gender, cardiovascular diseases (coronary artery diseases or chronic heart failure), hypertension, other comorbidities (e.g., diabetes mellitus, cancer, immune deficiency, cirrhosis, and chronic renal failure), clinical symptoms (abdominal pain, jaundice, diarrhea, and chills) at ICU admission. Laboratory examinations of blood cell components and other analyses were collected within 24 h during hospitalization.
Results: According to the bile culture results, 322 patients with acute cholangitis were divided into the following group: bacteria in bile—group I (212) and control (110) groups—group II.
Positive blood culture was frequently reported in patients with AC (n = 240/322). Bile culture was only performed in 145/322 and was positive in 75% of the cases (250). microbiological data are summarized in Table 1. in blood or bile culture, the most frequently identified bacteria were gram-negative bacilli (82%) and gram positive (17%). The most frequently identified bacteria were Escherichia coli (47%), Kl.pneumonia (11%), Enterococcus faecalis (7%), Enterobacter cloacae (6.5%) and Pseudomonas aerugenosa (4.5%). finally, an infection caused by Extended spectrum beta lactamase (ESBL)—producing bacteria was observed in 35 AC patients.
.

Table 1 Microbiological data in blood and bile culture

Germs	Blood	Bile
Positive culture	240 (75%)	145 (45%)
Total pathogens	318 (98%)	250 (78%)
Gram negative bacilli	264 (82%)	196 (61%)
Escherichia coli	152 (47%)	82 (25%)
Kl.pneumonia	35 (11%)	20 (6%)
Enterobacter cloacae	21 (6.5%)	16 (5%)
Kl. oxytoca	15 (4.5%)	8 (2.5%)
Ps.aeruginosa	15 (4.5%)	18 (5.6%)
ESBL	35 (11%)	30 (9.3%)
Gram positive bacilli	54 (17%)	54 (17%)
Enterococcus faecium	23 (7%)	25 (7.8%)
Streptococcus spp.	19 (6%)	6 (1.9%)
Enterococcus faecalis	16 (5%)	38 (12%)
Staphylococcus aureus	4 (1.3%)	6 (1.9%)
Other GP	13 (4%)	11 (3.5%)

Conclusions: The commonly isolated bacteria from bile samples in patients with acute cholangitis were *E. coli*, *Kl. pneumoniae*, and *E. faecalis*. Age, C-reactive protein, duration of antibiotic usage, alanine aminotransferase level were independent risk factors, and the predictive model could efficiently identify the patients with a high risk of bacteria in bile when invasive operations are conducted.

Introduction: Valproic acid (VPA) is highly binding to albumin, which is affecting both the free fraction and overall clearance of the drug in patients with hypoalbuminemia. There is a lack of data regarding patients with hypoalbuminemia receiving VPA. Thus, this study aims to evaluate the impact of adjusted VPA levels (aVPAc) in predicting effectiveness and potential adverse effects compared to total VPA levels (tVPA) in patients with hypoalbuminemia.
Methods: Retrospective cohort study among adult patients who were known to have seizures or epilepsy between January 1, 2016, and December 31, 2022. tVPA was compared with aVPAc based on albumin levels using receiver operating characteristics (ROC) curves and differences in the area under the curves (AUCs) by the DeLong method. Hepatotoxicity, hyperammonemia, hyponatremia, and thrombocytopenia were considered the safety endpoints, while effectiveness endpoints included predicting seizure occurrence, status epilepticus, and requiring additional antiepileptic medications during hospitalization.
Results: Out of 1622 screened patients, 71 with hypoalbuminemia received VPA therapy. The ROC analysis results revealed that an aVPAc threshold of 154.19 mg/dL demonstrated a higher sensitivity (86%) but lower specificity (47%) for predicting hepatotoxicity compared to a tVPA threshold of 67.53 mg/dL (sensitivity: 71%, specificity: 72%). While the ROC-AUC for aVPAc was 0.64 (95% CI 0.41–0.86), the difference in predictive ability between aVPAc and tVPA was not statistically significant ($p = 0.51$). Furthermore, five patients, representing 23%, developed significant hyperammonemia during their admission. An aVPAc threshold of 188.00 mg/dL exhibited superior sensitivity (100%) and lower specificity (82%) for predicting hyperammonemia compared to a tVPA threshold of 74.32 mg/dL (sensitivity: 40%, specificity: 88%). The ROC-AUC for aVPAc in predicting hyperammonemia was 0.95, suggesting a strong predictive ability.
Conclusions: Adjusted valproic acid concentrations (aVPAc) show increased sensitivity and specificity in predicting hepatotoxicity and hyperammonemia, highlighting their potential for improving safety monitoring in hypoalbuminemia patients. Future randomized control trials with larger sample sizes are required to confirm these findings.

Intensive Care Medicine Experimental 2025,* 13(1)*:001543

Introduction: Traumatic brain injury (TBI) is a common cause of mortality, morbidity and socio-economic losses in India. Patients with TBI generally present to the emergency department with altered sensorium. Various scores, scales, and tools have been devised for the assessment of patients with altered sensorium.
The Glasgow Coma Scale (GCS) was the first scale devised to assess altered sensorium in head injury patients. (1) GCS-Pupil (GCS-P) score is an extension of GCS and is calculated by subtracting the pupillary reactive score from the total GCS.(2) The Full Outline of Unresponsiveness (FOUR) Score was developed in 2005 as a proposed substitute for GCS. (3)Having various options for assessing patients with TBI poses a dilemma as to which score could be relied upon when different levels of professionals, such as doctors and nursing officers (NO), assess and diagnose the patients.
Objectives: The objective of this study is to assess the interobserver variability among junior resident (JR) doctors and NO during assessment of GCS, GCS-P, and FOUR score in TBI patients.
Methods: After approval from the Institutional Ethics Committee and CTRI registration, informed consent was obtained from the patient's next of kin. Patient's demographic data, diagnosis, vital signs, and blood sugar on admission were recorded. The assessment of GCS, GCS-P and FOUR score was performed within 6 h of admission by a JR and NO separately. GCS, FOUR score, and GCS-P were assessed after adequate resuscitation and after the effect of sedatives and/or neuromuscular blockers, if any, had worn off.
Results: We recruited 136 patients with TBI. The mean age of patients in this study was 40.04 ± 16.33 years. This study consisted of 79.4% males and 20.6% females. The mean pulse rate, mean systolic blood pressure and diastolic blood pressure were 89.50 ± 21.31 bpm, 129.57 ± 24.89 mmHg, and 80.24 ± 15.85 mmHg, respectively. The kappa value for the GCS best eye response, best verbal response and best motor response was 0.834, 0.881, and 0.823, respectively, indicating perfect agreement between raters. The GCS total score had a lower kappa value of 0.670, indicating substantial agreement. For the GCS-P left eye response, the kappa value was 0.908; for the right eye response, the kappa value was 0.812, showing good agreement. The GCS-P total score had a kappa value 0.718, indicating substantial agreement. The kappa value for the FOUR score eye response, motor response, brainstem reflexes, and respiration score was 0.865, 0.848, 0.724, and 0.821, respectively. The FOUR total score showed moderate agreement with a kappa value of 0.593.
Conclusions: GCS-P had the highest inter-observer agreement compared to total GCS and FOUR score. However, among the individual components, best verbal response had the highest inter-observer agreement for GCS score assessed by JR and NO. In contrast, eye response had the highest inter-observer agreement for the FOUR score.

Introduction: Despite the widespread incidence of multidrug-resistant organisms (MDROs) within burn centers, there is a lack of research investigating infection risks in critically ill burn patients. This study aimed to identify the risk factors associated with the acquisition of MDROs among critically ill burn patients admitted to the Burn Intensive Care Unit (BICU) and to determine the prevalence of MDROs in this population.
Methods: This was a multicenter observational case–control study that included adult patients (age ≥ 18) patients admitted to BICU between January 2015 and December 2022. Patients were excluded if the burn injury affected < 10% of body surface area (BSA), died within 24 h of ICU admission, unknown timing of burn injury, history of MDROs within 1 year prior to the admission, or antibiotics use within 3 months prior to the admission. We identified the risk factors and prevalence of MDROs, ICU length of stay (LOS), hospital LOS, 30-day mortality, and in-hospital mortality rates as the study outcomes. An exact matching approach with 1:1 ratio was used to match the groups based on age, gender, and admission year. Stepwise Forward selection logistic and linear regression tests were used as appropriate.
Results: A total of 173 patients were included, 84 patients in the case group (MDRO) were matched with 84 patients in the control group (non-MDRO). Patients who had MDR organisms has lower GCS baseline (unadjusted OR: 0.88, P = < 0.01), higher baseline SOFA score (unadjusted OR: 1.19, P = < 0.01), APACHE II score (Unadjusted OR: 1.11, P = < 0.01), invasive MV status at admission (unadjusted OR: 3.76; 95%, 1.96, 7.20 P = < 0.01), and higher affected total body surface area (TBSA) (unadjusted OR: 1.04, P = < 0.01) compared to the non-MDRO group. However, regression analysis showed that those with lower baseline GCS [(95%CI): 0.094 (0.828–0.987), P = 0.024], higher TBSA affected [(95% CI): 1.023 (1.002–1.045), P = 0.031], and UTIs [(95% CI): 7.198 (1.973–26.259) were significantly more prone to MDRO infections. The most common isolated pathogens in the MDRO group was *Acinetobacter Baumannii* (57%), while the most common infection was pneumonia (52.4%). The MDRO group had significantly longer MV duration and ICU LOS (median: 12 vs. 0 day, P = 0.0002) and (median: 28 vs. 17 days, P = 0.0002), respectively. There was no significant difference between the groups in other outcomes.
Conclusions: This study showed a significantly increased risk of infections with MDROs in burn patients who had larger TBSA burns, lower GCS, and higher SOFA and APACHE II scores. Future studies with larger sample size are needed to confirm our results.

Scoping review of AI-supported pain assessment and management in intensive care units

N. Unal[1]; B. TOSUN[2]
[1]Faculty of Nursing, Midwifery Department, Ankara University, Ankara, Turkey; [2]Faculty of Nursing, Hacettepe University, Ankara, Turkey
Correspondence: N. Unal
Intensive Care Medicine Experimental 2025,* 13(1)*:001546

Introduction: Pain assessment and management are among the most complex and vital responsibilities in intensive care units (ICUs), especially for patients with impaired consciousness or verbal limitations. Traditional pain assessment tools often fall short in such populations. With the rise of artificial intelligence (AI), particularly machine learning algorithms, innovative methods have emerged to enhance objectivity and consistency in pain evaluation.
Objectives: This scoping review aimed to evaluate pain assessment and management studies using AI in ICUs.
Methods: A comprehensive literature search was conducted in PubMed, Scopus, and ScienceDirect databases, targeting studies published between 2015 and 2025. The search strategy included keywords such as ("Artificial Intelligence" OR "Machine Learning") AND ("Pain" OR "Pain Management") AND ("Intensive Care Units" OR "unconscious patient"). Of the 225 publications identified, 15 studies met the inclusion criteria and were analyzed in detail. Duplicates were removed and eligibility was assessed through title/abstract screening followed by full-text review.
Results: AI systems in neonatal ICUs can detect pain by analyzing multimodal data such as facial expressions, body movements, crying sounds, and vital signs. Studies report high concordance between AI systems and expert evaluations. In adult ICU patients, communication barriers—due to language differences, cognitive impairments, psychiatric conditions, or tracheostomy—complicate self-reporting of pain. Thus, behavioral assessments based on facial expressions are the standard in non-verbal patients. However, medical equipment (e.g., oxygen masks and tubes), lighting, and camera angles hinder facial analysis. Deep sedation can mask pain behaviors, making behavioral scales less consistent. Deep learning-based systems attempt to classify pain severity by analyzing facial features, leveraging prior knowledge, extracting image patches, and generating synthetic expressions. Despite their accuracy, video privacy and data security concerns limit clinical use. Physiological markers such as vital signs, pupil diameter, and sweating have been explored but are insufficient on their own. Wearable devices with accelerometers show potential for continuous tracking of mobility, comfort, sedation, and sleep, offering a user-friendly and cost-effective solution compatible with ICU routines.
Conclusions: AI-assisted pain assessment applications in ICUs are on the rise, with significant advances in face recognition, vital sign-based prediction, and analgesic dosage recommendations. However, the integration of these systems into clinical decision-making processes is limited. Shortcomings in standard algorithms and ethical frameworks remain significant. In order for AI-based systems to be used in wider clinical practice, comprehensive, multicenter studies are needed to address factors such as privacy, user-friendly design, and algorithm transparency.

Prevention of in-hospital cardiac arrests: the role of early warning systems

MG. Kaya[1]; A. Conway Morris[1]; M. Trivedi[1]; R. Mahroof[1]
[1]Department of Intensive Care Medicine, Cambridge University Hospitals NHS Foundation Trust, Cambridge, United Kingdom
Correspondence: M.G. Kaya
Intensive Care Medicine Experimental 2025,* 13(1)*:001547

Introduction: In-hospital cardiac arrests (IHCAs) are major adverse events with an incidence of 0.92 per 1000 bed days [1]. There has been a downward trend in mortality rates over the years [2]. Early recognition of a deteriorating patient is a pivotal aspect of the afferent limb of rapid response team (RRT) initiation [3]. Physiological vital observations criteria-based scoring systems such as NEWS2 have been incorporated into UK hospitals for many years, including ours.
Objectives: The aim of this study was to identify whether IHCAs were preceded by clinical deterioration through analysis of patients' National Early Warning Score 2 (NEWS2) data 24 h prior to the CA, and whether an RRT review would have been indicated at the time.
Methods: Data were collected by retrospectively analysing electronic medical records (EMRs) of patients who had been admitted to a 32 bed UK University tertiary centre adult ICU following ROSC from an IHCA over a period of 2 years from January 2023. Data were collated onto an MS Excel spreadsheet and analyzed using SPSS.
Results: A total of 854,319 bed-days occurred during the time period examined (736,878 of which resulted from emergency admissions). A total of 194 inpatients had an IHCA in the selected time period, 0.23 arrests per 1000 bed-days. 18 (9.3%) patients gained ROSC and were transferred to ICU – who were analysed in this study. The median age was 71.5 (IQR 61.8–77.5). Median ICU LOS was 2 days (IQR 1–7). Average downtime was 18.6 $\pm$ 19.3 min. 14/18 patients (78%) had an initial non-shockable rhythm. Most common cause of CA was thrombosis and hypoxia, collectively comprising 33.3% of the cohort. Overall ICU mortality rate was 77.8%. Notes review showed that almost all of the IHCAs (94%) were sudden. They also had a preceding median NEWS score of 2 (IQR 1–3) 24 h prior to the CA and would not have triggered a RRT review. 7 out of 18 patients had RRT reviews—5 in person and 2 remotely prior to their CAs. Median NEWS score at time of RRT referral was 5 (IQR 4–6.5). This subgroup had an average respiratory rate of 23 $\pm$ 5 and average heart rate of 95 $\pm$ 2 bpm at time of review. 29% were on supplemental oxygen. Mortality rate for the RRT referred subgroup was higher (85.7%) compared to the non RRT subgroup (72.7%) indicating sicker patients were being identified appropriately; however, this was not statistically significant ($p = 0.485$).
Conclusions: For those gaining ROSC post IHCAs, a significant number of all IHCAs were sudden in nature and we see little improvements that can be made to NEWS2 or RRT system from an afferent limb perspective. Efforts should be focused on optimal post-ROSC care to improve patient outcomes. While the overall rate of cardiac arrest is low, further insight into preventability maybe gained by analyzing IHCA not gaining ROSC.

Risk factors for mortality in severe pneumocystis jirovecii pneumonia: retrospective insights from admissions to a tertiary intensive care unit over the last 15 years

RF. Gomes[1]; A. Dias[1]; M. Maneira Sousa[1]; R. João[1]
[1]Intensive Care Medicine Department and ECMO Referral Center, Hospital de Santa Maria (ULSSM), Lisboa, Portugal
Correspondence: R.F. Gomes
Intensive Care Medicine Experimental 2025,* 13(1)*:001548

Introduction: Pneumocystis jirovecii pneumonia (PJP) is a life-threatening opportunistic infection that affects immunocompromised individuals. It was the first described AIDS-defining disease. The increasing use of immunosuppressive drugs and new biotherapies for solid organ transplantation, immune-mediated inflammatory diseases and hematological malignancies has contributed to its rising incidence. As a result, PJP-related ICU admissions are increasing, mainly due to non-HIV cases.
Objectives: To assess clinical outcomes and identify factors associated with in-hospital mortality in PJP patients requiring ICU admission.
Methods: We conducted a retrospective cohort study including all patients diagnosed with PJP admitted to the polyvalent Intensive Care Unit of Santa Maria University Hospital (Lisbon, Portugal) between January 2010 and December 2024. Epidemiological, demographic, and clinical data were extracted from electronic medical records and inserted into an anonymized database. Statistical analysis was performed using GraphPad Prism 10.1.1, focusing on mortality associated factors.
Results: During the study period, 55 ICU patients were diagnosed with PJP, but 4 were excluded due to negative microbiologic tests available only after ICU discharge. Among the 51 included, the diagnosis was definitive in 43 (84.3%) and presumptive in 8 (15.7%), based on typical clinical and radiologic findings in immunocompromised patients when appropriate microbiologic tests could not be obtained.
Patients mean age was 56.1 years (SD 14.4), 68.6% were male, and median ICU stay was 10 days (IQR 5–16). Mean SAPS II and SOFA scores at admission were 50.5 (SD 18.8) and 8.0 (SD 4.1), respectively. Respiratory support included high-flow oxygen therapy ($n = 17$, 33.3%), non-invasive ventilation ($n = 20$, 39.2%), invasive mechanical ventilation ($n = 41$, 80.3%; median duration: 13 days), and VV-ECMO ($n = 7$, 13.7%; median ECMO run: 24 days). In-hospital mortality rate was 62.7%. However, it was lower in patients aged 30–45 years (33.3%).
PJP-related ICU admissions markedly increased over the study period, from 13 in the first 7 years to 35 in the last. This trend can be partially explained by a growing number of admissions of patients with a history of solid organ or stem cell transplantation (from 0 to 7 cases—0–20% of the total admissions).
Mortality was associated with the need for invasive mechanical ventilation ($p = 0.006$), neuromuscular blockade ($p = 0.004$), and prone positioning ($p = 0.007$); as well as bacterial co-infection ($p = 0.020$), shock ($p = 0.003$), septal thickening on chest CT scan ($p = 0.044$), and advanced radiologic stage according to Mu et al. classification ($p = 0.030$).
Conclusions: This study provides valuable insights into the evolving clinical profile of PJP patients requiring ICU admission and allows the identification of key clinical and radiologic factors associated with increased in-hospital mortality. It also adds important information for prognostication and tailoring of management strategies.

Intensive Care Medicine Experimental 2025,* 13(1)*:001549

Introduction: Critically ill patients often experience significant skeletal muscle wasting, which is associated with mortality. Patients with traumatic brain injury (TBI) are at increased risk due to neuroinflammation, immobility, and catabolic stress. Ultrasound can be used to assess muscle mass in the ICU, but data on *vastus intermedius* muscle loss in ICU patients are limited (1).
Objectives: To compare muscle mass loss between survivors and non-survivors with TBI during ICU stay, via ultrasound evaluation of the *vastus intermedius*.
Methods: This prospective cohort study included adult patients with moderate to severe TBI admitted to the ICU at San Juan del Río Hospital, Querétaro, Mexico, from January 2023 to February 2024. Ultrasound measurements of *vastus intermedius* were performed every 3 days from ICU admission to discharge. Muscle mass at admission, day 7, and discharge, along with muscle loss percentage at discharge, were compared between survivors and non-survivors using Student's *t* test. A Poisson regression model with robust standard errors was used to estimate the effect of muscle mass on mortality risk.
Results: We included 54 patients (median age: 47 years; 70.4% male). The median length of hospital stay was 12 days (IQR: 7–18). Eight patients (14.8%) died during ICU stay. Differences in *vastus intermedius* muscle thickness were observed between survivors and non-survivors at various timepoints during their ICU stay. At admission, survivors had a significantly greater muscle thickness (mean 0.75 cm, SE = 0.03) compared to non-survivors (0.55 cm, SE = 0.04; $p < 0.001$). This difference remained significant on day 7 (0.65 cm, SE = 0.0332 vs. 0.49 cm, SE = 0.0536; $p = 0.02$) and at discharge (0.67 cm, SE = 0.04 vs. 0.50 cm, SE = 0.06; $p = 0.02$). In contrast, the percentage of muscle loss at discharge did not differ significantly between groups: 6.64% (SE = 8.91) in survivors vs. 11.74% (SE = 10.73) in non-survivors ($p = 0.4738$). Lower muscle mass was associated with a higher risk of ICU mortality at different timepoints in regression models (Table 1). Specifically, greater *vastus intermedius* thickness at admission and on day 7 were significantly associated with reduced mortality risk. A similar trend was observed at discharge, although this did not reach statistical significance. Conversely, the percentage of muscle loss during ICU stay was not significantly associated with mortality.

Table 1 Mortality risk according to *vastus intermedius* muscle mass (cm) at different timepoints

Variable	B	RR	95%CI	*p* value
At admission	− 0.044	0.957	0.918–0.997	0.04
At day 7	− 0.080	0.923	0.855–0.997	0.04

Variable	B	RR	95%CI	*p* value
At discharge	− 0.048	0.953	0.904–1.004	0.07
Percentage of muscle mass loss	0.007	1.007	0.977–1.038	0.64

Conclusions: Lower *vastus intermedius* muscle thickness was significantly associated with ICU mortality in patients with TBI. Bedside ultrasound may serve as a valuable tool for early risk stratification and monitoring of muscle mass in this population.

Intensive Care Medicine Experimental 2025,* 13(1)*:001550

Introduction: Timely management of delirium has been shown to reduce duration of delirium and length of stay, with significant cost savings and better cognitive and functional outcomes. Management of delirium is multidisciplinary and focuses on early detection and managing underlying causes, e.g., sepsis, reviewing high risk medications, regular orientation and early rehabilitation. In our Surgical ICU, the prevalence of delirium was 26% of patients admitted in january 2024, but initiation of delirium care bundle remains at the discretion of the clinicians.
Objectives: We worked to improve timely delirium management in all appropriate patients in the surgical intensive care unit.
Methods: Following the principles of quality improvement from December 2024, our multidisciplinary team studied and analysed root causes that contributed to inadequate delirium management. Our team focussed on education interventions to the clinical staff, specifically nursing and medical team, and created CAM-ICU pocket cards to promote routine screening for delirium, as well as promoted a delirium care bundle to enable timely delirium specific interventions by our occupational therapists, to improve timely management of delirium in the patients admitted to our surgical intensive care unit.
Results: Auditing the electronic records, we saw a dramatic increase of CAM–ICU documentation by our nurses and implementation of the delirium specific care bundle that let to timely intervention by our occupational therapist for patients who screened positive for delirium. The timely delirium specific management was sustained above the our target 50% of cases in the next 3 months following the initiation of the interventions.
Conclusions: Simple interventions can lead to sustained improvements on timely delirium management of ICU patients.

Timely Delirium Management in our ICU after initiation of interventions.

Critical illness in obstetric patients: a 3-year retrospective analysis in a resource-limited mexican hospital

OR. Perez-Nieto[1]; AS. Henales-Ocampo[2]; E. Deloya[1]; RA. Reyes-Monge[3]; I. Rodríguez-Guevara[4]; JG. Henales-Almaraz[5]
[1]Intensive Care Unit, Hospital General San Juan del Río, San Juan del Río, Mexico; [2]Facultad de Medicina, Universidad Autónoma de Querétaro, Querétaro, Mexico; [3]Intensive Care Unit, Hospital General de Uriangato, Uriangato, Mexico; [4]Anesthesiology Department, Hospital General San Juan del Río, San Juan del Río, Mexico; [5]Obstetrics and Gynecology Department, Hospital General San Juan del Río, San Juan del Río, Mexico
Correspondence: O.R. Perez-Nieto
Intensive Care Medicine Experimental 2025,* 13(1)*:001551

Introduction: Pregnancy and the puerperium are well-established risk periods for increased morbidity and mortality in women of reproductive age. This vulnerability is primarily due to significant physiological and anatomical changes that complicate clinical management (1). A systematic review reported ICU admission rates of up to 16% among obstetric patients in resource-limited settings, with a median of 2.7 admissions per 1000 deliveries—substantially higher than in high-income countries (2). In Mexico, the estimated maternal mortality ratio is 16.5 per 100,000 live births, with the highest burden observed in women aged 30–34, according to the 2024 Epidemiological Surveillance Report (3). This study aimed to assess diagnostic patterns among critically ill obstetric patients in a low-resource Mexican hospital over a 3-year period.
Objectives: To describe diagnostic trends and clinical characteristics of critically ill obstetric patients admitted to a resource-limited hospital from 2022 to 2024, with the goal of identifying the most frequent

causes of critical illness and guiding improvements in early detection and management.

Methods: We performed a retrospective chart review of all obstetric patients admitted to the intensive care area of a second-level hospital in Mexico between January 1, 2022, and December 31, 2024. Demographic and clinical data, including age and primary diagnosis, were extracted from medical records.

Results: Severe preeclampsia was the most common diagnosis, peaking in 2023 with 25 cases before declining to 11 in 2024. Obstetric haemorrhage showed a bimodal pattern, with 8 cases in both 2022 and 2024, and an increase to 15 in 2023. Ruptured ectopic pregnancies remained infrequent throughout the study period. Notably, two rare but clinically significant cases were recorded under the "other" category in 2023: one diabetic ketoacidosis and one prolonged septic shock. The latter resulted in the only maternal death during the study period, occurring within 2 h of hospital admission, emphasising the consequences of delayed referral and advanced disease at presentation (Fig. 1).

Conclusions: This review underscores that severe preeclampsia and obstetric haemorrhage are the leading causes of critical illness in obstetric patients within low-resource settings. While most cases were managed successfully, the single maternal death highlights the urgent need for timely diagnosis, efficient referral systems, and robust clinical protocols to improve outcomes in this vulnerable population.

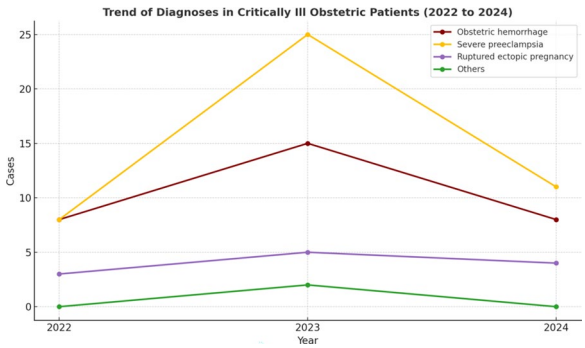

Figure 1 Trends in diagnoses among critically ill obstetric patients (2022–2024)

Chronic critical illness in the ICU: definitional perspectives from a prospective study

MA. Şahin[1]; EK. Kaya[2]; M. Yildirim[2]; A. Topeli[2]; B. Halacli[2]
[1]Department of Internal Medicine, Hacettepe University Faculty of Medicine, Ankara, Turkey; [2]Department of Internal Medicine, Division of Intensive Care Medicine, Hacettepe University Faculty of Medicine, Ankara, Turkey

Intensive Care Medicine Experimental 2025,* 13(1)*:001554

Introduction: Although advances in intensive care have enabled more patients to survive from acute critical illness, this has also led to the emergence of a large and increasing population of patients who remain dependent on mechanical ventilation (MV) and other intensive care therapies for prolonged periods. These patients experience chronic conditions requiring multi-organ support (1). This condition is referred to as chronic critical illness (CCI) and has become a significant burden on healthcare systems (2). However, a universally accepted definition of CCI is lacking in the medical literature.

Objectives: This study aimed to compare the prevalence and characteristics of four commonly used CCI definitions in the literature by evaluating patients admitted to the our Medical Intensive Care Unit. In addition, as a subgroup of CCI, the characteristics of patients with PIICS (Persistent Inflammation, Immunosuppression and Catabolism Syndrome), was studied.

Methods: A total of 1074 patients admitted to Medical Intensive Care Unit between 01/10/2023 and 31/03/2025. Among them, 22 patients transferred from other centers and 229 with repeated admissions during the study period were excluded. The remaining 823 patients were assessed according to four previously described CCI definitions, and CCI prevalence rates were determined.

The four CCI definitions were as follows: CCI 1: Prolonged need for MV (at least 6 h per day, MV duration $\geq$ 21 days) (3); CCI 2: MV or tracheostomy required for 14–21 days or longer (4); CCI 3: ICU stay of 8 days or more with at least one of the following: MV (at least 96 h in a single period), tracheostomy, stroke, head trauma, sepsis, or major trauma (5); CCI 4: Prolonged ICU stay ($\geq$ 14 days) with a cardiovascular SOFA score $\geq$ 1 or other parameter scores $\geq$ 2 on day 14 of the ICU stay (6). The PIICS diagnostic criteria were as follows: ICU stay of 14 days or longer; CRP > 50 µg/dL; total lymphocyte count < 0.80×10^9/L; albumin < 3.0 g/dL; pre-albumin < 10 mg/dL; creatinine elevation index < 80% (7).

Results: Of the 823 patients included in the study, 460 (55.89%) were male. The median age of the patients was 67 years (IQR: 54–77). The prevalence of CCI was found to be as follows: CCI 1: 5.22% (n = 43); CCI 2: 8.99% (n = 74); CCI 3: 23.94% (n = 197); CCI 4: 19.90% (n = 163). The prevalence of PIICS was 8.02% (n = 66) (Table 1). Among patients meeting the CCI 4 criteria, the prevalence of PIICS was 40.49%.

Table 1 Prevalence of chronic critical illness (CCI) and PIICS

Conditions	*n*	Prevalence (%)
CCI 1	43	5.22
CCI 2	74	8.99
CCI 3	197	23.94
CCI 4	163	19.90
PIICS	66	8.02

Conclusions: This is the first study in the literature to prospectively compare different definitions of "Chronic Critical Illness" and to evaluate the prevalence of PIICS. The findings that different definitions yield different prevalence rates demonstrates the need for an ideal and easily applicable definition for CCI and further researches focusing on PIICS.

Role of ICIS score in sepsis prediction and its association with disease severity in intensive care patients

VB. Cuong[1]; D. Son[2]; VN. Trong[1]; MH. Hoan[1]; QB. Han[1]; MV. Tam[3]; K. Nguyen[4]; HB. Giang[1]; CN. Tan[1]; TN. Tung[3]; D. Tuan[5]

Correspondence: K. Nguyen
Intensive Care Medicine Experimental 2025,* 13(1)*:001558

Introduction: Sepsis, a life-threatening condition, has a high mortality rate in ICUs, necessitating early detection, severity assessment, and mortality prediction. The Intensive Care Infection Score (ICIS) uses five hematological parameters to gauge the body's immune response to infection.
Objectives: The aim of this study is to assess the ICIS score's effectiveness in predicting sepsis development, disease progression, and mortality in ICU patients with Systemic Inflammatory Response Syndrome (SIRS).
Methods: An observational cohort study was conducted on 357 patients with SIRS scoring ≥ 2 within 48 h of ICU admission at Bach Mai Hospital from February 2023 to March 2024. Sepsis was diagnosed at baseline (D0) using Sepsis-3 criteria, confirmed by two doctors. Patients were monitored over 28 days at multiple timepoints, with blood samples taken to measure ICIS and other routine parameters.
Results: The patient cohort predominantly consisted of middle-aged males, accounting for 68% of participants (mean age: 60 ± 15.1). A significant difference in ICIS was observed at D0, with median scores of 6 for the sepsis group and 4 for the non-sepsis group. The area under the curve (AUC) for ICIS in predicting sepsis was comparable to that of C-reactive protein and interleukin-6 (0.71, 0.70, 0.72, respectively). At a cutoff value of 5, ICIS demonstrated a predictive capability for sepsis with a specificity of 76.22% and negative predictive value (NPV) of 80.3%. Over 28 days, mortality was 2.3 times higher for patients with ICIS ≥ 4 vs. ICIS < 4 (30.7% vs. 13.33%, $P < 0.05$).
Conclusions: The ICIS is a practical, cost-effective tool easily integrated into routine blood cell analysis, providing rapid results for timely treatment decisions. Its high NPV is crucial for assessing antimicrobial resistance, and it effectively predicts mortality in critically ill ICU patients, underscoring its importance in intensive care management.

Sepsis diagnostic performance of ICIS and other markers at baseline.

ICIS score in association with 28-day mortality.

Antibacterial activity of serum in vitro is mediated via immunoglobulins and the soluble membrane attack complex

G. Tettamanti[1]; S. Zhang[2]; N. Lodh[3]; D. Brealey[4]; M. Singer[5]; N. Arulkumaran[3]
[1]Anestesia e Rianimazione, Università degli Studi di Milano Bicocca, Milano, Italy; [2]Medicine, The First Affiliated Hospital of Zhengzou University, Zhengzhou, China; [3]Bloomsbury Institute of Intensive Care Medicine, University College London, London, United Kingdom; [4]Bloomsbury Institute for Intensive Care Medicine, University College London, London, United Kingdom; [5]Bloomsbury Institute for Intensive Care Medicine, UCL, London, United Kingdom
Correspondence: G. Tettamanti
***Intensive Care Medicine Experimental 2025,* 13(1)**:001559

Introduction: Healthy human serum has inherent antimicrobial and immunomodulatory properties conferred by various circulating mediators, including immunoglobulins (Igs) and complement proteins. Igs and complement proteins work in combination to exert potent direct antimicrobial effects via formation of the membrane attack complex (MAC) (1). The MAC is a complex of complement proteins C5b-C9 which forms a pore on bacterial membranes. Spontaneous MAC formation is

inhibited by endogenously formed CD59. Low levels of complement proteins are associated with increased mortality risk in sepsis (2), while immunoglobulin replacement may improve outcomes (3).
Objectives: To investigate the relative effects of IgG, IgM, and soluble CD59 on bacterial growth in serum in vitro.
Methods: *Escherichia coli* (strain K12) (106 cells/mL-1) was added to healthy volunteer serum ($n = 7$) ± soluble CD59 (10 mcg/mL) (Biotechne) or antibodies against the Fc portion of IgG or IgM (100 mcg/mL) (ThermoFisher). Samples were incubated overnight at 37o C and colony forming units (CFUs) counted on nutrient Agar plates. Control samples included bacteria in broth alone.
Results: Following overnight incubation, 5 × 108/mL CFU were identified in broth alone. Serum significantly suppressed bacterial growth, with no growth seen in 4 of 7 serum samples. Inhibition of the Fc portion of IgG, or IgM partially reversed the antibacterial effect of serum; albeit not statistically significant. Addition of soluble CD59 partially reversed the antibacterial effect of serum ($p = 0.023$) (Fig. 1).
Conclusions: Healthy volunteer serum has inherent antimicrobial activity against E coli; this effect seems to be mediated by IgG, IgM and the MAC. The potential benefits of immunoglobulin or complement protein supplementation in sepsis warrant investigation.

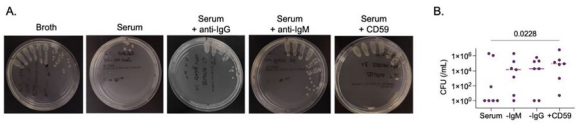

Figure 1 **A** Agar plates demonstrating CFU of E coli following incubation in broth or serum, with/without soluble CD59 or antibodies against the Fc portion of IgG or IgM. **B** Inhibition of IgG or IgM Fc portions, or soluble CD59 partially reversed antibacterial effects of serum.

Economic burden of inappropriate intensive care unit utilization: a narrative review
M. Akatsuka[1]; Y. Nakamura[2]
[1]Department of Intensive Care Medicine, Sapporo Medical University School of Medicine, Sapporo, Japan; [2]Division of Clinical Engineering, Sapporo Medical University Hospital, Sapporo, Japan

Intensive Care Medicine Experimental 2025,* 13(1)*:001560

Introduction: The escalating costs of ICU care necessitate a thorough examination of utilization practices. Alarmingly, there are increasing concerns that financial incentives may drive the inappropriate prolongation of ICU stays, raising ethical questions regarding patient welfare and resource allocation. This review analyzes the existing literature on the economic implications of inappropriate ICU utilization, with a critical perspective on the definitions, impacts, and proposed strategies.
Objectives: This study aims to identify the various definitions and criteria used to determine inappropriate ICU utilization, to evaluate its economic impact (including costs and resource allocation), and to explore proposed strategies for cost reduction and the optimization of ICU resource allocation from an economic perspective.
Methods: A comprehensive literature review was conducted using PubMed. The search strategy included terms related to ICU utilization, economics, and ethics. The identified articles (including the initial set of 31 relevant publications) will be analyzed to extract data on: (1) specific numerical data related to ICU costs and length of stay, (2) factors associated with prolonged or potentially unnecessary ICU admissions, (3) ethical arguments regarding resource allocation in the ICU, and (4) concrete proposals for improving the economic efficiency of ICU utilization. The extracted information will be compared and categorized based on these themes to provide a synthesized overview of the current knowledge.
Results: The reviewed literature highlights several key contexts associated with potentially inappropriate ICU utilization, including prolonged lengths of stay, particularly in patients with limited potential for further clinical improvement; admissions for conditions manageable in lower-acuity settings based on retrospective analyses; and significant variability in discharge practices across different institutions and patient populations. Economic factors identified as contributing to this issue include fee-for-service reimbursement models that may incentivize prolonged stays, a lack of alignment between physician incentives and resource stewardship, and the absence of universally accepted, evidence-based guidelines for ICU admission and discharge. Proposed strategies to mitigate inappropriate utilization and reduce costs frequently involve the implementation of standardized admission and discharge criteria, the application of risk stratification tools to guide admission decisions, and the development of step-down units or intermediate care pathways. Ethical considerations regarding these strategies, such as the potential for restricted access to necessary care and the impact on patient autonomy, are also prominent in the literature.
Conclusions: The findings of this critical review underscore the urgent need for stricter oversight and ethical guidelines to prevent the inappropriate prolongation of ICU stays driven by financial incentives. Failure to address this issue risks compromising patient well-being, distorting resource allocation, and eroding public trust in the healthcare system. Future research should focus on developing robust mechanisms to detect and deter such practices, ensuring that ICU utilization decisions are based solely on patient needs and evidence-based medicine, rather than financial gain.

Bacterial opsonisation by complement C3b in vitro is impaired in patients with sepsis compared to healthy volunteers
G. Tettamanti[1]; N. Lodh[2]; D. Brealey[2]; S. Rofael[3]; T. Mchugh[3]; M. Singer[4]; N. Arulkumaran[5]

Intensive Care Medicine Experimental 2025,* 13(1)*:001561

Introduction: Healthy human serum has inherent antimicrobial and immunomodulatory properties conferred by various circulating mediators, primarily antimicrobial peptides, complement proteins, and immunoglobulins. Patients who die from sepsis have lower levels of complement C3 compared to survivors, suggestive of depletion (1). C3b, derived from C3, is an opsonin which promotes bacterial phagocytosis (2).
Objectives: To investigate differences in serum from healthy volunteers (HV) compared to patients with sepsis (and age-matched preoperative patients) on C3b deposition on bacteria in vitro.
Methods: Serum was collected from seven septic ICU patients, three patients undergoing major elective surgery, and three healthy volunteers. 50µL of bacterial suspension (1 × 1010 colony forming units of E coli bacteria (strain K12)/ml in phosphate-buffered saline (PBS)) was added to an equal volume of serum, or PBS alone, and incubated for 30 min at 37 °C. Samples were then incubated with PE-labelled anti-C3b antibodies (Biolegend) for 20 min at a 1:250 dilution, washed, and resuspended in PBS. Co-localization of C3b on bacteria (and absence with PBS alone) was first confirmed by confocal laser microscopy. Flow

cytometry (Fortessa X20 flow cytometer running BD FACSDiva v9) was then performed to ascertain C3b deposition on bacteria. Data were analyzed using FlowJo (version 10.7.1, BD) and presented as median fluorescence intensity (MFI) (Arbitrary Units). Data were compared using Kruskal–Wallis test (GraphPad Prism v10).

Results: Confocal microscopy confirmed C3b deposition (red) on bacteria (blue) in healthy volunteer serum, but not in PBS alone (Fig. 1A). Flow cytometry analysis demonstrated that levels of C3b deposited on bacteria was significantly lower in ICU patients compared to healthy volunteers (Fig. 1B, C). Levels of C3b deposition in elective surgical patients were lower than HV, albeit not statistically significant (N.B. more patients are being enrolled).

Conclusions: The functional consequences of decreased C3 in patients with sepsis has not previously been explored. We demonstrate that compared to HV, patients with sepsis have lower C3b deposition on bacteria. This may contribute to impaired bacterial clearance or recurrent infections in sepsis.

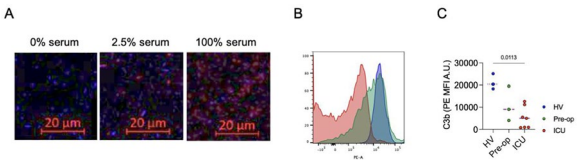

Figure 1 **A** Confocal microscopy demonstrating C3b (red) deposition on bacteria (blue) in serum but not PBS. (**B**) Flow cytometry histograms demonstrating PE-labelled C3b deposition on bacteria in serum; (**C**) with differences between volunteers and ICU patients

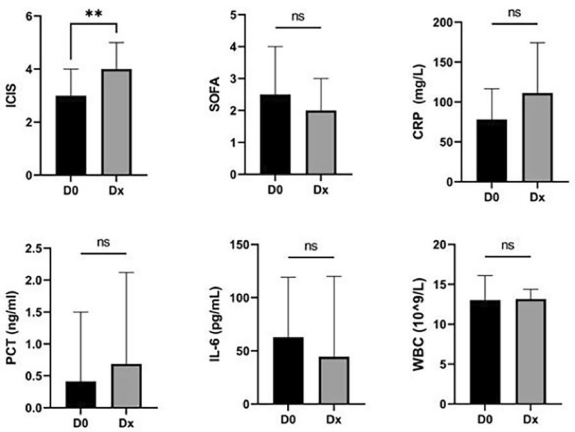
Introduction: Infection, caused by pathogenic microorganisms, can lead to severe outcomes like septic shock and death. While various biomarkers are used for diagnosis, the Intensive Care Infection Score (ICIS) reflects the immune response to infection but lacks research in Vietnam.

Objectives: This study aims to evaluate the cutoff point of the ICIS score in diagnosing infections in patients with systemic inflammatory response syndrome (SIRS) admitted to the Intensive Care Unit, and compare its diagnostic performance with that of other well-established biomarkers.

Methods: A cohort observational study was conducted on 357 critically ill patients admitted to the Intensive Care Unit (ICU) at Bach Mai Hospital from February 2023 to March 2024. Patients were assessed for infection on the first day at ICU (D0), and those without infection were monitored to detect ICU-acquired infections (Dx) during their stays. The diagnosis of infection was confirmed using microbiological tests and imaging diagnostics. Measurements of ICIS, procalcitonin (PCT), C-reactive protein (CRP), and interleukin-6 (IL-6) were taken at D0 and Dx, along with clinical changes indicative of infection.

Results: Middle-aged men (mean age: 60 ± 15.03) represented 73.2% of the study population, with infections primarily affecting the respiratory, digestive, and urinary systems. A significant difference in ICIS scores on day D0 was observed between infected and non-infected patients. The area under the receiver operating characteristic curve (AUC) for ICIS in predicting infection was 0.76, higher than CRP's 0.70 At a cutoff score of 4, ICIS demonstrated a sensitivity of 60.43% and a specificity of 81.82% for detecting infections, with a superior positive predictive value (PPV) compared to PCT (88.6% vs. 82.4%). Over a 28-day longitudinal observation period, the ICIS score was the only biomarker that significantly distinguished between the groups with and without acquired infections, surpassing PCT, CRP, and IL-6 (*P* value: 0.005, 0.44, 0.32, and 0.45, respectively.



Conclusions: The ICIS proves to be a significant hematological tool for the diagnosis and management of infections in critically ill patients. It offers enhanced capabilities in identifying infections associated with Systemic Inflammatory Response Syndrome (SIRS) and supports the prompt initiation of antibiotic treatment in the ICU environment.

Infection diagnostic performance in patients with SIRS of ICIS and other markers at ICU.

Variable	Cut-off	AUC	Sensitivity (%)	Specificity (%)	PPV	NPV
APACHE	≥8	0.803	82.70	70.34	86.67	63.54
SOFA	≥3	0.813	73.64	73.73	86.74	54.52
CRP (mg/L)	≥32.4	0.743	86.61	55.93	82.10	64.16
ICIS	**≥4**	**0.763**	**60.43**	**81.82**	**88.58**	**46.98**
IL_6 (pg/mL)	≥84.93	0.703	56.07	76.27	84.65	42.66
PCT (ng/mL)	≥0.161	0.795	92.05	54.24	82.44	74.52
WBC (g/L)	≥19.14	0.547	24.27	88.98	83.71	33.49

Comparison of various markers in infection diagnostic.

Changes in the values of ICIS (A), SOFA (B), CRP (C), PCT (D), IL-6 (E), WBC (F) between the day without infection (D0) and the day of infection progression (Dx). Only the ICIS value showed a statistically significant difference (according to the Mann–Whitney test).

***Intensive Care Medicine Experimental 2025,* 13(1)**:001563

Introduction: This study explored the feasibility of "Connect My Care," a web-based mobile phone application (an m-health tool), as a family communication adjunct in critical care. It is known that families act as support lynchpins for patients but struggle with receiving communication in critical care (O'Gara et al. 2022). Central to family-centred care is information sharing. Developing family-centred interventions is crucial for improving care satisfaction, clinical outcomes and mental wellbeing (Duong et al., 2022).
Objectives: To explore family members' and nurses' perceptions of the feasibility, acceptability, and usability and experiences of a m-health tool (App).
Methods: We conducted a feasibility study in a single centre (District General Hospital ICU in the UK). We recruited family members of patients with an anticipated length of stay > 48 h. Ethical approval was obtained via the Health Research Authority (Ref: 271,378) and informed consent was provided. We gathered quantitative data from participants who tested the App using the Acceptability of Intervention Measure (AIM), Intervention Appropriateness Measure (IAM), and Feasibility of Intervention Measure (FIM) alongside analysis on App content and in-depth qualitative interviews with families/professionals.
Quantitative data were analyzed and reported using descriptive statistics. Qualitative data were audio-recorded, transcribed, and analysed using Thematic Analysis.
Results: 16 family members and 1 nurse were recruited. Analysis of communication content showed a focus on patient condition and general enquiries. Family questions to staff centred on treatment (including medication), and planned treatment schedules. 100% of those completing questionnaires reported liking Connect my Care; 88% found it fitting/appealing (AIM); 75% reported that CMC is implementable, doable and easy to use; 100% found the intervention appropriate (IAM).
Interview themes were analyzed and four key themes identifed: *communication facilitation; response characteristics; technical issues;* and *value of content*. Participants suggested more instantaneous responses from bedside staff would make it more proactive and maximise family benefits.
Conclusions: Families found the CMC app to be acceptable, appropriate, and feasible; however, staff engagement was identified as problematic. Future challenges centre on creating more appealing, interactive content, maximising staff engagement the Connect My Care m-health App, and incorporating it into routine care.

Introduction: Excessive inspiratory efforts complicate the transition to assisted mechanical ventilation and can result in lung injury. Monitoring lung mechanics and patient effort in spontaneously breathing patients is particularly difficult. We evaluated a novel method based on the estimation of patient's effort contribution during a low inspiratory assist maneuver (LAM) to monitor transpulmonary pressure (PL), lung compliance and patient effort without the need of esophageal pressure (Pes) measurement during assisted mechanical ventilation.
Methods: In ICU patients on assisted ventilation, Pes and the electrical activity of the diaphragm (EAdi) were simultaneously recorded. All were ventilated with neural-pressure support (*n*-PSV), a modified PSV mode in which the pneumatic signal is replaced by the EAdi signal for breath triggering and cycling-off. A LAM (2 cmH2O-assisted cycle) was programmed every 3 min. LAM-derived PL (PLLAM) was estimated by

comparing assisted and LAM breaths with similar respiratory output confirmed by EAdi matching.
PLLAM was obtained by dividing ventilator pressure (PVENT), i.e., the difference between the assisted-breath (Passist) and unassisted breath (PLAM) pressure divided by 1 minus the squared patient-ventilator breath contribution (tidal volume ratio between the LAM and the assisted breath) [1]. By knowing PLLAM, lung compliance (CL) and patient-generated pressure (PPAT) are obtained using the following formulas: CL = VT/PLLAM and PPAT = (PASSIST – PLAM) – PLLAM.
PLLAM, CL and PPAT were compared with the reference Pes derived values (PLPes, CLPes and Pes). Patients were submitted to three sequential 30min n-PSV ventilation periods at different levels of assist: clinically adjusted, over-assistance (50% increase) and under-assistance (50% decrease).
Results: We included 25 patients in which a total of 867 LAM breaths were compared to 18,395 assisted breaths. PLLAM, CL and PPAT were in good agreement and correlated well with the respective reference methods: PLPes Bias 0.1 cmH2O (LoA ± 3.7 cmH2O, R2 0.74), CLPes Bias 0 ml/cmH2O, (LoA ± 17 ml/cmH2O, R2 0.72) and Pes Bias 0.1 cmH2O (LoA ± 3.7 cmH2O, R2 0.65). The continuous monitoring allowed to detect patient trajectories during n-PSV, informing about patient contribution to assisted breathing and helping to identify unfavorable conditions of high PLLAM and PPAT (increased lung stress risk) or low PLLAM and PPAT (risk of diaphragmatic deconditioning).
Conclusions: The LAM-EAdi-based method provides good estimates of transpulmonary pressure, lung compliance and patient generated pressure measured in a continuous way without the need of esophageal pressure measurements. This opens possibilities to monitor patients during assisted ventilation, facilitating real time recognition of unsafe lung and diaphragmatic ventilation and helping to improve ventilator setting adjustments.

***Intensive Care Medicine Experimental 2025,* 13(1)**:001565

Introduction: Right ventricular (RV) dysfunction affects outcome in ARDS. Ventilatory settings can modify the characteristics of the pulmonary vascular system, affecting right ventricle afterload. The RV diastolic pressure gradient (RVDPG) has been described as an early marker of right ventricular dysfunction.
Objectives: To evaluate how RVDPG is affected by different lung conditions and PEEP settings in a porcine model of ARDS.
Methods: A model of ARDS in 5 pigs was established combining lung saline lavage and injurious mechanical ventilation for 2 h. Following a lung recruitment maneuver, the PEEP level associated with the highest dynamic compliance during a decremental PEEP trial was determined. Subsequently, three PEEP levels were randomly applied: overdistention (OD), 6 cmH2O above, optimal (OPT) 2 cmH2O above and collapse (COL), with 6 cmH2O below the highest dynamic compliance PEEP level, respectively. Respiratory mechanics, gas exchange, pulmonary vascular mechanics and RV pressure were measured at baseline (BL), after ARDS induction (VILI), and following each PEEP level application. Effective arterial elastance (EAeff), calculated as the difference between mean pulmonary artery (PA) and wedge pressures divided by stroke volume, was used as a global index of RV arterial load. The RVDPG was calculated as the difference between the RV end-diastolic and early diastolic pressures (Fig. 1). Comparisons across different PEEP levels were performed using repeated measures ANOVA with Bonferroni correction for post-hoc analysis.
Results: Compared to BL, VILI worsened Pa/FiO2 (524 ± 41 vs. 153 ± 113 mmHg, $p = 0.003$), PaCO2 (45 ± 7 vs. 60 ± 6 mmHg, $p < 0.001$), dynamic pulmonary compliance (27 ± 6 vs. 13 ± 4 ml/mmHg, $p < 0.001$) and pulmonary vascular resistance (279 ± 80 vs. 511 ± 56dyn/s/cm5, $p = 0.002$), EAeff (0.34 ± 0.15 vs. 0.66 ± 0.23 mmHg/ml, $p = 0.007$) and increased the RVDGP (3.5 ± 1.0 vs. 5.9 ± 2.3 mmHg, $p = 0.038$).
Among the three PEEP level strategies, OPT showed the best dynamic compliance (29 ± 5ml/mmHg) compared to OD (20 ± 3ml/mmHg, $p = 0.004$) and COL (15 ± 4ml/mmHg, $p < 0.001$). COL showed the lowest PaO2/FiO2 (161 ± 50mmHg) compared to OD (543 ± 66mmHg, $p < 0.001$) and OPT (548 ± 57mmHg, $p < 0.001$) and the highest PaCO2 (67 ± 8mmHg) compared to OD (59 ± 5mmHg, $p = 0.032$) and OPT (53 ± 4, $p = 0.001$).
RVDGP was lower in OPT (3.9 ± 0.9mmHg) than in COL (7.5 ± 2.8mmHg), $p = 0.023$ and no differences were found between OPT and OD (4.5 ± 1.3mmHg), $p = 1$ nor between OD and COL, $p = 0.05$. Similar behavior was found in both EAeff and pulmonary vascular resistance.
Conclusions: The application of optimal PEEP improved pulmonary mechanics and gas exchange, which translated into favorable pulmonary hemodynamics. These improvements were associated with a reduction in the RVDPG, suggesting a better condition for RV performance. Furthermore, RVDPG may serve as a feasible bedside parameter to monitor the hemodynamic effects on RV of lung conditions and ventilatory settings in ARDS.

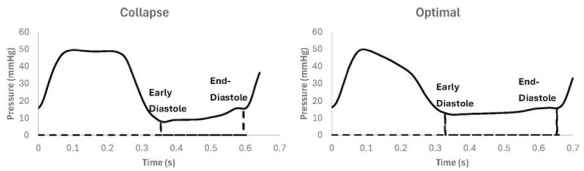

Figure 1 Representative example of the right ventricle diastolic pressure gradient in the same animal under collapse (COL, left) and optimal PEEP level (OPT, right) conditions. Note the steeper increase of the diastolic pressure during COL, resulting in an increased right ventricle diastolic pressure gradient compared to OPT

Effects of intraoperative and early postoperative bicarbonated vs. acetated Ringer's solutions on acid–base status and kidney injury following orthotopic liver transplantation: a randomized clinical trial

L. Ke[1]; C. Lv[1]; B. Zhou[2]; B. Li[1]; W. Li[3]

***Intensive Care Medicine Experimental 2025,* 13(1)**:001566

Introduction: Intraoperative and postoperative intravenous fluid is necessary for patients undergoing liver transplantation (LT) because of blood loss and major surgical intervention. However, chloride-liberal fluids like normal saline in LT recipients were associated with an increased risk of metabolic acidosis and postoperative acute kidney injury (AKI), which is a common complication post-LT (1). Therefore, balanced solutions with more physiological chloride concentration are preferred in this population. Currently, most commercially available balanced solutions are buffered with organic anions (acetate, lactate, or malate), which rely on liver metabolism to maintain acid–base balance (2). Alternatively, bicarbonated Ringer's solution (BRS) contains no organic anions and can function independently of liver metabolism. In patients undergoing LT, when liver function was severely compromised, the use of BRS, compared with balanced solutions with organic anions, may confer clinical benefits.
Objectives: The aim of the present trial is to compare the use of BRS with acetated balanced solution (ARS) on acid–base status and kidney injury in patients undergoing orthopedic LT.
Methods: This is a single-center, investigator-initiated, single-blind, randomized, parallel-group trial. Patients aged 18 years or older who were recipients undergoing LT surgery at the study site were eligible for inclusion. Patients who underwent combined transplantation, or received renal replacement therapy (RRT) or had increased serum creatinine levels within 1 week before the operation were then excluded. Patients assigned to the BRS group received BRS whenever isotonic intravenous crystalloid is ordered during the orthotopic LT operation and the following 48 h after the operation, whereas patients in the ARS group received ARS during the same period. The primary outcome is the change of standard base excess (SBE) during the operation, calculated by the difference of SBE measured before and after the operation (ΔSBE = SBEpost—SBEpre). Secondary outcomes include ΔSBE at multiple timepoints and renal function related measures.
Results: During the study period, 86 patients undergoing LT were assessed for eligibility, and 72 were randomized (35 in the BRS group and 37 in the ARS group). The LT operation was aborted in six patients (2 in the BRS group, and 4 in the ARS group). Eventually, 33 patients in the BRS group and 37 in the ARS group completed the LT operation and received the allocated intervention. At 0 h post the LT operation, the ΔSBE in the BRS group was 2.2 ± 4.2 mmol/L compared with 1.7 ± 4.1 mmol/L in the ARS group (mean difference 0.4 mmol/L [95%CI − 1.6–2.5 mmol/L], $p = 0.69$). For other timepoints, SBE was significantly less affected in the BRS group at inferior vena cava (IVC) block (ΔSBE − 1.4 ± 1.7 mmol/L vs. − 3.8 ± 1.7 mmol/L, mean difference 2.4 mmol/L [95%CI 1.6–3.2 mmol/L], $p < 0.001$) and shortly after IVC reperfusion (ΔSBE − 4.3 ± 2.9 mmol/L vs. − 6.1 ± 2.8 mmol/L, mean difference 1.8 mmol/L [95%CI 0.5–3.2 mmol/L], $p < 0.01$). Changes in serum acetate concentration, arterial standard base excess, and estimated glomerular filtration rate are shown in Fig. 1. For renal function-related measures, there was a numerous reduction of AKI incidence in the BRS group during the first 48 h post operation (13/33 (39.4%) vs. 20/34 (58.8%), $p = 0.11$).
Conclusions: This randomized controlled trial showed that compared with ARS, the use of BRS in patients undergoing LT operation resulted in less affected acid–base status during the LT operation. Moreover, a numerous reduction in AKI incidence was observed during the first 48 h postoperation, suggesting that the physiological superiority may be translated into clinical benefits.

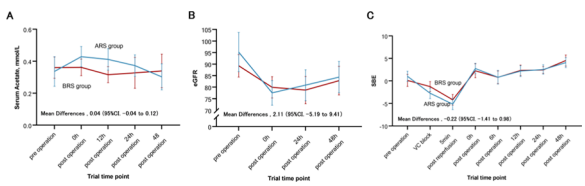

Figure 1 Changes in serum acetate concentration, arterial standard base excess (SBE), and estimated glomerular filtration rate (eGFR). Generalized estimating equations (GEE) model was used to estimate the effect of bicarbonated Ringer's solution (BRS) vs. acetated balanced solution (ARS) on serum acetate, SBE and eGFR with adding interaction term of treatment and timepoint.

Introduction: Hemodynamic instability in the early postoperative period remains one of the major challenges in pediatric cardiac surgery. Infusion therapy, as a key method for correcting volume status in children after heart surgery, significantly affects central hemodynamic parameters. However, there is still no consensus on the most effective strategies for fluid management and their impact on echocardiographic parameters over time. Given the high sensitivity of the pediatric population to fluctuations in circulating blood volume and cardiac function, studying the changes in hemodynamic parameters during infusion therapy is of particular clinical importance. The results of such studies may help optimize infusion strategies, reduce complication rates, and improve outcomes in this patient group.
Objectives: To improve the approach to intensive care in the early postoperative period after cardiac surgery in children by evaluating central and peripheral hemodynamic parameters. For this purpose, we analyzed hemodynamic parameters during infusion therapy in 120 children (aged 1 month to 5 years) after radical correction of conditions such as TGA, TAPVR (groups 1 and 2), and Tetralogy of Fallot (groups 3 and 4). All children received balanced crystalloid solutions as part of infusion therapy. Groups 1 and 3 received a fluid volume 25% greater than that given to groups 2 and 4. The study was conducted in the pediatric cardiac intensive care unit at the National Children's Medical Center.
Methods: In the early postoperative period, clinical data and central and peripheral hemodynamic parameters were assessed in all patients. These included echocardiographic measurements (LVEDV, LVESV, EF, and SV), SpO_2, heart rate, arterial blood pressure, and central venous pressure. In addition, blood gas analysis was performed. Inotropic support included adrenaline and milrinone; in 63 patients, dopamine was also used at doses of 5–10 μg/kg/min.
Results: Significant differences were observed between subgroups in mean systolic and mean arterial pressure at 6 h and in LVEDV at 24 h after surgery. These differences were associated with the additional use of dopamine in inotropic support. Group 1, compared to group 2, showed a small but statistically significant increase in LVEDV at 24 h. Group 3 demonstrated better improvement in myocardial contractility than group 4 ($p < 0.0001$). The most variable and informative parameters—LVEDV, EF, and SV—allowed for the evaluation of both intergroup and intragroup differences in the postoperative period (in most cases, $p < 0.01$).
Conclusions: Changes in central and peripheral hemodynamic parameters during low-volume infusion therapy (groups 2 and 4) were associated with better outcomes in the early postoperative period, including shorter stays in intensive care. Deterioration of

hemodynamic parameters in children does not always require additional fluid administration and is often linked to insufficient inotropic support in the early postoperative phase.

ECHO parametres in first and second groups

ECHO parametres in third and fourth groups

Introduction: Many minimally invasive methods are available for measuring cardiac output in critically ill patients, one being Pressure Recording Analytical Method (PRAM).
Objectives: We aimed to assess the agreement between PRAM and intermittent transpulmonary thermodilution (PiCCO) in hemodynamically unstable patients.
Methods: In this prospective observational study, we included 25 hemodynamically unstable ICU patients ICU patients and carried out 250 paired cardiac output measurements using PiCCO and PRAM methods. Bland–Altman analysis was performed to find out the mean bias and limits of agreement between two methods.
Results: Bland–Altman plot demonstrated a mean bias of – 0.2 L/min/m2 with upper and lower limits of agreement of 1.26 L/min/m2 and of – 2 L/min/m2, respectively, in CI measurements. The percentage error (PE) was 44.48% between CI-PRAM and CI-TPTD.
Conclusions: Determination of CO measurement with PRAM in hemodynamically unstable patients did not show acceptable agreement with transpulmonary thermodilution. Further studies are required to explore its use in patients with hemodynamic instability.

Bland–Altman analysis of cardiac index by PRAM and PiCCO.

Introduction: Critically ill patients are more likely to have infections and infections-related complications, which can result in death. The optimal choice of β-lactam antibiotic for patients diagnosed with proven methicillin-susceptible Staphylococcus aureus (MSSA) pneumonia remains unclear. Moreover, to our knowledge, no study has addressed the efficacy of cefazolin compared to antistaphylococcal β-lactam antibiotics for treating MSSA pneumonia in critically ill patients. The study aimed to evaluate the effectiveness of cefazolin compared to antistaphylococcal β-lactam in treating MSSA pneumonia in critically ill patients admitted to intensive care units.
Methods: This multicenter retrospective cohort study was conducted in three tertiary hospitals around Saudi Arabia from January 2016 to July 2021. Inclusion criteria were any adult patients (≥ 18 years) admitted to the intensive care unit with confirmed MSSA respiratory culture who received any de-escalated antibiotics with anti-MSSA activity

as definitive antibiotics. Eligible patients were categorized into two groups based on the de-escalated antibiotic received (cefazolin vs. non-cefazolin). The primary outcome was the treatment failure rate, while other outcomes were considered secondary. Logistic, linear, and negative binomial regression analyses were utilized for study endpoints as appropriate.
Results: A total of 54 patients were included in the study (27 patients in cefazolin vs. 27 patients in non-cefazolin). The treatment failure rate was significantly higher in the cefazolin group compared to non-cefazolin (OR 5.73; 95% CI (1.303–25.191), $P = 0.0209$). Moreover, the rate of re-escalation to other antibiotics was higher in the cefazolin group, too (OR 17.98; 95% CI (2.731–118.425), $P = 0.0027$). No significant difference was found in MSSA recurrence infection rate within 3 months, time of microbiological sterilization, or time to defervescence. In addition, the 30-day and in-hospital mortality rates, ICU re-admission, ICU and hospital length of stays, and ventilator-free days were similar between the two groups.
Conclusions: In critically ill patients with MSSA pneumonia, Anti-MSSA β-lactam antibiotics, other than cefazolin, showed a lower treatment failure rate and rate of re-escalation to different antibiotics. Further studies with larger sample size are needed to validate the study findings.

Introduction: Venoarterial extracorporeal membrane oxygenation (VA-ECMO) is utilized as a last-resort intervention for refractory cardiogenic shock (CS). However, the prognostic value of lactate dynamics during ECMO support and after weaning remains unclear. This study aimed to evaluate lactate trends and their association with 28-day mortality.
Methods: We retrospectively analyzed all consecutive patients receiving VA-ECMO for longer than 48 h from January 2018 to May 2024. Blood lactate was measured before ECMO implantation, at 4, 6, 12 and 24 h during ECMO support, 1 h before weaning as well as 2 and 24 h post-weaning. Hyperlactatemia was defined as lactate $\geq$ 5 mmol/L. Subgroup analysis was performed based on initial lactate levels and 24-h lactate clearance (LC).
Results: Among the 248 patients with available baseline lactate measurements, lactate levels were consistently higher in non-survivors at each timepoint ($p < 0.001$). The area under the receiver operating characteristic (ROC) curve (AUC) for baseline lactate in predicting 28-day mortality was significantly higher than that of 24-h LC (0.73 [0.64–0.82] vs. 0.55 [0.45–0.65], $p = 0.023$). In addition, lactate levels exceeding 5 mmol/L at any time during the first 24 h of ECMO were associated with an increased risk of 28-day mortality. Kaplan–Meier curves showed significant differences in 28-day mortality across baseline lactate categories, with hazard ratios of 2.59 (95% CI, 1.14–5.91, $P = 0.024$) for lactate 5–10 mmol/L and 3.42 (95% CI, 1.71–6.83, $P = 0.001$) for lactate $\geq$ 10 mmol/L. Among patients with baseline hyperlactatemia, survivors exhibited a significantly higher LC over the first 24 h (24 h LC: 79.4% [71.6–84.6] vs. 62.4% [30.3–80.5], $P = 0.003$). In 37 patients with lactate measured peri-weaning, elevated post-weaning lactate levels were more predictive of outcome than pre-weaning levels (AUC at 2 h post-weaning: 0.88 [0.77–0.99] vs. 0.60 [0.34–0.86], $p = 0.042$; at 24 h: 0.90 [0.78–0.99] vs. 0.60 [0.34–0.86], $p = 0.011$).
Conclusions: Baseline lactate is a valuable predictor of prognosis in VA-ECMO patients, allowing better risk stratification. LC provides additional predictive value in patients with hyperlactatemia, while post-weaning lactate trajectory offers crucial insight into outcomes. These findings underscore the importance of dynamic lactate monitoring throughout the course of ECMO support.

Introduction: Evidence is limited on the optimal utilization of the Medication Regimen Complexity–Intensive Care Unit (MRC–ICU) scores for predicting clinical outcomes in critically ill patients. Therefore, this study aims to examine how a high score on the MRC-ICU within 24 h of ICU admission predicts clinical outcomes for critically ill patients in ICUs.
Methods: A single-center retrospective cohort study included adult ICU patients admitted for > 72 h between January 2021 and December 2021. Patients were categorized into two groups based on MRC-ICU scores ($\geq$ 9 vs. < 9) assessed within 24 h of ICU admission. The primary endpoint was the multiorgan dysfunction (MOD) score at 72 h of ICU admission. Other clinical outcomes were secondary such as ICU length of stay (LOS), hospital LOS, vasopressors-free days (30 days), organ support-free days, ICU readmission within 3 months, 30-day mortality, and in-hospital mortality. Multivariable logistic and linear regression analyses were used as appropriate.
Results: Among 1422 patients, those with MRC–ICU scores $\geq$ 9 had significantly higher MOD scores at 72 h (median 5 vs. 3, $p < 0.001$), longer hospital LOS, and higher 30-day and in-hospital mortality rates in crude analyses. Moreover, the linear regression analysis showed a significant association between MRC–ICU score and MOD score at day 3 of ICU admission (coefficient: 0.49, 95% CI 0.07–0.92, $p = 0.02$). However, no significant differences were observed with ICU LOS, vasopressor-free days, or mortality after adjusting for possible confounders.
Conclusions: Higher 987MRC-ICU scores might be linked to worse outcomes, including greater organ dysfunction, longer hospital stay, and higher mortality. However, after adjusting for potential confounders, no significant difference in mortality was observed. Further

research is needed to optimize medication regimens and improve critical care outcomes.

***Intensive Care Medicine Experimental 2025,* 13(1)**:001572

Introduction: Critically ill patients are at a higher risk of developing infections and related complications, which can lead to death. Each additional day of antipseudomonal β-lactam use increases resistance risk; therefore, de-escalation is highly recommended to improve antibiotic use. To our knowledge, no study has evaluated the clinical impact of de-escalation in critically ill ICU patients with proven MSSA pneumonia. Therefore, this study aimed to address the clinical impact of the de-escalation strategy compared to non de-escalated strategy in critically ill patients with proven MSSA pneumonia.
Methods: This multicenter retrospective cohort study was conducted in three tertiary hospitals from January 2016 to July 2021. Adult critically ill patients admitted to the intensive care unit with proven MSSA respiratory culture who received antibiotics with anti-MSSA activity were screened for eligibility. The primary outcome was the treatment failure rate, while the secondary outcomes included time to defervescence, time of microbiological sterilization, rate of recurrence of MSSA infection and ICU readmission within 3 months of completing treatment, 30-day mortality, ICU and hospital LOS, and ventilator-free days. Propensity score (PS) matching was applied at a 1:1 ratio, and multivariate regression analyses were utilized as appropriate.
Results: After PS (1:1), 58 patients were included in the study (29 patients in non-deescalated vs. 29 patients in de-escalated). The treatment failure rate was significantly higher in the de-escalated group compared to non-de-escalated (OR 16.98; 95% CI (3.304–87.225), $P = 0.0007$). In addition, the time of microbiological sterilization was longer in the de-escalated group (Beta. 0.71; 95% CI (– 0.10–1.52), $P = 0.08$); however, it failed to reach statistical significance. Moreover, no significant difference was found in the 30-day mortality rate, hospital and ICU length of stays, ventilator-free days, ICU re-admission rate, recurrence MSSA infection rate, and time to defervescence.
Conclusions: Our results show that non-de-escalated patients had lower treatment failure and non-significantly longer time of microbiological sterilization. Further studies with larger sample sizes are needed to validate these findings and draw more definitive conclusions to guide clinical management.

Introduction: Long-term sequalae and disabilities associated with Coronavirus disease 2019 (COVID-19) are currently poorly defined, specifically in patients who have been discharged from intensive care units. We hypothesized that functional and pulmonary capacity, as well as mental health and cognitive function, would remain outside the normal range for up to 12 months after ICU discharge.
Methods: We hypothesized that functional and pulmonary capacity, as well as mental health and cognitive function, would remain outside the normal range for up to 12 months after ICU discharge.
Results: 340 patients from 9 sites in 6 countries (Ireland, Spain, Italy, USA, Singapore, and Colombia) admitted to the ICU from January 2021 to December 2023 for COVID-19 were included in the study. Median (IQR) age was 59 years (SD 13y), 32.1% were females and median length on ICU was 21 days. 200 (58.8%) and 233 patients (68.5%) received invasive and non-invasive ventilation respctively, and 188 patients (55.3%) were diagnosed with ARDS. During the 12-month follow-up, 14 patients (4.1%) died.
The 6-min walking test was outside a normal range in 67/68, 121/125 and 95/100 of the patients at 3, 6, and 12 months, with a mean walking distance of 367, 409, and 461 m, respectively (Fig. 1A). The BIS score was not normalized in 17.9%, 10.5%, and 8.3% (Fig. 1B), while the WHODAS score in 39.4%, 33.0%, and 23.4% (Fig. 1C) at 3, 6, and 12 months, respectively. FVC and FEV1 were outside normal limits in 40.7% and 33.3% of the patients at 3 months, 19.8% and 11.9% at 6 months, 10.3% and 6.3% at 12 months (Fig. 1D, E). DLCO was abnormal in 62.0%, 47.3% and 31.3% (Fig. 1F) of patients at 3, 6, and 12 months. As shown by the HADS, anxiety was present in 30.1%, 15.0%, and 10.8% (Fig. 1G) of the patients, while 18.1%, 10.0%, and 8.1% (Fig. 1H) had significant depression at 3, 6, and 12 months. The PHQ-9 was outside normal limits in 64.6%, 57.9%, and 45.4% (Fig. 1I) of the patients, while the MoCA test revealed cognitive impairment in 41.0%, 21.6%, and 11.8% of the patients at 3, 6, and 12 months.
Conclusions: The assessment of severely ill COVID-19 patients indicates that even though functional status, pulmonary assessment, mental health, and cognitive function improve over time but still affect a significant number of patients 12 months after ICU discharge.

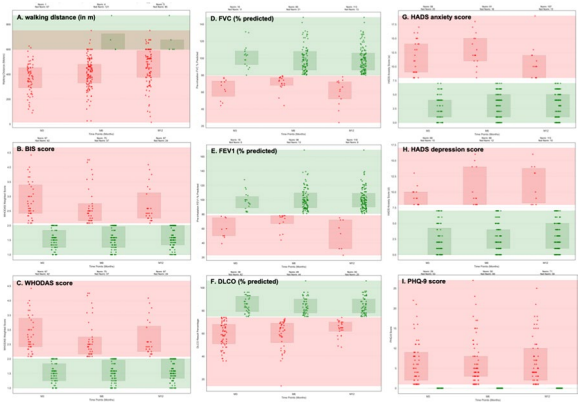

Figure 1 Results at 3-, 6-, and 12-month post-ICU discharge, grouped by normalized and non-normalized values. For each graph, *Y* values within normal range are highlighted in green. **A** walking distance. **B** BIS score. **C** WHODAS score. **D** FVC. **E** FEV1. **F** DLCO. **G** HADS anxiety score. **H** HADS depression score. **I** PHQ9 score

Inflammatory stimuli-induced neutrophil-derived exosome (TNF-Exo) induce macrophage pyroptosis via the A20/NEK7/NLRP3 axis in sepsis-associated acute kidney injury

KY. Lui[1]; X. Qian[1]; C. Cai[1]; X. Guan[1]

***Intensive Care Medicine Experimental 2025,* 13(1)**:001575

Introduction: Sepsis is a systemic inflammatory response syndrome triggered by infection or trauma, rapidly progressing to multi-organ dysfunction, with sepsis-associated acute kidney injury (SA-AKI) as one of the most frequent and severe complications. Recent studies have shown that neutrophils contribute to inflammation in sepsis not only through phagocytosis and the release of inflammatory mediators but also by secreting extracellular vesicles (exosomes), thus amplifying inflammatory signaling and tissue injury. However, the specific mechanisms of neutrophil-derived exosomes under inflammatory stimulation (TNF-Exo) in SA-AKI remain unclear. Elucidating the role of TNF-Exo in SA-AKI may identify new therapeutic targets and diagnostic biomarkers.
Objectives: This study aimed to explore whether TNF-Exo contributes to SA-AKI progression, clarify the molecular mechanism by which miR-519c-5p within TNF-Exo promotes macrophage pyroptosis via targeting A20 and activating the NEK7/NLRP3 signaling pathway, and evaluate the clinical potential of plasma exosomal miR-519c-5p in predicting SA-AKI severity and patient outcomes.
Methods: TNF-Exo were first isolated from neutrophils stimulated by inflammatory conditions (TNF-α) in mice and characterized using transmission electron microscopy (TEM), nanoparticle tracking analysis, and western blot. A mouse model of SA-AKI was established to evaluate renal function markers (serum creatinine and urea–nitrogen) and renal histopathological changes after injection of TNF-Exo. Confocal microscopy was used to investigate macrophage uptake of TNF-Exo. Flow cytometry, RT-qPCR, Western blot, and proteomics were performed to assess macrophage polarization and pyroptosis. Next-generation miRNA sequencing was conducted to identify key exosomal miRNAs, followed by transcriptomics, dual-luciferase reporter assays, and immunoprecipitation to confirm the target gene and signaling interactions. Critical molecular pathways were further validated using animal models and gene knockdown experiments. Finally, a prospective observational study was performed, enrolling septic patients to investigate plasma exosomal miR-519c-5p as a predictive biomarker for SA-AKI severity and mortality risk.
Results: We successfully isolated exosomes from inflammatory-stimulated neutrophils (TNF-Exo) and found that administration of TNF-Exo to mice led to their accumulation in renal tissues, significantly elevated serum creatinine and urea nitrogen levels, increased kidney wet/dry weight ratios, and induced prominent histopathological injury and inflammatory cell infiltration, indicating exacerbated SA-AKI. Both in vivo and in vitro experiments demonstrated substantial uptake of TNF-Exo by renal macrophages and RAW264.7 cells, accompanied by significant macrophage M1 polarization, increased pyroptosis, and elevated inflammatory cytokine levels (TNF-α and IL-1β). MiRNA sequencing revealed notably increased expression of miR-519c-5p in TNF-Exo and plasma exosomes from SA-AKI patients. Mechanistically, miR-519c-5p directly targeted and suppressed A20 expression, enhancing

NEK7 K63-linked ubiquitination and subsequent activation of the NLRP3 inflammasome, thereby promoting macrophage pyroptosis. Inhibition of miR-519c-5p or overexpression of A20 markedly reduced TNF-Exo-induced macrophage pyroptosis and alleviated renal injury and mortality in the sepsis mouse model. Clinically, plasma exosomal miR-519c-5p levels were significantly higher in SA-AKI patients compared to non-AKI or AKI stage 1–2 patients ($P < 0.01$). The predictive value of plasma exosomal miR-519c-5p within 24 h post-sepsis diagnosis for SA-AKI stage 3 (AUC = 0.813) and 30-day mortality (AUC = 0.745) was substantial. Multivariate analysis further confirmed that elevated miR-519c-5p was an independent predictor of SA-AKI stage 3 and 30-day mortality.
Conclusions: This study demonstrates that TNF-Exo significantly exacerbates the progression of SA-AKI. TNF-Exo-delivered miR-519c-5p targets and suppresses A20, enhancing NEK7-mediated activation of the NLRP3 inflammasome, ultimately inducing macrophage pyroptosis. Moreover, plasma exosomal miR-519c-5p is a promising early biomarker for predicting SA-AKI severity and mortality risk in sepsis patients. These findings provide new insights and potential therapeutic targets for the diagnosis and treatment of SA-AKI.

Topic: Acute kidney injury and haemofiltration.

***Intensive Care Medicine Experimental 2025,* 13(1)**:001576

Introduction: Sepsis due to difficult-to-treat (DTR) resistant Gram-negative bacilli is a major cause of hospital morbidity and mortality. Ceftazidime/avibactam (CAZAVI) is a therapeutic option whose pharmacokinetics is increasingly being characterized using real-world data from critically ill patients. Glomerular filtration rate is a key determinant of CAZAVI pharmacokinetics; however, despite preserved renal function as inferred from serum creatinine (SCr), a spectrum of renal dysfunction may be present, potentially impacting the pharmacokinetic profile of CAZAVI in critically ill patients.
Objectives: To describe the pharmacokinetics and PK/PD Target Attainment of CAZAVI in critically ill patients with normal renal function.
Methods: Critically ill patients receiving CAZAVI were prospectively enrolled. Plasma levels of CAZAVI at steady state were measured every hour over an 8-h dosing interval. CAZAVI was administered at a dose of 2.5 g TID, adjusted based on estimated renal function using SCr. In parallel, creatinine clearance (CrCl-24 h) was measured from a 24-h urine collection. Pharmacokinetic parameters were calculated using a non-compartmental model. Pharmacodynamic target attainment (PK/PD) was assessed using three criteria: (1) fCFZ4h > MIC × 1 (8 mg/L) with fAVI > 1 mg/L; (2) fCFZ8h > MIC × 1 (8 mg/L) with fAVI > 1 mg/L; and (3) fCFZ8h > 4 × MIC (32 mg/L) with fAVI > 4 mg/L. This study was approved by the institutional ethics committee, and informed consent was obtained from all patients or their relatives.
Results: Ten patients were enrolled (Table 1). Median SCr was 0.6 [0.50–0.89] mg/dL, and all had an estimated glomerular filtration rate > 50 mL/min, thus receiving standard dosing of CAZAVI. However, CrCl-24 h measurements revealed that four patients had acute kidney injury (AKI) with reduced CrCl (43.5 [30.5–54.5] mL/min), and 2 patients exhibited augmented renal clearance (ARC), with CrCl values of 192.5 and 149 mL/min, respectively. Significant differences were observed among the three groups in average 8-h AVI concentrations ($p = 0.026$), AVI area under the curve (AUC, $p = 0.032$), and AVI clearance ($p = 0.037$). Comparing AKI vs. non-AKI patients revealed differences in AVI-avg 8 h ($p = 0.01$) (Fig. 1), AVI–AUC ($p = 0.01$), and AVI-Cl ($p = 0.019$). Comparing ARC vs. non-ARC patients showed differences in CFZ-avg 8 h ($p = 0.044$), CFZ–AUC ($p = 0.044$), CFZ-Cmax ($p = 0.044$), CFZ-T1/2 ($p = 0.044$), CFZ-Cl ($p = 0.044$), CFZ-Ke ($p = 0.044$), AVI-T1/2 ($p = 0.044$), and AVI-Ke ($p = 0.044$). All patients achieved PK/PD target according to criterion 1. According to criterion 2, only ARC patients failed to achieve the PK/PD target. Based on criterion 3, only 4 patients achieved target PK/PD—2 with AKI and 2 with normal renal function.

Table 1 Description of patients treated with ceftazidime/avibactam

	All patients *N* = 10
Male, *N* (%)	8(80)
Age, years	65 [65–67]
APACHE II, points	15 [13–18]
SOFA, points	8 [5–10]
IMV, *N* (%)	9 (90)
Norepinephrine, *N* (%)	9 (90)
Critical care LOS, days	47 [39–69]
Hospital LOS, days	59 [40–123]
Bloodstream, *N* (%)	3 (30)
Hospital mortality, *N* (%)	2(20)

APACHE II: Acute Physiology and Chronic Health disease Classification System II. SOFA: Sepsis-related Organ Failure Assessment. IMV: Invasive Mechanical Ventilator. LOS: Length of stay.

Conclusions: Patients with low serum creatinine and CrCl > 50 mL/min may represent a heterogeneous group in terms of renal function when assessed via CrCl-24 h, which significantly influences pharmacokinetic parameters and the attainment of more stringent PK/PD targets. ARC patients were identified as being at the highest risk of not achieving optimal PK/PD targets.

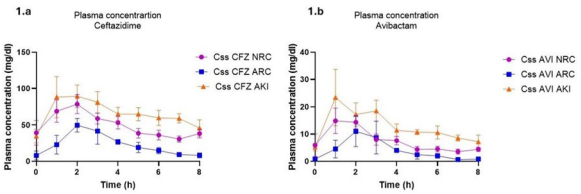

Figure 1 Plasma concentration–time profiles of ceftazidime (1.a) and avibactam (1.b) over 8 h in critically ill patients categorized by renal function. Css CFZ and Css AVI represent steady-state plasma concentrations of ceftazidime and avibactam, respectively. NRC: normal renal clearance; ARC: augmented renal clearance; AKI: acute kidney injury. Data are presented as average ± SEM

Topic: Pharmacology and Toxicology/Poisoning.

Enhancing sedaconda ACD-S reflection efficiency through thermocycling: a bench study with isoflurane

I. Camyurdu[1]; D. Kellner[1]; K. Scheffler[1]; T. Volk[1]; A. Meiser[1]; F. Albrecht[1]
[1]Department of Anesthesiology, Intensive Care and Pain Therapy, Saarland University Medical Center and Saarland University Faculty of Medicine, Homburg, Germany
Correspondence: I. Camyurdu
***Intensive Care Medicine Experimental 2025,* 13(1)**:001577

Introduction: The Sedaconda ACD-S is widely used for inhaled sedation in intensive care. As volatile anesthetics like isoflurane are potent greenhouse gases, reducing their consumption supports greener anesthesia [1]. Thermocycling, the cyclical warming and cooling of the reflector, has been shown to enhance reflection efficiency [2].

Objectives: To determine the optimal temperature difference between clinical conditions and thermocycling to maximize reflection efficiency for isoflurane using 5 °C increments.
Methods: Isoflurane was administered via syringe pump at infusion rates of 0.5, 1, 2, and 5 ml/h. A test lung was ventilated in IPPV mode (tidal volume = 500 ml; respiratory rate = 12/min) and maintained under BTPS and normocapnic conditions, which were continuously monitored within the test lung. Inspired gas was actively heated to 37 °C.
The expiratory limb directed gas through a copper tube placed in a freezer. Temperature was varied in six steps between 26 °C and 1 °C in 5 °C increments by modifying freezer settings, copper exposure, and insulation (Fig. 1). Temperature before the ACD-S was measured. Isoflurane concentration was recorded under steady-state conditions (5 min average, repeated three times). Reflection efficiency was calculated. A clinical baseline was measured using a shorter tube system and without heating and cooling the breathing system.
Results: By intensifying thermocycling, higher isoflurane concentrations were achieved at identical infusion rates in the test lung. To maintain a concentration of 0.5 Vol%, it would be possible to reduce the infusion rate from 2.46 ml/h under clinical conditions to 0.74 ml/h at a thermocycling temperature of 1 °C, resulting in a 70% reduction in isoflurane consumption (Fig. 2). At all tested concentrations, thermocycling increased reflection efficiency in a non-linear manner (Fig. 3).
Conclusions: Reflection efficiency increases with cooling intensity, following a first-order pattern with the highest increase during moderate cooling and leveling off around 16 °C. Even a moderate thermocycling approach had a significant effect on reflection efficiency, suggesting that complex cooling systems may not be required and offering a promising step toward greener anesthesia.

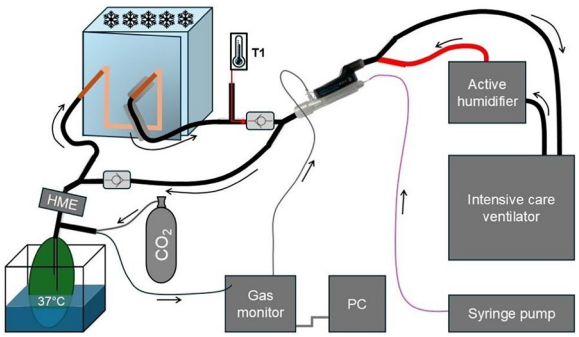

Figure 1 Experimental setup for thermocycling trials with isoflurane and the ACD-S

Severe acute respiratory infections (SARI): insights from a tunisian sentinel surveillance study 2022–2025

N. Ben Slimene[1]; S. Cherif[1]; B. Ben dhia[1]; K. Ben Ismail[1]; M. Ben Nessib[1]; F. Essafi[1]; T. Merhabene[1]

[1]Intensive care unit, Zaghouan Regional Hospital, Faculty of medicine of Tunis, University of Tunis El Manar, Tunisia

Correspondence: N. Ben Slimene

Intensive Care Medicine Experimental 2025,* 13(1)*:001578

Introduction: Severe acute respiratory infections (SARI) remain a significant public health concern globally, particularly in resource-limited settings. In Tunisia, sentinel surveillance systems play a crucial role in monitoring SARI trends, etiological agents, and risk factors.

Objectives: This study aims to describe the clinical and therapeutic features of SARI cases admitted to a sentinel surveillance center in Tunisia and to determine the factors associated with mortality.

Methods: We conducted a retrospective analysis of SARI cases admitted between October 2022 and April 2025 (during three influenza seasons) in the intensive care unit (ICU) of Zaghouan's regional hospital, a Tunisian sentinel site. Data on demographics, clinical presentation, comorbidities, outcomes, and laboratory results were collected. Descriptive statistics and multivariate analyses were performed to identify factors associated with severe outcomes.

Results: Among 131 patients meeting the WHO SARI case definition who underwent a nasopharyngeal sampling, 65 (49%) were positive. The mean age was 52 years ± 16SD, with 90% having underlying conditions (chronic respiratory disease in 58%, heart disease in 29%, diabetes in 35%). Seventeen percent of patients admitted already required home mechanical ventilation or home oxygen therapy. Severity scores were calculated upon admission using the Simplified Acute Physiology Score II (SAPS II) and Chronic Health Evaluation II (APACHE II), with values of 27 ± 14SD and 10 ± 6SD, respectively. Influenza viruses were detected in 52% of cases (respectively, A/H1N1 in 40%, A/H3N2 in 8%, B in 5%), while other pathogens accounted for 48% (Rhinovirus 21%, RSV 5%, SARS-CoV-2 9%, bacterial co-infections 4%). All patients had signs of respiratory distress upon admission, circulatory failure was noted in 13 cases (20%), neurological distress in 8 (12%) and acute kidney injury in 12 (18%). Invasive mechanical ventilation (IMV) was needed in 23 patients (35%) with a mean duration of 6 days ± 2. Antibiotics were initially prescribed for 51 patients (78%) and antivirals for 31 (48%). Health-associated infections occurred in 19 patients (29%). Ventilator-associated pneumonia (VAP) was the most frequent infection (15%) followed by urinary tract infection (UTI) (6%). Intra-hospital mortality was 18%, with a higher rate among elderly patients and those with comorbidities.

In multivariate analysis, *rhinovirus* infection emerged as a protective factor against mortality ($p = 0.042$), with antiviral treatment showing similar significance ($p = 0.042$). Significant risk factors associated with mortality included COVID-19 infection ($p = 0.002$), organ failure ($p = 0.001$), invasive mechanical ventilation ($p < 0.001$) and septic shock ($p < 0.001$).

Conclusions: *Rhinovirus* infection was protective against mortality, while COVID-19, organ failure, and invasive ventilation were associated with poor outcomes. These results emphasize the importance of pathogen-specific management and critical care optimization in resource-limited settings.

Topic: Acute respiratory failure and mechanical ventilation.

Immunotherapies for sepsis induced-immunosuppression: recombinant IL-7 but not Nivolumab partially restores CD4 + lymphocyte function in septic patients ex vivo

TAC. Snow[1]; W. Pisciotta[1]; F. Ryckaert[1]; A. Cesar[1]; N. Saleem[1]; S. Elkhodair[2]; M. Singer[1]; D. Brealey[3]; N. Arulkumaran[1]

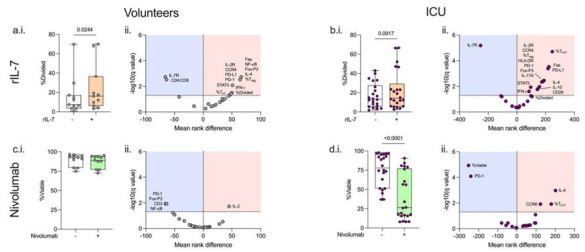
[1]Bloomsbury Institute of Intensive Care Medicine, University College London, London, United Kingdom; [2]Emergency Department, University College London Hospital, London, United Kingdom; [3]Biomedical Research Centre, University College London Hospitals, London, United Kingdom

Correspondence: T.A.C. Snow

Intensive Care Medicine Experimental 2025,* 13(1)*:001579

Introduction: Sepsis survivors are at increased risk of subsequent infection due to persistent immunosuppression. This is associated with characteristic features in lymphocytes including lymphopenia, increased apoptosis mediated by increased PD-1 expression, cell anergy (reduced cytokine release), and an increase in immunosuppressive regulatory subtypes (Treg). [1].

Immunotherapies targeting lymphocyte proliferation pathways (e.g., recombinant IL-7 (rIL-7) or the PD-1–PD-L1 pathway (e.g., nivolumab) have not yet shown clinical benefit.[2].



This may be because immunotherapies which target and improve one specific lymphocyte pathway may not improve overall cell immunophenotype or function.

Objectives: Do immunotherapies targeting CD4 + lymphocytes improve overall cell function in response to a secondary infection?

Methods: Peripheral blood mononuclear cells (PBMCs) were isolated from healthy volunteers and from septic ICU patients. To model the lymphocyte response to a secondary infection, PBMCs were stimulated ex vivo for 72 h with or without CD3/28 beads, and co-incubated with or without rIL-7 (100 ng/ml) or nivolumab (10 mg/ml).

Spectral flow cytometry was used to assess multiple CD4 + lymphocyte immunophenotype and functions including: **activation** (CD3, CD4, CD8, CD19, CD28, HLA-DR, NF-κB), **suppression** (CTLA-4, PD-L1), **proliferation** (CellTrace, IL-7R), **differentiation** (IL-2R, IL-2, CCR4,

CCR6, IL-4, IL-17A, FoxP3, STAT5, T-bet), **cell death** (Live-dead, Fas, PD-1), and **cytokine Release** (IL-10, IFN- γ).
Proliferation was assessed by calculating the percentage (%) of divided cells and viability by calculating the % of live cells and compared using Wilcoxon or Mann–Whitney test (paired and unpaired data, respectively). Lymphocyte function was analysed using multiple Mann–Whitney tests, Volcano plots were generated using a false discovery rate of 5%.
Results: 24 ICU patients (10 [42%] non-survivors) and 11 volunteers were recruited.[3] CD4 + lymphocytes from ICU patients displayed a blunted response to bead stimulation with features of anergy (data not shown) compared to volunteers.
After stimulation with rIL-7, volunteer CD4 + lymphocytes showed increased proliferation (*Fig a.i.*), while ICU patients only demonstrated a non-significant increase (*Fig b.ii.*). However, in both cohorts, there were increases in markers of activation, differentiation and cytokine release (*Fig a.ii.* and *b.ii.*) suggestive a reversal of the anergic immunophenotype.
After stimulation with nivolumab, there was no effect on volunteer CD4 + lymphocytes cell viability (*Fig c.i.*) but a reduction in viability in ICU patients (*Fig d.i.*). This effect was not seen in lymphocytes in the absence of CD3/28 beads (data not shown). Few additional effects were seen in volunteers (*Fig c.ii.*) but in ICU patients there was an increase in markers of differentiation (*Fig d.ii.*).
Conclusions: CD4 + lymphocytes from septic patients display an immunosuppressive phenotype and are unable to respond to a secondary infection. rIL-7 partially restores CD4 + lymphocyte function with increases in cell proliferation and multiple other cell functions suggesting a clinical benefit. Nivolumab; however, paradoxically enhanced cell death although further work is required to explore this finding.

PBMCs from volunteers (n = 11, grey dots) and ICU patients (n = 24, purple dots) were stimulated for 72h with CD3/28 beads and in the presence or absence of rIL-7 (top row, a. and b.) or nivolumab (bottom row, c. and d.). The effect of rIL-7 on cell proliferation was assessed using CellTrace (expressed as percentage of cells which had divided, a.i. and b.i.), while the effect of nivolumab was assessed using cell viability (c.i. and c.ii.). Data compared using Wilcoxon test and dispalyed as individual volunteer/patient (dot), median (horizontal line), interquartile range (box) and range (whisker).
The effect of the immunotherapy on overall cell function is displayed using volcano plots (ii.), where the shaded red area shows markers which have significantly increased with the therapy, while the blue area shows markers which have significantly decreased and all are listed. Each dot represents the median of all the volunteers or patients.

Introduction: Electroencephalogram (EEG) is commonly used in ICU to evaluate brain function in patients with severe traumatic brain injury (TBI). While its diagnostic value is well established, its prognostic role remains unclear.
Objectives: This study aims to assess the performance of EEG to predict prognosis in critically TBI.
Methods: We conducted a retrospective descriptive study over 6 years (2019–2025) in the ICU of Zaghouan Regional Hospital. We included patients with severe TBI. EEG was performed in cases of delayed awakening, suspected encephalitis, or epilepsy to assess brain function and prognostic value.
Results: A total of 35 patients with severe TBI were included. The mean age was 43 ± 17 years, with a gender ratio of 7. Median SAPS II and APACHE II scores were 36 [27–41] and 13 ± 6, respectively. Relevant past medical history included psychiatric disorders (5%), epilepsy (10%), and chronic alcohol use (40%).
At admission, 12% of patients had experienced cardiac arrest (mean downtime 9 ± 1 min). Seizures were present in 60%. Median initial Glasgow coma scale was 6 [3–10], with preserved brainstem reflexes in all cases. Initial brain CT scan was abnormal in 80%, revealing edema (50%), ischemic stroke (15%), hemorrhage (80%), and hematoma (65%).
Osmotherapy was indicated in 60% of patients, and neurosurgical intervention in 16% of cases. Antiepileptic drugs were prescribed in 84% of patients. Orotracheal intubation was indicated in all patients with a median length of mechanical ventilation of 21 days and 63% of patients underwent tracheostomy. Vasoactive agents were used in 71% of cases. Median ICU stay was 32 days, and the mortality rate was 20%.
EEG was primarily indicated for delayed awakening (60%), epilepsy monitoring (28%), and suspicion of seizures (12%). The median time to

first EEG was 8 days [6–17] within X days after discontinuing sedation. EEG findings were normal in 32%of cases, showed cerebral suffering in 52% of cases (93% moderate, 7% severe), status epilepticus in 11%of cases, and post-anoxic encephalopathy in 5% of cases. A second EEG was performed in 15% of patients (median day 12 [11–14]), showing improvement in 5% of patients, worsening in 5% of patients, and stable findings in 5% of patients.
At discharge, 40% of patients had neurological sequelae: motor deficits (10%), frontal syndrome (10%), memory impairment (5%), fluctuating consciousness (5%), and vegetative state (5%).
Univariate analysis revealed that cardiac arrest was significantly associated with cerebral suffering on EEG ($p = 0.037$), the development of neurological sequelae ($p = 0.009$), and a trend toward higher mortality ($p = 0.07$). Multivariate analysis confirmed that cardiac arrest remained an independent risk factor for neurological sequelae ($p = 0.035$, OR = 22.9; IC95%[1.237–423.816]).
Conclusions: Cerebral suffering was a significant risk factor for the persistence of neurological sequelae.
EEG can predict neurological prognosis of patients with severe TBI, particularly in detecting cerebral suffering and guiding clinical management.

Introduction: COVID-19 is an inflammatory disease with a complex pathophysiology that involves a dysregulated systemic immune response. The development of multiple organ failure has been related to endothelial activation and widespread microthrombosis (1). Therefore, there is a compelling need for studying microcirculation in COVID-19 critical patients. Nevertheless, reports about the characteristics of sublingual microcirculation in this population are controversial. In fact, total vascular density has been described as decreased, normal, or increased (2, 3).
Objectives: Our goal was to assess comprehensively the sublingual microcirculation in patients with COVID-19, comparing it with that of patients with septic shock and with healthy volunteers.
Methods: This was a multicenter cross-sectional study. IRB approval was obtained from all the ICUs. We included mechanically ventilated patients with ARDS secondary to COVID-19 ($n = 62$) and with septic shock ($n = 20$), from four intensive care units. We also studied healthy volunteers ($n = 20$). Sublingual microcirculation was assessed by videomicroscopy.
Results: Patients with COVID-19 exhibited a distinctive pattern of sublingual microcirculation, mainly characterized by increased vascular density. This finding could be secondary to enhanced angiogenesis. TVD was independently associated with PPV, SOFA score, base excess, and hematocrit. On the other hand, the convective variables of microvascular perfusion only showed minor alterations. Therefore, this study adds evidence showing that patients with COVID-19 have a distinctive pattern of microcirculatory flow.
Conclusions: Patients with COVID-19 exhibited a distinctive pattern of sublingual microcirculation, mainly characterized by increased vascular density. This finding could be secondary to enhanced angiogenesis. TVD was independently associated with PPV, SOFA score, base excess, and hematocrit. On the other hand and contrary to septic patients, the convective variables of microvascular perfusion only showed minor alterations.

Patients with COVID-19 exhibited a distinctive pattern of sublingual microcirculation, mainly characterized by increased vascular density. This finding could be secondary to enhanced angiogenesis. TVD was independently associated with PPV, SOFA score, base excess, and hematocrit. On the other hand, the convective variables of microvascular perfusion only showed minor alterations. Therefore, this study adds evidence showing that patients with COVID-19 have a distinctive pattern of microcirculatory flow.

Intensive Care Medicine Experimental 2025,* 13(1)*:001583

Introduction: Severe burns induced hypercoagulable state, either in the acute or recovery phase, and exposed patients to thromboembolic complications, often underdiagnosed. Few studies were interested to these complications in burned children, highlighting the importance of our research.
Objectives: The aim of this study was to determine the incidence of thromboembolic complications (TBEC) in burned children and study their clinical and evolutionary characteristics.
Methods: A retrospective descriptive study conducted in the burn intensive care unit over an 8-year period (January 1, 2018–January 1, 2025). All patients under 18 years admitted for severe burns and developed thromboembolic complications (deep veinthrombosis and pulmonary embolism) were included. Epidemiological, clinical, and prognostic data of these patients were collected and analyzed.

Results: During the study period, 511 children with burns were admitted. Among them, 11 developed thromboembolic complications (incidence of 2.2%). The median age of these patients was 16 [9–16] years, with a sex ratio of 4.5. Burns were secondary to domestic accidents in eight cases and suicide attempts in three cases. Thermal burns occurred in eight cases and electrical burns in three cases. All patients were transferred from other hospitals. The median burned body surface area was 40% [20–55]. All patients had burns involving the lower limbs and were fitted with central venous catheters. Nine patients required invasive mechanical ventilation. TBEC occurred after a mean delay of 20 ± 10 days. Deep veinthrombosis was observed in five cases, and pulmonary embolismin 6 cases. All patients had received prophylactic anticoagulation upon admission. Thrombolysis was necessary for two patients. The median length of ICU stay was 29 days [10–67], with a mortality of 82% (9/11 patients).
Conclusions: This study reveals that the incidence of thromboembolic complications in burned childrenis was 2.2%. These complications occur late, primarily in patients with extensive burns, lower limb burns, and venous catheterization.

Topic: Cardiovascular issues in ICU.

Intensive Care Medicine Experimental 2025,* 13(1)*:001585

Introduction: Severe asthma exacerbations may result in acute respiratory failure requiring ventilatory support: noninvasive ventilation (NIV) has emerged as a potential alternative to invasive mechanical ventilation (IMV) in selected cases.

Objectives: This study aimed to evaluate the effectiveness and outcomes of NIV in patients admitted to the ICU for severe asthma exacerbations.
Methods: We conducted a retrospective descriptive study over 6 years (2019–2025) in the ICU of Zaghouan Regional Hospital, Tunisia. We included all patients admitted for severe asthma exacerbation who received at least one NIV session. NIV was initiated at admission, with each session lasting 2–4 h, up to three sessions per day. The need for IMV defined NIV failure. NIV-related complications were recorded as secondary outcomes.

Results: Twenty-four patients were included (mean age: 41 ± 15 years). Mean SAPS II was 22.5 ± 10, and median APACHE II was 8 [2–28]. Median asthma duration was 10 years [4–20]. Asthma was intermittent in 33.3%, mild persistent in 37.5%, moderate persistent in 20.8%, and severe persistent in 8.2%. Maintenance therapy was lacking in 12.5%. Adherence was good in 47.6% and poor in 52.4%. One-third had prior ICU stays; 8.3% had required IMV before.
Triggers included allergens (12.5%), poor adherence (12.5%), and COVID-19 (5%). Pneumonia was present in 45% of cases (viral: 54% mostly rhinovirus; bacterial: 42% mainly pneumococcus; mixed: 4%). Tracheobronchitis was observed in 25%.
At admission, the respiratory rate was 32 ± 6 breaths/min. Speech limitation was noted in 58.3%, and 87.5% showed signs of increased work of breathing. ABGs showed: pH 7.33 ± 0.12, $PaCO_2$ 44.6 ± 14.4 mmHg, PaO_2 95.8 ± 45.3 mmHg, HCO_3 25 ± 8 mmol/L, and SaO_2 93 ± 5%.
NIV was indicated for altered respiratory mechanics (75%) and hypoxemia (25%). Initial settings included IPAP 8 ± 2 cmH_2O, PEEP 5 ± 2 cmH_2O, FiO_2 49 ± 24.6%, inspiratory trigger − 1 to − 2 cmH_2O, expiratory trigger 25%, and rise time 300–500 ms. Median session duration was 3 ± 1 h.
Post-NIV ABGs showed improved gas exchange: pH 7.40 ± 0.05, $PaCO_2$ 36.7 ± 8 mmHg, and P/F ratio 285 ± 100. NIV succeeded in 79% of patients; 20.8% required IMV. No barotrauma was reported. One nasal pressure ulcer occurred.
Median ICU stay was 5 [3–8] days. In-ICU mortality was 8.3%. NIV success was associated with higher survival ($p = 0.004$). Favorable factors included male sex ($p = 0.034$), younger age (37 vs. 53 years, $p = 0.041$), lower SAPS II (18 vs. 36, $p = 0.00$), shorter symptom duration (4 vs. 6 days, $p = 0.008$), lower PEEP (5 vs. 10 cmH_2O, $p = 0.008$), and lower FiO_2 (42% vs. 100%, $p = 0.001$). NIV success significantly reduced IMV need ($p < 10–3$).
Conclusions: NIV improved respiratory parameters and reduced IMV requirement in severe asthma exacerbations. Its success was linked to better survival and specific clinical and ventilatory factors.

Topic: Acute respiratory failure and mechanical ventilation.

Nosocomial urinary tract infections: a 10-year tale of prevention, surveillance and microbiological challenges

AC. Cunha[1]; O. Gomes[1]; S. Costa[1]; V. F. Vieira[1]; A. Albuquerque[1]; M. Magno[1]
[1]Intensive Care Unit, Unidade Local de Saúde da Região de Leiria, Leiria, Portugal
Correspondence: A.C. Cunha
Intensive Care Medicine Experimental 2025,* 13(1)*:001588

Introduction: Patients in intensive care units (ICUs) are at high risk for healthcare-acquired infections (HAI) due to the high prevalence of invasive procedures and devices, induced immunosuppression, comorbidity, frailty and increased age.
Urinary tract infections (UTIs) are among the most common HAIs. The presence of a urinary catheter and the duration of exposure—allowing continuous access of organisms into the urinary bladder—are the main risk factors, but other host factors and healthcare related variables can also affect the risk of its development.
Quality improvement actions focused primarily on antimicrobial management and prevention of healthcare-associated infection are feasible and have the potential to decrease antibiotic use and healthcare-associated infection rates. Periodic audit procedures allow for protocol updates, with the goal of future improvements in outcomes.
Methods: A single-centre retrospective analysis was made, including all patients admitted in the intensive care unit (ICU) for more than 48 h over a period of 10 years (2015–2024). The main focus was on the assessment of incidence in the context of the broadening of admission criteria witnessed in this period, length of ICU stay and previous hospitalisation time, length of use of urinary catheter and emergence of multirresistant microorganisms. Furthermore, this included an audit of antibiotic prescription and preventative care practices. The diagnosis of nosocomial infections was done using the criteria from the HELICS-ICU program.
Results: A total of 2742 admissions were included in this analysis, accounting for 26,458 days of urinary catheterisation. A total of 112 nosocomial UTIs were diagnosed in this period.
The number of catheterisation days kept stable over the period of study, which means an actual reduction in catheterisation period per patient, as the number of ICU admissions per year.
nearly doubled in the same period. The length of ICU stay has noticeably decreased from an average of 12.2 days in 2015 to under 9 in 2024.
The number of infections per year also decreased over time, as have the percentages of multirresistant to drugs (MDR) bacterial isolates. In 2024 the lowest number of diagnosis was achieved for the period and none of the infections was caused by MDR bacteria.

Conclusions: Consistent preventative efforts and assertive antimicrobial stewardship programmes, along with increased support from the microbiology laboratory correlates with improving ICU results.

Topic: Infections and prevention.

Intensive Care Medicine Experimental 2025,* 13(1)*:001589

Introduction: Azithromycin (AZM) has been used in sepsis treatment due to its bacteriostatic and immunomodulatory effects and seems to decrease mortality and ICU stay in critically ill patients [1, 2]. Even though AZM has been shown to induce autophagy in smooth muscle cells, mainly in proliferating ones that are critical for remodeling [3] and arrhythmogenic effects have been reported [4], the effects on vessels have not been elucidated yet. However, the implication of vascular effects in sepsis is of great importance, due mainly to the use of vasoreactive drugs during sepsis treatment.
Objectives: The aim of the present study was to investigate the effect of AZM on vessels, using both rabbit aortic SMC primary cultures (cellular level) and rabbit aortic rings (tissue level).
Methods: Cells and tissues were incubated with AZM (1-10 μM) in actively proliferating (in the presence of 10%FBS) and non-proliferating cells for 24–72 h. In cell cultures, the effect of AZM on autophagy was observed microscopically, in the presence or absence of the autophagy inhibitor 3methyladenine (3MA, 5 mM). Cell viability was evaluated with Trypan blue staining. In aortic rings, the AZM (10 μm) effect was studied after tissue sectioning and with the use of Cresyl Violet, Toluidine Blue and H&E stains as well as immunofluorescent localization of the autophagy markers Beclin1 and LC3. The inhibition of inflammation by AZM was examined with ELISA for IL-1b and TNF-a concentrations evaluation.
Results: In vascular smooth muscle cell (VSMCs) cultures, cell incubation for 24–72 h with AZM (1-10μM), in both cell phenotypes (Fig. 1A, B), reduces cell number and induces the appearance of autophagic vacuoles (Fig. 1C). In proliferating VSMCs the effect of AZM on their number became apparent as early as after 24 h in culture (Fig. 1B). This effect was reversed by either AZM exclusion from the culture or in the presence of 3MA (5 mM), verifying the induction of autophagy. Furthermore, incubation of aortic rings for 24 h with AZM (0.1 or 10μM) increased Beclin1 and LC3 immunoreactivity and promoted alterations in smooth muscle appearance (Fig. 2). In addition, AZM reduced IL-1b and TNF-a concentrations, showing the anti-inflammatory effect of AZM.
Conclusions: AZM induces autophagy in vascular smooth muscles both in the cellular and the tissue level. The observed effect could demonstrate a positive way of azithromycin action beyond its antimicrobial and anti-inflammatory properties that could be of significance during sepsis.

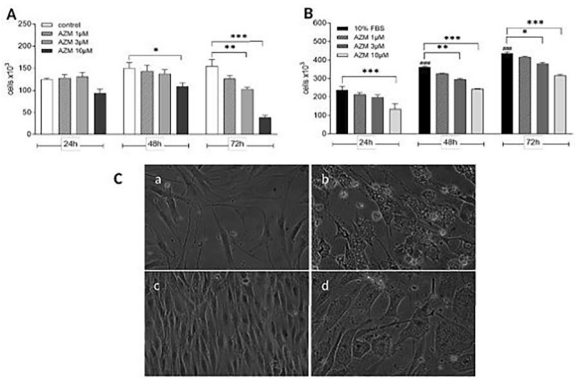

Figure 1 **A, B** Effect of azithromycin (AZM 1 μM, 3 μM and 10μM) on VSMC number after 24h, 48h and 72h of incubation, in non-proliferating (A) or proliferating in the presence of 10%FBS cells (**B**). Values are presented as means (SE) of 4 independent experiments. *$p < 0.05$, **$p < 0.01$, ***$p < 0.001$, compared to values of the relative control or 10% FBS alone and ###$p < 0.001$, compared to cells incubated in the presence of 10% FBS for 24h
AZM 10-7M
AZM 10-5M
C Effect of azithromycin (10μM) for 72h on VSMC morphology. Non-proliferating cells were incubated in the absence (a) or presence of AZM (b) or proliferating cells incubated in 10% FBS alone (c) and 10% FBS with AZM (d). Photos were taken with inverted microscope at 40 × magnification.

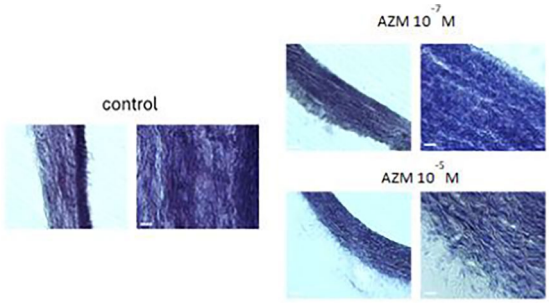

Figure 2 Histochemistry in rabbit aortic ring slices using cresyl violet. Photos are taken under an optical microscope in 10 × magnification (left panel, scale = 100μm) or 40x (right panel, scale = 20μm).

Introduction: Early and precise prognosis determination in cardiac arrest survivors remains challenging despite multimodal approach. Currently, the only guidelines-recommended biomarker for early prognostication is neuron-specific enolase (NSE).
Objectives: The aim of this study was to compare prognostic values of NSE with novel biomarkers serum tau protein (Tau), neuro-filament light chain (Nfl) and Galectin-3 (Gal) at different timepoints after cardiac arrest and with combination of all four biomarkers.
Methods: This single-center prospective study included out-of-hospital cardiac arrest survivors. All patients underwent targeted temperature management (33 °C for 24 h) using an endovascular cooling device. Blood samples for measuring NSE, Tau, NfL, and Gal levels were collected at 24 h (D1), 48 h (D2), 72 h (D3), and 96 h (D4) after hospital admission. Neurological outcomes at 30 days were assessed using the Modified Rankin Scale (mRS), with poor outcomes defined as mRS scores of 4–6. The prognostic value of each biomarker for predicting poor outcomes was evaluated using receiver operating characteristic (ROC) analysis.
Results: A total of 82 cardiac arrest survivors (mean age 62 years) were enrolled in the study. The area under the ROC curve (AUC) for NSE was 0.793 ($P < 0.0001$) at D1, 0.911 ($P < 0.0001$) at D2, 0.966 ($P < 0.0001$) at D3, and 0.976 ($P < 0.0001$) at D4. For Tau, the AUC was 0.798 ($P < 0.0001$) at D1, 0.914 ($P < 0.0001$) at D2, 0.925 ($P < 0.0001$) at D3, and 0.952 ($P < 0.0001$) at D4. The AUC for NfL was 0.727 ($P = 0.0001$) at D1, 0.873 ($P < 0.0001$) at D2, 0.935 ($P < 0.0001$) at D3, and 0.932 ($P < 0.0001$) at D4. Gal showed an AUC of 0.644 ($P = 0.0259$) at D1, but was not significant at later timepoints (D2–D4).
Comparison of ROC curves revealed significantly lower AUC for Gal in comparison to other biomarkers from D2 to D4. Numerically, Tau had the highest AUC at D1, while NSE showed the highest AUC at D2, D3, and D4. The highest sensitivity for the prediction of poor prognosis with 100% specificity was detected for Tau at D1 (14.3%) and for NSE at D2 (69.4%) D3 (79.3%) or D4 (82.6%). Multiple logistic regression revealed that combination of all four biomarkers may predict poor prognosis already at D1 with 100% specificity and 21% sensitivity (AUC 0.8291, $P < 0.0001$).
Conclusions: Our findings suggest that the novel biomarkers Tau and NfL have comparable prognostic value to NSE between 48 and 96 h after cardiac arrest. On the first day, Tau demonstrates the highest predictive accuracy, followed by NSE. Gal provides prognostic information only at 24 h. Combining all four biomarkers may enhance early outcome prediction, offering high predictive value as early as the first day post-admission.

Topic: Cardiac arrest.

Intensive Care Medicine Experimental 2025,* 13(1)*:001593

Introduction: Septic shock is a critical condition requiring vasopressor support and mechanical ventilation. The sequence of vasopressor weaning may affect clinical outcomes, such as mechanical ventilation duration and patient survival.
Objectives: This study assesses how vasopressor weaning order affects hemodynamic stability, clinical outcomes, and the length of mechanical ventilation in critically sick septic shock patients.
Methods: A retrospective cohort study was conducted at Prince Sultan Military Medical City, Riyadh, Saudi Arabia, from January 2022 to December 2023. Critically ill adult patients receiving intravenous norepinephrine and vasopressin for septic shock and requiring mechanical ventilation were included. Patients were classified into two groups: vasopressin weaned first or norepinephrine weaned first. The duration of mechanical ventilation was the main outcome. These were secondary outcomes: mean arterial pressure (MAP) stability, 30-day in-hospital mortality, length of stay (LOS) in the intensive care unit and hospital, and rates of reintubation.
Results: Among 100 patients (mean age: 65.1 ± 19.7 years; 58% male), vasopressin was weaned first in 47 patients (47%) and norepinephrine first in 53 (53%). Patients extubated while on vasopressors (vasopressin weaned first) had a shorter median duration of mechanical ventilation (4 days) and lower odds of mortality (adjusted OR = 0.30, 95% CI 0.09–0.98; $P = 0.046$) compared to those weaned off norepinephrine first. No significant differences were observed in MAP stability, reintubation rates, or LOS.
Conclusions: Weaning vasopressin before norepinephrine may be associated with improved survival and reduced mechanical ventilation duration in septic shock patients, although further research is needed to validate these findings and optimize vasopressor weaning strategies.

***Intensive Care Medicine Experimental 2025,* 13(1)**:001595

Introduction: Ventilator-associated pneumonia (VAP) caused by carbapenem-resistant *Acinetobacter baumannii* (CRAB), is a difficult to treat infection associated with significant morbidity and mortality. BV100 (Rifabutin for infusion) is under development for treatment of serious infections caused by CRAB and was recently evaluated in a Phase 2 clinical trial consisting of Part A mainly focused on PK in VAP patients and in a Part B designed as rescue therapy.
Objectives: We evaluated the efficacy, safety and tolerability of BV100 in Part B, as rescue therapy, in critically ill patients with VAP, caused by CRAB, in whom empiric treatment has failed, and/or CRAB was also resistant to colistin.
Methods: In the study were included adult patients with signs and symptoms of VAP caused by CRAB in whom empiric treatment has failed, and/or CRAB was additionally resistant to colistin. Initial diagnosis of CRAB was performed by a rapid diagnostic test and consequently confirmed by endotracheal aspirates (ETA) culture developing *A. baumannii*. BV100 300 mg twice daily was added to best available treatment. Follow-up ETA cultures were obtained and treatment duration ranged from 7 to 14 days. Microbiological success was defined as eradication of CRAB from ETA cultures and clinical success as remission of signs and symptoms of VAP.
Results: A total of eight patients were included in the study. Median APACHE II, SOFA, and CPIS score were 15, 6, and 8, respectively. In three patients, ETA cultures revealed polymicrobial infections, caused by *K. pneumonia*, *P. aeruginosa,* and *S. marcescens*. Best available treatment consisted of meropenem, colistin, linezolide, ampicilline/sulbactam, or ceftazidime/avibactam. Two patients succumbed due to septic shock: 1–2 days after initiation of treatment and the other post-treatment because of acalculus cholocystitis. Six patients survived achieving both microbiological and clinical cure. No treatment related serious adverse events or adverse events were reported.
Conclusions: BV100 demonstrated good tolerance and a favorable safety profile. It emerges as a promising therapeutic option for VAP caused by multidrug-resistant *A. baumannii*, thereby necessitating further investigation.

Topic: Infections and prevention.

Correspondence: R. Gomes Silva
Intensive Care Medicine Experimental 2025,* 13(1)*:001598

Introduction: Over the past decade, the number of patients aged 80 years or older admitted to intensive care units (ICUs) has steadily increased. This demographic trend raises important clinical and ethical challenges, as "very old" patients frequently present with multiple comorbidities and are at increased risk of poor outcomes, including high mortality and significant functional decline following ICU care.
Methods: We conducted a retrospective cohort study of 172 very old patients admitted to a mixed European ICU over a 3-year period. Primary outcome was hospital mortality. Demographic and clinical variables, including SAPS II and SOFA scores, were analysed to identify predictors of mortality. Discrimination was assessed using receiver operating characteristic (ROC) curves; calibration was evaluated using the Hosmer–Lemeshow test.
Results: The median age was 84 years (IQR, 82–87), and 64.5% were male. Hospital mortality was 48.8%. Median SAPS II and SOFA scores were 52 (IQR, 41–64) and 6 (IQR, 4–8.75), respectively, with a standardized mortality ratio of 0.94. Mortality was not associated with age, ICU stay, or hospital length of stay, but was significantly associated with male sex ($p = 0.030$), higher level of care, endotracheal intubation, and vasopressor use (all $p < 0.001$). SAPS II and SOFA scores were significantly higher among non-survivors ($p < 0.001$), demonstrated good discrimination (AUC = 0.735 and 0.737, respectively), and showed adequate calibration (Hosmer–Lemeshow $\chi^2 = 7.114$, $p = 0.524$). Both scores remained independent predictors of hospital mortality in multivariate analysis (SAPS II: adjusted OR 1.038, 95% CI 1.008–1.068; $p = 0.013$; SOFA: adjusted OR 1.161, 95% CI 1.012–1.331; $p = 0.033$). Point-biserial correlations confirmed moderate, significant associations between both scores and mortality ($r = 0.400$ and 0.403; $p < 0.001$).
Conclusions: In "very old" ICU patients, higher severity scores, level of care, and invasive interventions are strongly associated with hospital mortality. Further studies are warranted to clarify whether these variables reflect only acute severity of disease or also underlying functional status prior to admission. Prospectivestudies should also explore long-term impact on functional outcomes and quality of life after hospital discharge.

Reassessing the role of tracheostomy in TBI management: survival advantage without functional compromise?

B. Soares Nunes[1]; P. Batarda Sena[1]; C. Lume[1]; F. Côrte-Real[1]; G. Faro Silva[1]; JJ. Nóbrega[1]
[1]Intensive Care Medicine, Hospital Dr. Nélio Mendonça, Funchal, Portugal
Correspondence: B. Soares Nunes
Intensive Care Medicine Experimental 2025,* 13(1)*:001600

Introduction: Traumatic brain injury (TBI) remains a major indication for admission to Intensive Care Units (ICUs) worldwide. The requirement for prolonged invasive mechanical ventilation (IMV) in this context often raises the consideration for tracheostomy (TQ). However, its influence on long-term outcomes such as mortality and neurological recovery continues to be debated.
Objectives: To investigate the association between tracheostomy and key clinical outcomes in patients with TBI, including duration of IMV, ICU length of stay, mortality, and functional recovery assessed using the Glasgow Outcome Scale (GOS). A secondary objective was to examine whether the severity of TBI at admission influences mortality or functional prognosis.
Methods: We conducted a retrospective observational study of 82 adult patients admitted with TBI to a mixed medical-surgical ICU between 2021 and 2023. Collected variables included demographic characteristics, TBI severity (mild, moderate, severe), duration of IMV, ICU stay, occurrence of reintubation, TQ performance and timing, in-hospital mortality, and functional outcomes at 3 and 6 months. Favorable neurological recovery was defined as GOS 4 or 5.
Results: Among the 82 patients, 28 (34%) underwent TQ. Patients in the TQ group had significantly prolonged ICU stays (22.9 vs. 6.6 days, $p < 0.00001$) and IMV duration (18.8 vs. 5.4 days, $p < 0.00001$), reflecting greater clinical complexity. Notably, in-hospital mortality was markedly lower in the tracheostomised group (7% vs. 59%, $p = 0.000003$). Although the proportion of patients achieving favorable functional outcomes at 6 months was higher in the TQ group (32% vs. 24%), this

difference was not statistically significant ($p = 0.44$). TBI severity at ICU admission was positively correlated with mortality ($p = 0.003$), but not with long-term functional recovery ($p = 0.36$). A trend toward lower TBI severity in the TQ group was observed, though this did not reach statistical significance ($p = 0.066$), suggesting that the observed mortality benefit may not be entirely attributable to baseline injury severity.
Conclusions: Patients with TBI who underwent tracheostomy exhibited significantly lower mortality rates. Despite the absence of a statistically significant difference in favorable functional outcomes, a positive trend was noted in the TQ group. The mortality benefit observed does not appear to be solely explained by differences in initial TBI severity, supporting the potential role of tracheostomy as a beneficial intervention in the intensive care management of severe TBI.

Neurosurgery in TBI: intervening early, but are we impacting late?

B. Soares Nunes[1]; P. Batarda Sena[1]; C. Lume[1]; F. Côrte-Real[1]; G. Faro Silva[1]; JJ. Nóbrega[1]
[1]Intensive Care Medicine, Hospital Dr. Nélio Mendonça, Funchal, Portugal

Intensive Care Medicine Experimental 2025,* 13(1)*:001601

Introduction: Traumatic brain injury (TBI) remains a leading cause of morbidity and mortality in critically ill patients. Neurosurgical interventions are often required in moderate to severe cases, yet their independent impact on patient outcomes remains debated, especially when accounting for baseline severity. Understanding the real-world effect of neurosurgery in the context of modern intensive care is essential to guide decision-making and resource allocation.
Objectives: To evaluate the impact of neurosurgical intervention on clinical outcomes in TBI patients admitted to the intensive care unit (ICU), with a specific focus on functional outcome at 3 and 6 months, ICU and hospital mortality, and the influence of intracranial pressure (ICP), Glasgow Coma Scale (GCS), and other prognostic markers.
Methods: We conducted a retrospective observational study over 3 years, including 82 patients admitted to a general ICU with a diagnosis of TBI. Patients were divided in two groups: those who underwent neurosurgical intervention within the first 24 h of ICU admission ($n = 40$), and those managed conservatively (n = 42). Variables analyzed included age, sex, GCS on admission, initial lactate, ICP (when monitored), length of ICU stay, type of neurosurgery, and outcomes such as Glasgow Outcome Scale (GOS) at 3 and 6 months, ICU and hospital mortality.
Results: Neurosurgical patients had a higher median GCS on admission compared to the non-surgical group (7 vs. 6, $p = 0.08$) and significantly longer ICU stays (13 vs. 7 days, $p = 0.02$). No statistically significant differences were observed in ICU mortality (35% with neurosurgery vs. 47.6% without, $p = 0.35$) or hospital mortality (26.9% vs. 13%, $p = 0.48$). The proportion of patients achieving a favorable functional outcome (GOS 4–5) at 6 months was 37% in the neurosurgical group, compared to 33% in the non-surgical group ($p = 0.53$). In multivariate regression analysis, neurosurgical intervention was not independently associated with improved GOS or mortality. Age and elevated ICP at admission were the strongest predictors of poor outcome ($p < 0.01$ and $p = 0.04$, respectively). GCS and lactate showed only marginal associations.
Conclusions: In routine ICU practice involving patients with TBI, neurosurgical intervention was not associated with a statistically significant difference in mortality or functional outcomes after adjusting for key prognostic variables. Age and intracranial pressure remain the most powerful independent predictors of prognosis. These findings underscore the need for individualized decision-making and further prospective studies to clarify the role of surgical intervention in specific TBI subpopulations.

Cross-flow plasmapheresis in long-COVID: preliminary results from a double-blind, placebo controlled randomized clinical trial

R. Bihariesingh-Sanchit[1]; R. Bansie[2]; D. Bustamente[1]; R. Ma[1]; A. Nierich[3]

Intensive Care Medicine Experimental 2025, 13(1)*:001603*

Introduction: Background:
Long COVID presents a significant clinical and socioeconomic burden, often marked by persistent fatigue, cognitive impairment, and reduced physical function (1). Emerging evidence suggests a role for fibrin microclots and autoantibodies in its pathogenesis (1, 2, 3). Cross-flow plasmapheresis (PF) using gravity-driven microfiltration may offer a novel, scalable, and low-cost treatment by removing pathogenic plasma components (4).

Methods: A single-center, double-blind, placebo-controlled randomized clinical trial was conducted to evaluate the efficacy, safety, and feasibility of PF in patients with Long COVID. Twenty-four adults meeting specific diagnostic thresholds (Chalder Fatigue Scale $\geq$ 6/11; SF-36 Physical Function $\leq$ 65/100) were randomized (1:1) to receive five sessions of either PF (n = 12) or sham treatment (placebo, n = 12). The primary endpoint was defined as a $\geq$ 30% reduction in Chalder Fatigue Scale scores at 90-day post-treatment (5, 6). Secondary outcomes included absolute and relative changes in fatigue, physical function (SF-36), laboratory biomarkers, adverse events, and procedural feasibility.
Results: Fourteen participants completed 90-day assessments (PF: n = 9; placebo: n = 5). PF led to a statistically significant relative reduction of 55% in fatigue scores (mean Chalder score decreased from 21.1 to 9.56; p = 0.0004, with a p = 0.0004) (Fig. 1). In contrast, the placebo group saw a 37% reduction (20.4–12.8; p = 0.1879). Improvement in physical function (SF-36) was also observed, with PF patients demonstrating a 70% increase (305.1–519.7; p = 0.0019) vs. 47% in the placebo group (316.6–465.2; p = 0.0630). Between-group differences, however, did not reach statistical significance for Chalder score (p = 0.8194) and SF-36 score (p = 0.8094). The intervention was well-tolerated, with no severe adverse events or procedural complications. Vascular access was successfully achieved in all patients using only peripheral lines.
Conclusions: Interim results suggest that cross-flow plasmapheresis may offer a safe and effective approach to alleviating fatigue in long COVID patients. While improvements in physical function were promising, statistical significance was limited by a small sample size.

The procedure's technical feasibility and absence of adverse events further support its potential utility. Final results from the full trial cohort (n = 24) are awaited to confirm therapeutic efficacy and inform broader clinical application.

Intensive Care Medicine Experimental 2025,* 13(1)*:001605

Introduction: Sepsis is defined as life-threatening organ dysfunction triggered by an underlying infection. Sepsis includes a broad spectrum of conditions with various clinical manifestations and patterns of acute organ dysfunction. In this study, we evaluated the clinical difference and trends associated with sites of infection in sepsis and septic shock patients.

Objectives: The purpose of this study is to evaluate the clinical differences and trends according to the site of infection in patients with sepsis and septic shock.
Methods: This single-center, retrospective cohort study involved 118 adult patients (age ≥ 18 years) diagnosed with sepsis or septic shock at Kangwon National University Hospital between January 2023 and December 2023. We classified the infections into six main types typically found in hospitalized patients: respiratory, gastrointestinal, biliary, genitourinary tract infections, skin and undifferentiated. The four infection categories with statistically significant differences in patient characteristics are presented in Table 1.
Results: Approximately 49.2% of the patients were male. Among them, 44.1% were admitted to the ICU, 45.8% were diagnosed with septic shock, and 40.7% died. In cases of respiratory infection, variables such as $PaCO_2$, PaO_2, HCO_3^-, FiO_2, and qSOFA showed statistically significant differences depending on the presence or absence of infection. For gastrointestinal tract infections, CRP levels were significantly lower in the infected group compared to the non-infected group. In biliary tract infections, ALP demonstrated statistical significance based on infection status, while in genitourinary tract infections, WBC levels showed a significant difference depending on infection. Procalcitonin, SOFA score, SAPS 3 score, and length of stay did not show statistical significance based on infection site involvement.
Conclusions: This study examined variables related to infection sites and found notable trends in respiratory infections depending on infection status. Further large-scale studies are needed to clarify site-specific characteristics.

Table 1 Baseline characteristics of four infection categories

***Intensive Care Medicine Experimental* 2025, 13(1):001606**

Introduction:
Pulmonary hypertension (PH) is a hemodynamic disorder defined by an abnormal increase in pulmonary arterial pressure and pulmonary arteriolar vascular resistance, resulting from multifactorial endothelial dysfunction and pathological vascular remodeling. It is a progressive and severe disease. PH is a frequent complication in critically ill patients and is associated with a poorer prognosis. Echocardiographic evaluation has become an essential tool for the non-invasive detection of signs suggestive of pulmonary hypertension, especially in settings, where clinical conditions preclude invasive methods. Early diagnosis of pulmonary hypertension is important, and transthoracic echocardiography stands out as the primary tool for detecting this disease in an early and non-invasive manner. Pulmonary hypertension in the critically ill patient, although sharing some similarities, is a distinct entity. Properly managing an acutely ill patient with PH is quite a challenge.

Objectives: To determine the prevalence of the risk of pulmonary hypertension in critically ill patients using echocardiography in the intensive care unit of ABC Medical Center.
Methods: This is a single-center, observational, descriptive, longitudinal, prospective study conducted from January 2025 to June 2025. Critically ill patients over 18 years of age, without a previous diagnosis of pulmonary hypertension, admitted to the Intensive Care Unit, will be included. The parameter used was the estimated pulmonary arterial systolic pressure, with a cutoff value above 35 mm Hg. All echocardiograms were performed by cardiologists specialized in echocardiography. The information collected from the clinical records, as well as the echocardiogram findings, was gathered by the principal investigators.
Results: Twenty-five echocardiograms were analyzed, of which 17 exhibited elevated pulmonary arterial systolic pressure (greater than 35), resulting in a prevalence of 68%, as illustrated in Graph 1. In this scenario, the mortality rate in the group with elevated PSAP is approximately 17.6% (3/17), whereas in the group with normal PSAP, it is 0%.
Conclusions: In this study, we found a prevalence of elevated PSAP of 68%, which is slightly higher than the 46.6% reported by Ñamendys-Silva. Likewise, the mortality rate in the elevated PSAP group was 17.6%. Although these findings contrast with the reported incidence of pulmonary arterial hypertension in the general population, they underscore the need for larger studies to determine the true prevalence at admission to intensive care units, the necessity of individualizing management in certain circumstances, and the importance of subsequent follow-up for these patients.

Graph1. Distribution of PSAP in echocardiogram according to their value.

Table 1 Distribution of deaths and survivors according to value of PSAP

PSAP Category	Deaths	Survivors	Total
Elevated PSAP	3	14	17
Normal PSAP	0	8	8
Total	3	22	25

Intensive Care Medicine Experimental 2025,* 13(1)*:001607

Introduction: [18F]fluoro-2-deoxy-D-glucose–positron emission tomography (FDG–PET) combined with computed tomography (CT) is a widely used imaging modality for detecting inflammatory lesions in patients admitted to the ward. However, its diagnostic yield and utility in the ICU remain unclear. Moreover, FDG–PET/CT requires adequate patient preparation which can be challenging in the ICU.
Objectives: We evaluated the diagnostic yield of FDG–PET/CT in ICU patients with systemic inflammation and assessed the effect of patient preparation on scan quality.
Methods: In this multicenter, retrospective cohort study, we included all adult ICU patients who underwent FDG–PET/CT for systemic inflammation in two academic and two non-academic teaching hospitals in the Netherlands between December 2013 and December 2023. The primary endpoints were diagnostic yield (new diagnoses and changes in patient management resulting from FDG-PET/CT findings) and scan quality as assessed on a 3-point scale by an expert panel of nuclear

medicine physicians. We used binary logistic regression to identify predictors of new diagnoses and changes in patient management. Predictors of scan quality were analyzed using ordinal random forest analysis.
Results: A total of 151 patients and 169 FDG–PET/CT scans were included. A diagnosis was made in 112 scans (66.3%), with 82 scans (48.5%) identifying new diagnoses. FDG–PET/CT led to a change in patient management in 99 cases (58.6%). A history of diabetes was associated with fewer new diagnoses (OR 0.47, 95% CI 0.22–0.97). Higher CRP levels (OR 1.002, 95% CI 1.000–1.005), use of renal replacement therapy (RRT) (OR 2.36, 95% CI 1.13–5.04), fever on the day of the scan request (OR 1.84, 95% CI 0.94–3.66) and total body FDG–PET/CT (OR 1.93, 95% CI 0.99–3.82) were independently associated with more new diagnoses. Similarly, total body scans (OR 2.23, 95% CI 1.16–4.36), use of RRT (OR 2.60, 95% CI 1.17–6.05), and fever on the day of the scan request (OR 2.00, 95% CI 1.00- 4.06) were positively associated with changes in patient management. No association was found between scan quality and diagnostic yield. Pre-scan glucose, cumulative dose of corticosteroids and SOFA score on the day of scan request were identified as the most important predictors of scan quality (Fig. 1). However, inter-observer agreement on scan quality was moderate (Cohen's $\kappa = 0.46$), resulting in limited predictive accuracy of the random forest model (54%).
Conclusions: FDG–PET/CT provides valuable diagnostic information and contributes to patient management decisions in the majority of critically ill patients with systemic inflammation. Its diagnostic yield is highest in patients with fever, elevated CRP, and those requiring RRT. Preventing hyperglycemia and limiting corticosteroid exposure may enhance scan quality. The high diagnostic yield and impact on clinical management support broader consideration of FDG–PET/CT in the ICU, particularly in patients with clinical features associated with greater diagnostic benefit.

Variable importance to predict FDG–PET/CT scan quality.

Intensive Care Medicine Experimental 2025,* 13(1)*:001608

Introduction: Subarachnoid hemorrhage (SAH) represents a severe neurological condition which poses significant morbidity and mortality, the latter reaching up to 66%. While trauma is the leading cause, non-traumatic SAH predominantly stems from cerebral aneurysms (up to 85%), more frequently in women around 55 years and is associated with risk factors such as hypertension and smoking. Given its complex clinical course, SAH requires intensive management in an ICU setting.
Objectives: This study aims to characterize the clinical features, management and outcomes of ICU patients with SAH. Primary endpoints are ICU mortality and length-of-stay. Secondary endpoints include SAH etiology, complication rates and use of therapeutic modalities such as nimodipine and milrinone.
Methods: We conducted a retrospective analysis including adult patients admitted to the Intensive Care Unit between July 2023 and December 2024 which were diagnosed with SAH. Data collected included demographics, comorbidities, severity scores (SOFA, APACHE II, SAPS II), SAH etiology (traumatic vs. non-traumatic), complications, therapeutic strategies, and outcomes.
Results: We identified 46 ICU admissions. Median age was 59 years (23–85) and 54.35% were female. Common comorbidities included hypertension (21.82%), dyslipidemia (16.36%), and diabetes (12.73%). Median SOFA score was 2, APACHE II 14.5, and SAPS II 31. Non-traumatic SAH accounted for 76.09%, with aneurysmal SAH representing 65.71% of these. Other causes were considered angionegative or undetermined (28.57%), arteriovenous malformations (5.71%). ICU mortality was 15.22%, higher in non-traumatic cases (17.14%) vs. traumatic (9.09%). Early mortality (< 72 h) occurred in 6.52%, all in non-traumatic SAH. Median ICU stay was 15.1 days (1–73), with longer stays in non-traumatic SAH (26.97 vs. 9.88 days).
Cerebral vasospasm was the most frequent complication (36.96%), followed by hydrocephalus ($n = 4$), cerebral ischemia ($n = 3$), and status epilepticus ($n = 1$). Nimodipine was administered enterally in 33 patients and intra-arterially in 6 patients. Mortality was lower in patients receiving nimodipine (12.12%) than in those who did not receive (23.08%). Milrinone was used in 9 patients, with mortality of 11.11% vs. 16.22% in those not treated.
Conclusions: This interim analysis highlights the burden of SAH in the ICU. As with current evidence, the majority of cases occurred in middle-aged women and hypertension was the most prevalent risk factor. High frequency of non-traumatic cases may reflect referral patterns to specialized centers. Cerebral vasospasm remains the most frequent complication. Nimodipine use was associated with lower mortality, supporting its role in vasospasm prevention, and milrinone may offer benefits. Further analysis will explore this possible association and assess possible predictors of poor outcomes.

Intensive Care Medicine Experimental 2025,* 13(1)*:001609

Introduction: Healthcare-associated infections (HAIs) represent a significant global health challenge, contributing to increased morbimortality and healthcare costs. A major concern is the substantial

burden they place on antimicrobial treatment strategies, as HAIs are frequently caused by multidrug-resistant organisms.
Objectives: The aim of this study is to evaluate the clinical and economic impact of healthcare-associated infections.
Methods: We conducted a retrospective study including all patients admitted to the intensive care unit (ICU) of Zaghouan's regional hospital in Tunisia for over 48 h of the period between November 2024 and April 2025. Demographic, clinical, therapeutic, and evolutionary data were collected. The incidence of health-care infections was calculated and the cost of antimicrobial treatments including antibiotics, antivirals, antifungi, and corticosteroids was estimated in Tunisian Dinar (TND).
Results: We 100 included patients. Median age of 59 years [39–71], predominantly male. At admission, median severity scores SAPSII and APACHE II were 27 [19–40] and 11 [7–19]. The primary reasons for ICU admission were acute respiratory distress syndrome (16%), severe acute exacerbation of chronic obstructive pulmonary disease (13%), and severe traumatic brain injury (13%). The most prevalent comorbidities were chronic obstructive pulmonary disease (25%) and hypertension (21%). Noninvasive ventilation was required in 35% of patients (NIV 35%, HFNC 12%) for a median duration of 3 days, while 57% underwent invasive mechanical ventilation (IMV) upon admission, with a median duration of 10 days [1–45]. The incidence of HAIs was 31%, with the most common infections being lower respiratory tract infections (22%), urinary tract infections (11%), and bloodstream infections (2%). The most frequently identified agents were *Acinetobcter baumannii* (25%). *Klebsiella pneumoniae* (20%), and *Pseudomonas aeruginosa* (16%),
A duration of IMV ≥ 14 days (cut-off derived from ROC analysis in Fig. 1; AUC 0.93 [0.853–1]) was significantly associated with increased HAI risk. Multivariate analysis confirmed IMV (ORa = 8.7, 95%CI [1.513–50.251], p = 0.015), along with corticosteroid therapy (ORa = 6, 95%CI [1.2–30.14], p = 0.028) and renal insufficiency (ORa = 5.5, 95%CI [1.18–25.8], p = 0.03), as independent risk factors. According to the WHO AwaRE (Access, Watch, Reserve) classification restricted classes of Watch/Reserve antibiotics, including imipenem (21%), colistin (19%), and tigecycline (13%), were frequently prescribed, contributing to total antimicrobial costs of 92 342 TND (~ 27 039 EUR) (with a median cost of 2488 TND [903–4312] per patient ~ 728 EUR). Mortality rate was 13%.
Conclusions: A high incidence of HAIs in ICU patients is strongly associated with prolonged mechanical ventilation, corticosteroid use, and renal insufficiency. Strengthening prevention measures and promoting rational antibiotic use are crucial to reducing this economic burden.

Intensive Care Medicine Experimental 2025,* 13(1)*:001612

Introduction: Tissue hypoxia monitoring is crucial for guiding resuscitation. The ratio of the carbon dioxide veno-arterial difference to the oxygen arterial-venous difference ($PvaCO_2/CavO_2$) is considered a surrogate marker of anaerobic metabolism. This parameter requires both central venous and arterial blood gas (BG) analysis. Nevertheless, $PvaCO_2/CavO_2$ reflects the ratio of CO_2 production (VCO_2) to O_2 consumption (VO_2) [respiratory quotient (RQ)] which can also be obtained noninvasively using indirect calorimetry (IC).
Objectives: This study aims to evaluate the ability of the RQ derived from IC (RQic) and the $PvaCO_2/CavO_2$ ratio from BG analysis in identifying anaerobic metabolism in critically ill patients.
Methods: Mechanically ventilated patients with sepsis who had a central venous catheter in place were included. IC and BG measurements, including arterial lactate, were performed simultaneously within the first 3 days of ICU admission. IC-derived variables (VO_2ic, VCO_2ic, and RQic) were recorded over a 20-min measurement period. BG-derived variables (VO_2bg, VCO_2bg, RQbg, $PvaCO_2$, and $PvaCO_2/CavO_2$) were calculated using paired arterial and central venous blood samples. VO_2bg and VCO_2bg were estimated via the Fick principle, using echocardiography-derived cardiac output. Anaerobic metabolism was defined as a lactate level ≥ 4 mmol/L. Receiver operating characteristic (ROC) curve analysis was used to evaluate the predictive performance of RQic, including the area under the curve (AUROC) and optimal cut-off value.
Results: Among 31 patients (mean age 67.5 years; 28-day mortality rate 35%), $PvaCO_2/CavO_2$ showed moderate correlations with RQic and RQbg (r = 0.43 and 0.56; p = 0.017 and 0.001, respectively), but no correlation with lactate (r = 0.07, p = 0.70). Patients with elevated lactate levels (≥ 4 mmol/L) had significantly higher RQic values compared to those with lower lactate levels (< 4 mmol/L) (0.96 ± 0.20 vs. 0.79 ± 0.09, p = 0.004), whereas $PvaCO_2/CavO_2$ and other measured parameters did not differ significantly between the groups (Table 1). In a regression model, RQic showed a moderate positive association with lactate levels and emerged as the most significant predictor (R = 0.5, R^2 = 0.25) (Fig. 1). ROC curve analysis revealed an AUROC of 0.78 (95% CI: 0.59–0.91) for RQic in predicting anaerobic metabolism. An RQic cutoff value of 0.9 yielded a sensitivity of 83% and a specificity of 81%.

Table 1 Comparison of indirect calorimetry- and blood gas-derived parameters between lower and elevated lactate groups. Data are presented as median (interquartile range, IQR) or mean (standard deviation, SD), as appropriate

Parameters	Arterial blood lactate		*p*-value
	< 4 mmol/L (N = 25)	≥ 4 mmol/L (N = 6)	
VO_2ic (ml/min)	231 (189.5–290)	251 (210.8–289.8)	0.57
VCO_2ic (ml/min)	162 (147–219)	235 (194.8–306)	0.09
RQic	0.79 ± 0.09	0.96 ± 0.2	0.004
VO_2bg (ml/min)	166.6 (135.3–262.5)	161 (75.3–187.2)	0.27
VCO_2bg (ml/min)	188.3 ± 93.7	147.4 ± 95.2	0.35
RQbg	0.94 ± 0.31	0.98 ± 0.54	0.84
$PvaCO_2/CavO_2$ (mmHg/ml)	1.8 ± 0.6	2.1 ± 0.8	0.28

Conclusions: In this study, the respiratory quotient derived from indirect calorimetry (RQic) was more effective than blood gas–derived parameters in identifying anaerobic metabolism in septic, mechanically ventilated patients. RQic showed fair predictive performance for lactate levels and may serve as a noninvasive marker for detecting anaerobic metabolism in critically ill patients.

Intensive Care Medicine Experimental 2025,* 13(1)*:001613

Introduction: Endotracheal intubation in the intensive care unit (ICU) is a high-risk procedure, particularly when performed by junior operators. Videolaryngoscopy (VL) has emerged as a tool to improve glottic visualization, but its effectiveness based on operator experience remains poorly understood.

Objectives: This study compares first-pass success rates and complications of video laryngoscopy (VL)-assisted urgent intubation between junior and senior critical care residents.
Methods: We conducted a prospective observational study of emergency intubations performed by residents in the intensive care unit at Zaghouan's regional hospital in Tunisia. Junior (first and second year residents) and senior (third and fourth year residents) operators were compared. Data included patient demographics, indication for intubation, first-pass success, number of attempts, hemodynamic changes, and complications (hypoxemia, hypotension, esophageal intubation, or cardiac arrest).
Results: We included 55 patients with a median age of 54 years [17–78] and a male predominance (sex ratio of 2.1). Among the urgent intubations analyzed (31 by junior residents and 24 by senior residents), the most common indications were combined failure involving two organ systems (37%), acute respiratory failure (27%), neurologic deterioration (26%), and shock (4%). Mallampati class III/IV was documented in 13% of patients, with a similar distribution between junior and senior groups (10% vs. 17%, $p = 0.69$). Overall, patients with Mallampati class III/IV had lower first-pass success rates compared to those with class I/II (43% vs. 90%, $p = 0.01$). In the junior group, first-pass success rates were comparable between Mallampati class III/IV and I/II (67% vs. 82%, $p = 0.49$), whereas in the senior group, Mallampati class III/IV was associated with significantly lower first-pass success (25% vs. 100%, $p = 0.002$). Overall first-pass success rates were similar between junior and senior groups (81% vs. 88%, $p = 0.72$), with both groups requiring a median of 1 attempt. No significant differences were observed in rates of severe hypoxemia (13% vs. 25%, $p = 0.30$), esophageal intubation (3% vs. 4%, $p = 1.00$), or cardiac arrest (10% vs. 4%, $p = 0.62$).
Conclusions: Both junior and senior critical care residents achieved similar first-pass success and complication rates when performing VL-assisted intubations in the ICU. The absence of superior performance by senior residents may stem from slower adaptation to videolaryngoscopy, while junior residents adapted more readily. These findings suggest that structured simulation training and supervised clinical practice could further standardize proficiency across all experience levels, narrowing any residual performance gaps.

Intensive Care Medicine Experimental 2025,* 13(1)*:001614

Introduction: Subarachnoid haemorrhage (SAH) is a common cause for admission to critical care. SAH is a life-threatening condition that is often associated with a long ICU stay and places patients at risk of complications. Common complications include: nosocomial infection, vasospasm and delayed cerebral ischaemia, perturbations in serum sodium concentrations and seizures. The evidence bases for interventions to manage the complications of SAH is limited.
Objectives: This service evaluation was designed to capture the frequency of the major complications of SAH at our hospital and the breadth of treatments that are employed.
Methods: Medical records of all patients admitted between 17/04/2020 and 31/01/2023 with aneurysmal subarachnoid haemorrhage admitted to ICU were reviewed. Data were captured covering their ICU stay(s). All non-aneurysmal SAH were excluded from analysis. Frequency of complications of SAH are presented with descriptive statistics of number of events and percentage of all cases and quantitative variables are presented as median and range.

Results: 172 patients' data were reviewed. 62 patients (36%) were male. The median age of the patients was 54. They belonged to the age range of 22 years to 96 years. The Median Charlston Comorbidity Index was 1 (Range of 0 -9). The median Glasgow Coma Score was 14 (Range of 3–15). The median Fisher grade was 4 (Range of 1–4). Aneurysms were found mostly (73%) in anterior circulations (126 patients). 93 patients (54%) of SAH were associated with intraventricular haemorrhage and 65 patients (38%) of them developed hydrocephalus, with 27% requiring ventricular drain. 110 patients (64%) were managed by coiling and 33 patients (19%) were managed by clipping. 2 of the patients had both coiling and clipping and in 10 patients (6%) had other forms of management. 17 patients (10%) did not receive any intervention. Post intervention systolic blood pressure (SBP) targets were found to be extremely variable with 140–160 mmHg being the most common. The range of SBP targets varied between normotension to as high as 160–180 mmHg.
Rebleed happened in 10 patients (6%). 65 patients (38%) developed vasospasm and 43 patients developed delayed cerebral ischaemia (DCI) (25%). Most of the DCI was managed conservatively in 31 patients (74%). In 11 patients (25%) DCI was managed by angioplasties [chemical angioplasty in 8 patients (19%) and mechanical angioplasty in 3 patients (6%)]. In 1 patient, DCI management was not documented. Hyponatraemia occurred in 69 patients (40%). 19 patients (11%) developed diabetes insipidus.
Extended Glasgow Outcome Scores (GOS-E) at 12 weeks were calculated for 104 patients (68 patients were lost to follow-up). Mortality was 16% and good recovery (GOS-E 7 and 8) occurred in 33 patients (31%). 14 patients (13%) had severe disability including vegetative state (GOS-E 2, 3 and 4).
Conclusions: In this case series of aneurysmal subarachnoid haemorrhages form a tertiary referral centre in the United Kingdom, we found that complication rates were broadly in line with those reported in the published literature.

Intensive Care Medicine Experimental 2025,* 13(1)*:001615

Introduction: Eosinopenia is known to reflect systemic inflammation and physiologic stress. However, its prognostic value in community-acquired pneumonia (CAP) requiring intensive care remains unclear.
Objectives: The aim of this study was to assess eosinophil kinetics and their association with clinical severity and outcomes in ICU-admitted CAP patients.
Methods: We conducted a retrospective descriptive study over 2 years (March 2023–March 2025) in a medical ICU. All patients admitted for severe CAP were included. Eosinophil count was measured at ICU admission and monitored throughout the stay. Eosinopenia was defined as < 50 cells/µL. Clinical data and outcomes were recorded. Severity was defined by escalation of oxygen therapy, need for invasive mechanical ventilation, and ICU mortality.
Results: Sixty-three patients were included (mean age 58 ± 18 years; male/female ratio 3.2). Mean SAPS II was 31.6 ± 15; median APACHE II was 10 [20–40]. Hypertension (36.5%) and diabetes (27%) were the most common comorbidities. Pneumonia was bacterial in 68.3%, viral in 41.3%, with co-infection in 24% and fungal in 5%. Eosinopenia at admission was present in 57.1%, with a median eosinophil count of 40 [20–60]/µL. Initial FiO_2 requirement was 54 ± 24%. Bilateral radiological infiltrates were present in 82% (ground-glass opacities 70%, consolidations 45%). Lab tests showed WBC 12,337 ± 6000/mm^3, neutrophils 10,118 [10,970–40,720]/mm^3, and CRP 117 ± 48 mg/L. High-flow oxygen was used in 30%, and non-invasive ventilation in 65%. Invasive mechanical ventilation (IMV) was needed in 55.6% after 5 ± 3 days. Septic shock occurred in 22%, tracheostomy in 19%, extubation in 31%, and mortality reached 32%. Eosinopenia at admission was significantly associated with viral pneumonia ($p = 0.046$), oxygen escalation ($p = 0.003$), and mortality ($p < 0.001$). Risk factors for death included age ($p = 0.018$), APACHE II ($p < 0.001$), SAPS II ($p < 0.001$), septic shock ($p = 0.001$), and IMV ($p = 0.001$). Eosinopenia on day 3 ($p = 0.006$), increasing oxygen needs ($p < 0.001$), and eosinophil collapse during the stay ($p = 0.004$) were strongly associated with poor outcomes. ROC analysis showed an eosinophil cutoff of 45/µL predicted severity with an AUC of 0.77 [0.65–0.88], sensitivity 69%, and specificity 70%(see figure). IMV was significantly associated with diabetes ($p = 0.012$), viral pneumonia ($p = 0.02$), oxygen escalation ($p < 0.001$), and eosinophil decline ($p = 0.041$).
Conclusions: Early eosinopenia and its persistence during ICU stay are strongly associated with clinical deterioration and mortality in severe CAP. Eosinophil count may serve as a simple, early biomarker to help identify high-risk patients and guide management in critical care settings.

ROC Curve of Admission Eosinophil Count for Predicting Mortality.

Albumin in the neurocritical care patient: don't look back in anger

R. Torres[1]; AC. Cunha[2]; J. Rodrigues[3]; T. Mariana[4]; R. Salgado[1]; SB. Rodrigues[1]; É. Costa[5]; I. Jesus Pereira[6]
[1]Serviço de Medicina Intensiva Polivalente, Unidade Local de Saúde de Gaia e Espinho, Vila Nova de Gaia, Portugal; [2]Intensive Care Unit, Unidade Local de Saúde da Região de Leiria, Leiria, Portugal; [3]Serviço de Medicina Intensiva, Hospital de Abrantes, Abrantes, Portugal; [4]Serviço de Medicina Intensiva, Unidade Lo, Vila Nova Gaia, Portugal; [5]Department of intensive care, Centro Hospitalar Vila Nova de Gaia/Espinho, Vila Nova de Gaia, Portugal; [6]Emergency and intensive care unit, University Hospital Center of Algarve, Faro, Faro, Portugal
Correspondence: R. Torres
Intensive Care Medicine Experimental 2025,* 13(1)*:001616

Introduction: Albumin is an endogenous plasma protein involved in several physiological processes relevant to the critically ill patient. The therapeutic use in neurocritical care is controversial, due to scarce literature and low-quality evidence, as the neuroprotective benefits have not been consistently demonstrated in clinical trials. The study protocols varied in inclusion criteria, assessment metrics, dosage and even in the formulation used. The latter has particular relevance, as changes in outcome could be explained by the osmolarity differences between 4% and 20% albumin formulations used in the different studies.
Objectives: To evaluate the impact of 20% albumin administration on clinical outcomes in neurocritical patients. The endpoints studied were centered on mortality and length of ICU stay.
Methods: The authors conducted a single center retrospective analysis of patients admitted between 2021 and 2024 for level 3 neurocritical care. Patients admitted for potential organ donation were excluded.
Results: Data analysis returned 749 patients, 38 treated with albumin. Overall ICU mortality was 22.8%, while in the albumin-treated group mortality reached 51.2%. Mortality at 28 days was 38.4% in the albumin group, while in the overall sample was 25.6%, which correlates to the longer ICU stay of these patients—mean ICU length of stay was 12 days for all neurocritical patients, whereas in the albumin-treated group, the mean rose to 22.5.

The groups were also different in terms of demographics and severity of disease. No significant differences were found in gender distribution; however, median age was 62 years in the overall sample vs. 56 years in the albumin group. Severity of disease, calculated by APACHE II and SAPS II, shows an important difference between the groups: while the overall sample had a mean APACHE II of 17.77 and SAPS II of 38.95, the albumin group had a mean APACHE II of 23.05 and SAPS II of 49.64. Admissions for elective surgical, urgent surgical and medical patients were distributed similarly, but trauma admissions were more frequent in the albumin-treated group (36.8% vs. 29.6%). Mortality was lower in trauma patients of the albumin cohort, while in the elective surgery cohort the use of albumin proved detrimental to the outcome (despite a very small sample size of albumin treated cohort).
Conclusions: Data were collected subsequent to 2018, at which point the recommendations by ESICM were made to avoid the use of albumin in neurocritical care. Hence, these results could be interpreted in light of this guidance, i.e., the use of albumin seems to constitute a rescue treatment strategy. Therefore, the authors raise the question of whether, in such a retrospective approach, would it be more useful to conduct a statistical analysis of the impact of albumin administration on survival or to perform a morbimortality review of each clinical context, to establish specific indications supported by appropriately tailored protocols.

Developing a protocol for obstetric emergencies in intensive care unit

D. Silva[1]; M. Neves[1]; J. Abreu[1]; R. Rato[1]; N. Lourenço[1]; P. Costa[1]; J. Gabriel[1]
[1]Intensive Care, Hospital Amato Lusitano, Castelo Branco, Portugal

Intensive Care Medicine Experimental 2025,* 13(1)*:001617

Introduction: Severe acute maternal morbidity, or "near misses," refers to life-threatening complications during pregnancy or postpartum that require urgent care. The complexity of managing pregnant patients is increasing due to advanced maternal age and coexisting

conditions. Obstetric ICU admissions, most commonly for major hemorrhage, sepsis, and pre-eclampsia, serve as critical indicators of clinical severity and healthcare quality. Standardized protocols and multidisciplinary coordination improve maternal outcomes and reduce preventable mortality. Despite experienced teams, emergencies may still result in missed interventions, highlighting the need for clear, structured management protocols.
Objectives: To develop standardized, flowsheet-based protocols for common obstetric emergencies in the ICU, aimed at improving rapid assessment, clinical response, and overall maternal and neonatal outcomes.
Methods: We conducted a systematic review of current guidelines and recent studies in maternal critical care. We also analyzed Obstetric Admissions to the Intensive Care Unit in a secondary Portuguese hospital between January 2023 and January 2025 using SPSS. The protocol development process also included a review of an informal internal document and engagement of ICU staff through an expository presentation about Obstetric Emergencies and Emergencies and a feedback questionnaire.
Results: In our hospital, a rate slightly lower than 1% was observed in preliminary data, but in line with the low prevalence described of pregnant and postpartum women who required ICU admission.
Following an internal presentation session, majority of participating ICU staff agreed on the importance of formal protocols and the need for training in this area. Flowsheets for hemorrhage, pre-eclampsia (including HELLP and eclampsia), and maternal sepsis are currently under development, with planned inclusion of Amniotic fluid embolism and Acute fatty liver of pregnancy.

Conclusions:Developing structured, stepwise protocols for obstetric emergencies in ICU settings facilitates early recognition and intervention, reduces clinical errors, and promotes better maternal–fetal outcomes. ICU team engagement in protocol creation supports sustainable implementation.

Systemic inflammatory response and associated outcomes in cardiac surgery

JDJ. Nuño Pulido[1]; D. Manzur Sandoval[1]; N. Queb[1]
[1]Cardiovascular Intensive Care Unit, National Institute of Cardiology Ignacio Chavez, Ciudad de México, Mexico
Correspondence: N. Queb
Intensive Care Medicine Experimental 2025,* 13(1)*:001619

Introduction: The inflammatory response following cardiac surgery is triggered by a combination of surgical trauma, cardiopulmonary bypass (CPB), endotoxemia, and ischemia–reperfusion injury. 1 Additional contributing factors include temperature variation, anesthetic agents, and oxidative stress. 2 Patients often present with a chronic preoperative inflammatory state related to their cardiac condition or comorbidities such as diabetes and dyslipidemia.
Objectives: To determine whether systemic inflammatory response syndrome (SIRS) criteria are associated with adverse outcomes in patients undergoing cardiac surgery.
Methods: A retrospective observational cohort study was conducted from June 1, 2022, to December 31, 2023. Patients were classified based on compliance with SIRS criteria, and logistic regression was applied to assess associations with clinical outcomes.
Results: A total of 546 patients were included; 174 (31.86%) met SIRS criteria. The mean age was 57 years; 56.8% were male and 43.2% female. The most frequent comorbidities were hypertension (41.6%) and diabetes (22.8%). Patients with SIRS had a significantly longer aortic cross-clamp time (106 vs. 96 min) compared to those without postoperative SIRS. Multivariate analysis adjusted for age and sex revealed that SIRS was significantly associated with increased risk of:

Variable	OR	95% CI	*p*-value
Mediastinal bleeding	2.08	1.24–3.48	0.00
Vasoplegia	1.79	0.92–3.49	0.08
Postcardiotomy low cardiac output	1.71	1.02–2.85	0.04
Hypovolemia	1.44	0.99–2.08	0.05
Blood transfusion	1.54	1.07–2.22	0.02
Acute kidney injury	1.69	1.15–2.48	0.00
Renal replacement therapy	2.10	1.03–4.26	0.04
In-hospital mortality	1.83	0.90–3.72	0.09
Delirium	1.88	1.11–3.16	0.01

Conclusions:
SIRS criteria were present in 31.86% of post-cardiac surgery patients undergoing CPB. This condition was associated with a higher incidence of postoperative complications and hospital mortality, regardless of initial *C*-reactive protein levels or hemodynamic parameters. Early identification of these patients enables closer monitoring and timely intervention, potentially improving clinical outcomes in the cardiovascular intensive care unit.

Monitoring of respiratory and non-respiratory muscles at the spontaneous breathing onset of ARDS patients who received controlled mechanical ventilation more than 48 h

R. Cornejo; M. Campero; R. Brito; R. Hughes; D. Arellano; A. Bruhn; M. Lazo; A. Gajardo; A. Fuentes; E. Paredes; V. Rojas[1]; MF. Bravo[1]; MJ. Martin[1]; L. Miranda[1]; C. Morais[2]; JN. Medel[1]; N. Estuardo

Intensive Care Medicine Experimental 2025,* 13(1)*:001621

Introduction: Ventilator-induced diaphragmatic dysfunction (VIDD) and Intensive Care Unit-acquired weakness (ICUAW) are common complications associated with prolonged mechanical ventilation (MV) and critical illness in patients with acute respiratory distress syndrome (ARDS). Both conditions contribute significantly to delayed weaning from MV, increased hospital mortality, and long-term functional impairment among survivors. The transition from controlled to spontaneous breathing (SB) constitutes a critical—and still underexplored—phase for the early identification of VIDD and ICUAW.
Objectives: To characterize the respiratory pattern and functional status of the diaphragm, accessory respiratory muscles, and non-respiratory muscles at the onset of spontaneous breathing in patients with ARDS who received prolonged controlled MV.
Methods: Patients with ARDS who had undergone protective controlled MV for more than 48 h, with stable hemodynamic status and adequate consciousness and effort to initiate SB under pressure support ventilation, were prospectively enrolled. We performed a multimodal physiological assessment included conventional electromyography (EMG) of the external intercostal and anterior tibial muscles, electrical activity of the diaphragm (EAdi), diaphragmatic ultrasound, and measurement of respiratory mechanics—including esophageal and gastric pressures—to evaluate expiratory muscle activation.
Results: Nine patients were included (56 ± 14 years; PaO_2/FiO_2 210 [200–217] mmHg; 4 ± 2 days on MV); one of them was excluded due to the new diagnosis of Steinert myotonic dystrophy. EMG revealed that all patients exhibited neuromyopathic involvement. The main findings included increased insertional activity (8/8 patients), fibrillations/positive sharp waves (8/8 patients), early (3/6 patients) or reduced (3/6 patients) recruitment, predominantly polyphasic morphology (6/6 patients), and a poor or interferential pattern (6/6 patients). In 2 cases we observed the absence of voluntary activity. Diaphragmatic ultrasound showed that all patients had at least one parameter suggestive of diaphragmatic dysfunction (shortening fraction < 30% (5/7 patients), end-expiratory thickness < 2 mm (6/7 patients), or excursion < 2 cm (6/7 patients)). Activation of abdominal expiratory muscles was observed in 6 of 8 (75%) patients.
Conclusions: The main findings of the multimodal assessment in this patient population are consistent with denervation processes and/or mild to moderate myopathy, supporting the presence of VIDD and ICUAW. The diaphragm appears to be more severely affected than other respiratory muscles, and activation of expiratory muscles is highly prevalent. Both the apparent degree of myopathy and early signs of reinnervation suggest a favorable potential for functional recovery.

Intensive Care Medicine Experimental 2025,* 13(1)*:001622

Introduction: In septic shock patients, the response to a fluid bolus in terms of macrohemodynamic variables, i.e., cardiac output (CO) and mean arterial pressure (MAP), does not guaranty an improvement in tissue perfusion. The latter has been attributed to microvascular alterations. The passive leg raising test (PLR) is widely used to detect a state of preload responsiveness. Whether the assessment of the respiratory variations of red blood cell velocities (RBCv) in the sublingual capillaries may help to define the pattern of microcirculatory flow in different preload conditions is unknown.
Objectives: To compare the relationship between changes in CO and MAP induced by preload responsiveness tests and fluid infusion on the one hand and simultaneous changes in microcirculatory variables on the other hand, at the early and late phases of septic shock resuscitation.
Methods: Prospective, observational, cohort study. We included 15 septic shock patients on mechanical ventilation and 11 healthy volunteers.
Systemic hemodynamics, including continuous CO monitoring (PiCCO2 device), ventilatory parameters, perfusion indexes such as capillary refill time (CRT) and perfusion index (PI), and sublingual microcirculatory variables (IDF videomicroscope), were recorded at the early and late phases of septic shock resuscitation (Fig. 1).
Results: Fifty-three percent of septic patients were preload responders (PR +).
PLR test increased MAP both in PR + and PR- (from 80 ± 11 to 94 ± 21 mm Hg, p-value = 0.01, vs. 85 ± 15–90 ± 13 mm Hg, p-value = 0.03, respectively).
Microvascular parameters did not differ between PR + and PR- on study inclusion. However, during the PLR maneuver, perfused vascular density (PVD) had a trend toward an increase in PR + (from 16.5 [14.8–17.7] to 18.5 [17.2–21.0] mm/mm2, p = 0.07), while it did not change in PR- patients (from 17.0 [16.5–17.2] to 16.0 [14.9–19.0] mm/mm2, p = NS). RBCv, a convective parameter of microvascular flow, had a significant increase from baseline both during PLR test (from 757 [723–793] to 946 [893–995] µm/sec, p-value = 0.001) and after a fluid bolus (from 789 [734–860] to 971 [951–1025) µm/sec, p-value = 0.01).
There was no correlation of microvascular parameters-such as density and proportion of perfused vessels- and MAP or CI both at baseline and during PLR. Conversely, we found a significant correlation between changes in RBCv and variations in CI during the PLR test at admission and after 24 h (R2 = 0.48, p-value = 0.0006, R2 = 0.47 p = 0.014). On the third day, the strength of the simultaneous changes decreased and lost association (R2 = 0.26, p-value = 0.84).
The ratio of percentage of changes of RBCv over percentages of changes of CI (ΔRBCv/ΔCI) was 1.16 ± 0.85 in PR +, while it was larger -5.02 ± 8.15 in PR- (Fig. 4).

In this preliminary study, we found neither significant correlations between CRT and different microvascular parameters nor between CRT and PLR induced changes in MAP or CI.
Conclusions: In states of preload responsiveness, we found a correlation of changes in CI and RBCv of sublingual capillaries during PLR test and a trend toward an improvement in perfused vascular density. This association loses strength over the days. The ΔRBCv/ΔCI ratio could be an indicator of the degree of coherence between microvascular flow and cardiac index.

Effectiveness of artificial intelligence/machine learning in predicting respiratory failure in postoperative patients: a systematic review and meta-analysis

M. rosamystica[1]; R. Kashyap[2]; FA. Nawaz[3]; V. Bansal[2]
[1]Medicine, David Tvildiani Medical University, T'bilisi, Georgia; [2]Research, Department of Research, WellSpan Health, York, PA, USA., York, United States of America; [3]Psychiatry, Al Amal Psychiatric Hospital, Emirates Health Services Dubai, United Arab Emirates., Dubai, United Arab Emirates
Correspondence: M. rosamystica
Intensive Care Medicine Experimental 2025,* 13(1):*001623

Introduction: Postoperative respiratory failure (PRF) characterized by the requirements of mechanical ventilation ≥ 48 h or unplanned intubation, is a prevalent complication with high morbidity and mortality. (1) Reliance on administrative data, documentation accuracy, and outdated diagnostic codes, potentially hindering early intervention. Artificial intelligence (AI) and machine learning (ML) models are increasingly utilized in various medical fields to enhance predictive accuracy by integrating complex perioperative data.(2) (3) To address this issue, we conducted a systematic review and meta-analysis to investigate the effectiveness of AI/ML models for predicting respiratory failure in postoperative patients.
Methods: We conducted a comprehensive search of three databases, PubMed, Scopus, and Embase, and identified 139 relevant studies published within the past 10 years. A total of 95 articles underwent screening for detailed review which led to the inclusion of 12 articles in the systematic review, and 7 articles with suitable data were subjected to meta-analysis.
Our analysis included cohort studies comparing the predictive performance of 19 prognostic models (Random Forest, Conventional Deep Learning, GANomaly, LightGBM, XGBoost, Respire, Ariscat, SPORC-1, Lasso, Logistic regression, Generalized Linear Model Approach (GLM), Image-based Deep Learning Model) in identifying respiratory failure in postoperative adult patients.
Results: SPORC-1 achieved the highest sensitivity and identified 87% of patients who developed respiratory failure. Random Forest before the Synthetic Minority Oversampling Technique (SMOTE) which is a technique to handle the issue of data imbalance in the study, achieved the highest specificity and was able to identify 99.80% of patients who did not develop respiratory failure. XGBoost was able to discriminate between positive and negative cases with AUC 93% of the time.
The meta-analysis from seven studies predicted the risk of respiratory failure as a postoperative complication. The pooled sensitivity was 0.618 (95% CI: 0.517–0.71), indicating that the models correctly identified 61.8% of patients who developed respiratory failure.
The pooled specificity was 0.752 (95% CI 0.50–0.902), suggesting that the models correctly identified 75.2% of patients who did not develop respiratory failure.
There was substantial heterogeneity among the studies, as evidenced by the high I2 values for both sensitivity (I^2 = 0.992) and specificity (I^2 = 1).
Conclusions: Overall meta-analysis of the included models demonstrated moderate sensitivity and specificity for predicting respiratory failure in postoperative patients with substantial heterogeneity across the studies.

Intensive Care Medicine Experimental 2025,* 13(1):*001624

Introduction: The aim of this study is to assess whether a novel Modified Psoas Muscle Index (mPMI)—calculated by multiplying the longest and shortest diameters of the psoas muscle at L3 and normalizing by height squared—could serve as a reliable predictor of adverse outcomes in critically ill surgical patients.
Objectives: The aim of this study is to assess whether a novel Modified Psoas Muscle Index (mPMI)—calculated by multiplying the

longest and shortest diameters of the psoas muscle at L3 and normalizing by height squared—could serve as a reliable predictor of adverse outcomes in critically ill surgical patients.
Methods: In this retrospective study, 704 patients who underwent abdominal CT scans before intensive care unit (ICU) admission and during or after ICU stay were included. Demographic, clinical, and laboratory data were collected. Conventional psoas measurements and the mPMI were compared using receiver operating characteristic (ROC) analysis. Multivariable logistic regression and correlation analyses were performed to identify independent predictors of mortality and to explore associations between mPMI and clinical variables.
Results: Patients who experienced decreased muscle area had larger baseline psoas measurements ($p < 0.005$) and a higher proportion of females ($p < 0.005$). ROC analysis indicated that the mPMI outperformed conventional area measurements in identifying patients with reduced muscle reserves. After adjusting for confounding factors, the mPMI was independently associated with mortality (Exp(B) = 1.062, $p = 0.014$). Correlation analyses showed modest links between mPMI, age, and certain laboratory markers.
Conclusions: The mPMI offers a practical, imaging-based approach to evaluating sarcopenia in critically ill patients, circumventing the challenges of muscle strength assessment in the ICU. Its predictive value for sarcopenia highlights the potential benefit of including mPMI in routine ICU evaluations. Future prospective studies are warranted to validate these findings and refine sarcopenia management strategies in critically ill populations.

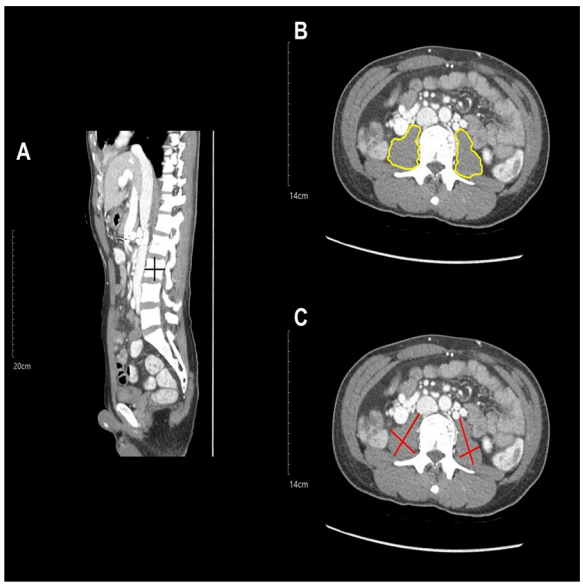

Figure 1 Measurement of the cross-sectional area of the psoas muscle and modified psoas muscle index (mPMI) at the level of the third lumbar vertebra (L3)
A Identification of the level of L3 (black cross) on the sagittal computed tomography (CT) image.
B Cross-sectional area of the bilateral psoas muscles (yellow line) on the axial CT image at the level of L3. The cross-sectional area was measured using the area measurement tool in the Picture Archiving and Communication System.
C Measure the mPMI of the bilateral psoas muscles on the axial CT image at the level of L3 (red lines). The mPMI is calculated by measuring the longest and shortest diameters of the psoas muscles, multiplying these values and normalizing by the square of the patient's height.

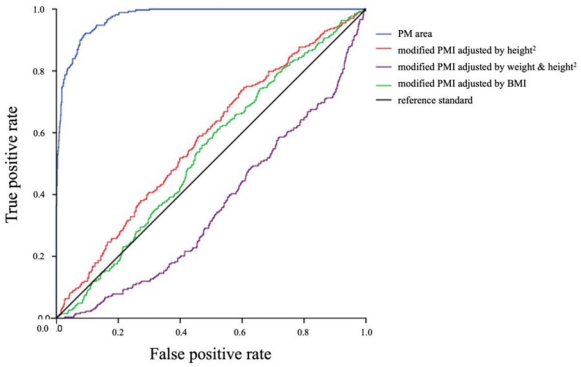

Figure 2 Receiver operating characteristic (ROC) curve comparing the conventional psoas muscle cross-sectional area, multiplication of psoas diameters, and various normalization methods of the modified psoas index (PMI). ROC curves comparing various forms of the PMI in predicting sarcopenia. The *y*-axis represents true positive rate (sensitivity), the *x*-axis represents false positive rate (1-specificity), and the diagonal reference line indicates a test with no discriminative power (area under the curve = 0.5). Each line represents the following, the conventional cross-sectional area of the psoas muscle (blue line); the modified PMI adjusted by height (red line); the modified PMI adjusted by weight and height (purple line); the modified PMI adjusted by body mass index (green line)

Topic: Nursing care and physiotherapy.

Physiological effects of prone positioning and thoraco-abdominal binding on muscle–ventilation dynamics in ARDS patients at the onset of spontaneous breathing

R. Cornejo[1]; R. Brito[1]; D. Arellano[2]; M. Campero[3]; R. Hughes[3]; A. Bruhn[4]; M. Lazo[5]; A. Gajardo[1]; A. Fuentes[1]; E. Paredes[1]; V. Rojas[1]; MF. Bravo[1]; MJ. Martin[1]; L. Miranda[1]; C. Morais[6]; JN. Medel[1]; N. Estuardo[1]

Correspondence: R. Brito
Intensive Care Medicine Experimental 2025,* 13(1)*:001625

Introduction: Prone positioning provides lung-protective effects during controlled mechanical ventilation (MV) in patients with acute respiratory distress syndrome (ARDS) (1). However, its role in mitigating effort-related lung and diaphragmatic injury during the transition to spontaneous breathing remains insufficiently characterized. On the other hand, abdominal binding has been shown to enhance the neuromuscular efficiency of the diaphragm in non-ventilated individuals (2), suggesting potential utility in ARDS patients spontaneously breathing with diaphragmatic weakness/dysfunction. Meanwhile, chest binding at the lower part of the thorax may contribute to the attenuation of paradoxical respiratory patterns associated with the recruitment of accessory respiratory muscles in this scenario.
Objectives: To evaluate the physiological effects of prone positioning and thoraco-abdominal binding on neuromuscular coupling, expiratory muscle activation and pendelluft magnitude in ARDS patients with more than 48 h of controlled MV who are initiating spontaneous breathing.

Methods: Study approved by the Institutional ethical committee (N.012/2022), including ARDS patients recovering spontaneous breathing after received at least 2 days of controlled ventilation (NCT05826847). A multimodal assessment of respiratory was performed at baseline. PEEP was individualized using electrical impedance tomography (EIT). Patients, under pressure support ventilation received either semi-recumbent position (SR) without and with thoraco-abdominal binding (BTA) and prone position (PP) in a crossover trial for 1 h each. Respiratory and EIT-related variables were recorded, including electrical activity of the diaphragm (EAdi), transdiaphragmatic pressure (Pdi), neuromuscular coupling (NMC = ΔPdi/ΔEAdi), the increase in expiratory gastric pressure (ΔPga-exp), as well as pendelluft magnitude. These variables were compared between the strategies using Mixed-ANOVA or Friedman test (including post-hoc tests). Spearman's test was used for correlations.
Results: Nine patients were included (56 ± 14 years; PaO_2/FiO_2 210 [200–217] mmHg; 4 ± 2 days on MV). Compared to SR, PP improves NMC (0.42 [0.25–1.08] cmH2O/μV vs. 0.82 [0.44–2.01] cmH2O/μV, $p = 0.004$) and decreases pendelluft magnitude (6.91 ± 4.2% vs. 3.43 ± 1.72%, $p = 0.014$). BTA has a trend to improve NMC with respect to SR (0.42 [0.25–1.08] cmH2O/μV vs. 0.68 [0.25–1.12] cmH2O/μV, $p = 0.119$)], but not reduces significantly pendelluft magnitude (6.91 ± 4.2% vs. 5.92 ± 4.29%, $p = 0.598$). No significant changes on ΔPga-exp are observed with PP or BTA considering the 6 patients who presented expiratory muscles activation (ΔPga-exp in SR, PP and BTA are 1.82 ± 0.78, 1.29 ± 1.48, 1.35 ± 1.13, respectively, $p = 0.410$). However, the decrease in pendelluft magnitude obtained with PP is directly correlated with the decrease in ΔPga exp ($r = 0.857$, $p = 0.024$).
Conclusions: In ARDS patients transitioning to spontaneous breathing after 48 h of controlled MV, PP enhanced neuromechanical coupling and reduced pendelluft magnitude compared to a semi-recumbent position. BTA exhibited a non- systematic effect on NMC and pendelluft. A higher sample size is needed to confirm these findings for the potential impact of simple strategies.

Intensive Care Medicine Experimental 2025,* 13(1)*:001627

Introduction: Higher levels of positive end-expiratory pressure (PEEP) and pressure support have been associated with a reduction in inspiratory effort. However, their impact on the magnitude of pendelluft remains inconsistent (1, 2). This study aimed to assess whether individualized settings of PEEP at different levels of ventilatory assistance can influence the magnitude of pendelluft, and to evaluate whether this effect is modulated by expiratory muscle activity in hypoxemic patients transitioning to spontaneous breathing, following a period of ≥ 48 h of protective controlled mechanical ventilation.
Methods: This physiological randomized crossover study compared individualized PEEP (PEEP-IND), set according to the lowest combination of collapse and overdistension according to electrical impedance tomography (EIT), with standardized PEEP (PEEP-ARDS), set according to the ARDS-Net protocol, in hypoxemic patients resuming spontaneous breathing under pressure support ventilation (PSV). Each patient underwent randomized application of pressure support levels at 5, 10, and 15 cmH_2O (each for 5 min) at both PEEP settings, which were also applied in a randomized order. The analysis was performed on data from the final 2 min of each pressure support level. Pendelluft magnitude was quantified as the percentage of lost volume from the non-dependent lung region displaced to the dependent region during inspiration using an EIT-based approach (3). Expiratory muscle activity was assessed by measuring the expiratory rise in gastric pressure (ΔPga-exp), while inspiratory effort was evaluated using esophageal pressure-derived variables, including muscular pressure (Pmus). Statistical analysis was conducted using repeated measures ANOVA and linear mixed-effects models. A p-value < 0.05 was considered statistically significant.
Results: Fifteen hypoxemic patients resuming spontaneous breathing on PSV (time on mechanical ventilation 9 [5–13] days and PaO2/FiO2 262 ± 51 mmHg, 6 females), were included. PEEP-IND was 11 [8–13] cmH2O and PEEP-ARDS was 6 [5–7] cmH2O. Expiratory muscle activation was observed in 13 patients. The main physiological variables are described in Table 1. Adjusting by pressure support, PEEP-IND was associated with a decrease in pendelluft magnitude (β of -1.99, $p = 0.042$) and an increase in ΔPga-exp (β of 0.56, $p = 0.015$) with respect to PEEP-ARDS. Meanwhile, adjusting by PEEP, pressure support was associated with a decrease in pendelluft magnitude (β of − 3.11, $p < 0.001$) and ΔPga-exp (β of − 0.75, $p < 0.001$). The intensity of the association between PEEP-IND and pendelluft magnitude increased when ΔPga-exp wasincluded in the model (β of − 2.48, $p = 0.027$); we observed an direct association between ΔPga-exp and pendelluft (β unadjusted of 2.13, $p < 0.001$), which remained after adjusting by PEEP and pressure support (β adjusted of 1.57, $p = 0.009$).
Conclusions: An EIT-guided PEEP strategy may reduce pendelluft magnitude in hypoxemic patients resuming spontaneous breathing. However, this potential benefit appears to be counterbalanced by increased expiratory muscle recruitment. The contribution of active expiration should be considered in future studies focused on the individualized titration of PEEP and pressure support during spontaneous breathing.

Early vs. delayed parenteral nutrition in sepsis: insights from a 50-patient ICU cohort

K. Karkoulias[1]; T. Alonistiotis[1]; AE. Zouridaki[2]; M. Avgoulea[1]; H. Christopoulou[1]; K. Kostoulas[1]; M. Stratouli[1]; M. Theodorakopoulou

Intensive Care Medicine Experimental 2025,* 13(1)*:001630

Introduction: Sepsis is a leading cause of mortality in intensive care units, often requiring specialized nutritional support. When enteral nutrition is not feasible or contraindicated, parenteral nutrition (PN) becomes essential. However, the timing (early vs. delayed) and effects of PN in septic patients remain controversial. Recent guidelines advocate for a balanced approach, often favoring delayed or supplemental PN in the sepsit patient. Early initiation of PN, however, may improve nutritional status and immune function but also carries a risk of complications.
Objectives: To investigate the clinical outcome of early vs. delayed initiation of PN in 50 septic patients admitted to the ICU.
Methods: A retrospective observational study was conducted on a 21-bed mixed ICU of a tertiary hospital involving 50 septic patients who received PN due to intolerance or contraindication to enteral feeding. Patients were divided into two groups: early PN (initiation $\leq$ 72 h from ICU admission) and delayed PN (> 72 h). Data collected included demographic characteristics, timing of PN initiation, duration of PN, duration of mechanical ventilation, infection rates, ICU length of stay, 28-day mortality and APACHE II and SOFA scores at admission. Descriptive statistics and comparative analyses were performed to assess differences between groups.
Results: The study population included 32 males (64%) and 18 females (36%), with a mean age of 65.4 $\pm$ 12.7 years. Early PN patients had a mean age of 64.1 $\pm$ 11.9 years, and delayed PN patients had a mean age of 67.0 $\pm$ 13.6 years. Mean APACHE II scores were 23.4 $\pm$ 6.1 in the early group and 22.7 $\pm$ 5.8 in the delayed group. Mean SOFA scores were 9.1 $\pm$ 2.7 and 8.8 $\pm$ 2.9, respectively. Early PN patients had a shorter mean ICU stay (13.2 $\pm$ 4.8 vs. 16.1 $\pm$ 5.7 days) and required PN for a longer duration (10.1 $\pm$ 3.2 vs. 7.4 $\pm$ 2.8 days). The early PN group experienced a higher rate of secondary infections (36% vs. 14%). The 28-day mortality rate was 35.7% in the early group vs. 31.8% in the delayed group. Median ventilation duration was slightly lower with early PN (7 vs. 9 days).
Conclusions: Early PN in septic ICU patients may reduce ICU length of stay and ventilation duration but is associated with a higher incidence infections. Comparable APACHE II and SOFA scores suggest that baseline illness severity did not differ between groups. These results, however, support a personalized approach to PN timing and highlight the need for randomized prospective trials to establish optimal nutritional strategies in sepsis care.

Disinfection effects of atomized fine-bubbled ozonated water on ICU beds: effectiveness and safety

K. Higa[1]; K. KAMIZATO[1]; D. Sakiyama[1]; M. Kakinohana[1]
[1]Aesthesiology, University of the Ryukyus Hospital, Ginowan, Japan

Intensive Care Medicine Experimental 2025,* 13(1)*:001632

Introduction: For all intensive care units, multidrug-resistant bacteria are becoming a serious problem. ICU beds used for an infected patient in hospitals must be cleaned completely before they are used by another patient. For this purpose, disinfection is performed for each patient, but complete cleaning is difficult to achieve. In addition, uniform disinfection is ideal, but it is not easy to achieve either.
Recently, it has been reported that disinfection can be performed efficiently by atomizing a new disinfectant containing a high concentration of fine-bubbled ozonated water.
We have also examined this method using cultured bacteria (S. epidermidis and E. coli) and confirmed that the number of bacteria was reduced by more than 99.99%.
Objectives: In this study, we investigated the disinfection effect of fine-bubbled ozonated water in the intensive care unit using ICU beds.
Methods: Experiments were conducted in our intensive care unit with a closed space enclosed by a vinyl tent. In addition, an experiment was conducted by atomizing fine-bubbled ozonized water using a special atomizer. Humidity and temperature inside the tent were monitored during disinfection. Bacterial counts on the bed surface were measured using commercially available standard agar media. Incubation conditions were 37 °C for 48 h. The monitoring sites considered in this study were the bed railing, the handle operating the fence, and the remote controller.
The amounts of bacteria before and after the atomization disinfection were compared to the area occupied by the agar medium after 48 h of incubation.
The free ozone concentration in the environment during the disinfection treatment was also measured to investigate whether contamination of the ICU environment occurred. We measured the ozone concentration using a suction-type ozone detector. Measurements were taken at a point 5 cm away from the tent.
Results: Significant bacterial culture area reduction was observed on the surfaces of the remote controller. The %change in the area occupied by standard agar medium was 54% on the surface of the remote controller, halving the amount of bacteria. On the other hand, no difference was observed on handrails (114%) and handles (112%).
In addition, free ozone was below detection sensitivity in the environment during disinfection operations.
Conclusions: In the intensive care unit environment, the fine-bubbled ozonated water could reduce bacteria on remote control surfaces.
In addition, free ozone in the environment during the implementation of the disinfection process was below detection sensitivity. Although this method uses ozone, it is safe for medical staff in the ICU.

Topic: Infections and prevention.

Intensive Care Medicine Experimental 2025,* 13(1)*:001633

Introduction: Obstetric hemorrhage continues to be the leading cause of maternal mortality in Mexico. Viscoelastic coagulation tests dynamically assess clotting initiation, clot formation, and lysis. Its use is widely described in different scenarios; however, evidence of its application in obstetric hemorrhage is limited. In critical scenarios, hemostatic alterations coincide with the obstetric pathology that conditions blood loss, which include: ruptured ectopic pregnancy, spontaneous abortion, uterine atony, uterine rupture, placental abruption and uterine tear. The use of viscoelastic testing during goal-directed resuscitation in obstetric haemorrhage has been shown to be useful as long as proper interpretation and post-performance planning is performed. The state of hypercoagulability presented by pregnant women during pregnancy is known, who gradually present an increase in coagulation factors, platelets, and fibrinogen levels; however, there is no adequate characterization depending on the trimester of gestation in which it is found.

Objectives: To characterize the thromboelastometry profile in patients with obstetric hemorrhage in the first and third trimesters of pregnancy admitted to intensive care and to identify the differences between them.

Methods: The following is a retrospective, descriptive, comparative, single-center study that included 19 patients between 15 and 40 years of age, who were admitted to the Intensive Care Unit with a diagnosis of obstetric hemorrhage, who underwent a thromboelatometry test to identify the need for blood component transfusion. A statistical analysis adjusted for covariates (age and BMI) was performed to compare the parameters of the ROTEM (EXTEM and FIBTEM) between the first and third trimesters. Nonparametric tests were used for initial comparison and a linear regression model was used to adjust for covariates. Descriptive statistics (median and IQR) were used for each parameter per group, and the Mann–Whitney test was used to compare parameters between quarters. In addition to multiple linear regression for each significant parameter, adjusting for age and BMI.

Results: The patients had a median age of 24 years and their thromboelastometry profile showed the following values: EXTEM: CFT: clot formation time is significantly shorter in the third trimester (median = 88 vs. 160.5), even after adjusting for age and BMI ($B = -78.2$\BETA $= -78.2$B $= -78.2$, $P = 0.012$). MCF: Maximum clot firmness is significantly higher in the third trimester (median = 67 vs. 52; B = 14.3\BETA = 14.3B = 14.3, $P = 0.008$). A5: amplitude at 5 min is highest in the third trimester (median = 46 vs. 29.5; $B = 13.8$\BETA = 13.8B = 13.8, $P = 0.022$). FIBTEM: no significant differences were found in TC, A5 or MCF.

Conclusions: The differences in CFT and MCF suggest a state of hypercoagulability predominant in the third trimester, which is physiologically expected with the aim of preventing postpartum hemorrhage. It is important to note that age and BMI do not significantly influence the differences observed, which reinforces that gestational age is considered the main factor in these differences, which we consider should be correlated with the clinical evolution of patients.

Table 1 .

Parámetro	Grupo	Mediana (IQR)	Mann-Whitney p	Regresión (β Trimestre, p)	Tamaño del efecto (r)
EXTEM CT	1er trimestre	71.5 (63, 87)	0.073	-	-
	3er trimestre	60 (50, 70)			
EXTEM CFT	1er trimestre	160.5 (84, 189)	0.006*	-78.2, 0.012	0.58
	3er trimestre	88 (70, 106)			
EXTEM A5	1er trimestre	29.5 (27, 49)	0.013	13.8, 0.022	0.52
	3er trimestre	46 (40, 50)			
EXTEM MCF	1er trimestre	52 (49, 67)	0.007*	14.3, 0.008	0.57
	3er trimestre	67 (60, 70)			
FIBTEM CT	1er trimestre	65 (50, 76)	0.225	-	-
	3er trimestre	54 (46, 71)			
FIBTEM A5	1er trimestre	13.5 (9, 14)	0.492	-	-
	3er trimestre	13 (9, 20)			
FIBTEM MCF	1er trimestre	16 (13, 20)	0.492	-	-
	3er trimestre	18 (10, 23)

Intensive Care Medicine Experimental 2025,* 13(1)*:001634

Introduction: Patients recovering from an intensive care unit (ICU) stay frequently experience mental health challenges such as post-traumatic stress disorder (PTSD), anxiety, and depression. These conditions are components of the post-intensive care syndrome (PICS) and adversely affect the survivors' quality of life. Currently, there is a notable gap in effective interventions for these issues [1, 2]. Virtual Reality (VR) has been explored as a safe and potentially beneficial method to provide informational and therapeutic experiences for ICU survivors, showing promise in improving their mental health outcomes [3–5].
Objectives: To investigate the impacts and optimal timing of a specialized VR program designed for ICU survivors—referred to as ICU-specific VR (ICU-VR)—on symptoms of PTSD, anxiety, depression, health-related quality of life (HRQoL), and satisfaction with post-ICU care, over a period of 12-month post-ICU discharge.
Methods: In this international randomized controlled trial with three arms in eleven hospitals, ICU patients who had received mechanical ventilation for at least 24 h and stayed in the ICU for at least 72 h were randomly assigned to either a control group or one of the two ICU-VR intervention groups (early or late). While all subjects received standard post-ICU care, including a 3-month follow-up clinic invitation, the intervention groups also participated in the ICU-VR session either within 2-week post-discharge (early group) or during their follow-up clinic (late group). The study measured participants' mental health and HRQoL at various intervals post-discharge and evaluated their satisfaction with the ICU-VR experience and overall aftercare.
Results: Between December 2021 and June 2024, 344 ICU survivors were included (median age 61; 62% male). No notable differences in PTSD, anxiety, depression symptoms, or HRQoL scores across the groups were found up to 6-month post-ICU discharge. The overall aftercare satisfaction was rated an 8 (95% range 5–10) and the intervention groups rated the contribution of ICU-VR to the aftercare with an 8 (95% range 1–10). The ICU-VR intervention received an overall rating of 8 out of 10 (95% range 3–10) and the likelihood that participants would recommend ICU-VR to other patients was rated an 8 (95% range 4–10). Participants rated whether ICU-VR improved their understanding of the ICU admission with an 8 (95% range 1–10).
Conclusions: The ICU-VR intervention did not improve mental health or HRQoL in ICU survivors up to 6-month post-ICU discharge. ICU-VR was well-received and may improve ICU survivors' comprehension of ICU treatment. Future studies should explore a different ICU-VR approach potentially including AI-driven adaptability.

Intensive Care Medicine Experimental 2025,* 13(1)*:001635

Introduction: Extracorporeal membrane oxygenation (ECMO) is a life-saving intervention for severe respiratory or cardiac failure. The inflammatory response induced by the extracorporeal circuit may influence outcomes [1]. This study investigates the effect of ECMO on inflammatory and haematological parameters, considering ECMO mode and COVID-19 status.
Objectives: To determine whether the use of ECMO affects inflammatory and haematological parameters (C-reactive protein, procalcitonin, haemoglobin, and platelets), and to evaluate differences between veno-venous (VV) vs. veno-arterial (VA) ECMO and COVID-19 positive vs. negative patients.
Methods: We analyzed 260 patients supported by ECMO (143 VV, 91 VA, 26 veno-arterial-venous [VAV]; 128 COVID-19 positive). Laboratory parameters were collected on the day of ECMO initiation (day 0) and daily thereafter (days 1–5). After exclusion of VAV-ECMO patients, the Friedman test was used for comparisons from day 0 to day 5, with subgroup analyses for ECMO mode and COVID-19 status, and when $p < 0.05$, we performed comparisons between days.
Results: Three parameters showed significant changes after ECMO: PCT, hemoglobin and platelets (each Friedman $p < 0.001$; day 0 vs. day 5 medians: 0.49 vs. 0.41 ng/mL, 11.6 vs. 10.1 g/dL and 230 vs. 141 $\times$ 10^3/µL, Wilcoxon $p = 0.003$, < 0.001 and < 0.001, respectively; Fig. 1). PCT changed significantly in VV-ECMO patients (Friedman $p < 0.001$; day 0 vs. day 5 medians: 0.595 vs. 0.38 ng/mL, Wilcoxon $p < 0.001$) but not in VA-ECMO patients, and the difference between day 0 and 5 remained significant only in COVID-19 positive VV-ECMO subgroup (medians 0.55 vs. 0.38 ng/mL, Wilcoxon $p = 0.001$). Hemoglobin and platelets deceased significantly in both VA patients and the

VV COVID-19 positive subgroup (each Friedman $p < 0.02$) but not in the VV-ECMO COVID-19 negative subgroup.
Conclusions: Our results confirmed that ECMO support is associated with a decrease in haemoglobin [2] and platelets [3], suggesting a haematological effect. However, the effect on PCT, although significant in VV-ECMO patients, does not appear to reflect an inflammatory response to extracorporeal circuit [4]. It also remains a challenge to distinguish ECMO-related changes from those caused by infection or disease progression.

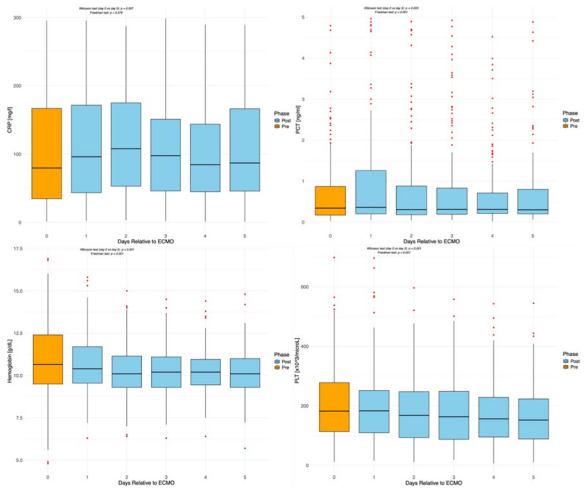

Figure 1 C-reactive protein (CRP), procalcitonin (PCT) and haemoglobin levels (g/dL), and platelet count [PLT] from day 0 to day 5 of ECMO. Medians (horizontal lines), interquartile ranges (IQR; boxes), 1.5 IQR (vertical lines) and outliers (dots) are shown. Friedman test across days and Wilcoxon test for comparisons between days 0 and 5 are calculated

Intensive Care Medicine Experimental 2025,* 13(1)*:001636

Introduction: Cell-free DNA (cfDNA)/neutrophil extracellular traps (NETs) are recently recognised alarmins which are causally linked with ischaemia–reperfusion injury (IRI). We previously demonstrated that NucleoCapture® selective cfDNA/NETs apheresis significantly reduced IRI and improved organ function in poor quality donor liver and lung transplants, potentially making them suitable for transplantation. cfDNA analysis of animals subjected to extracorporeal cardiopulmonary resuscitation (eCPR) has revealed a positive correlation between cfDNA levels after eCPR and brain injury as measured by histology and S100B.
Objectives: To investigate the use of NucleoCapture® in a clinically relevant porcine eCPR model.
Methods: Cardiac arrest was induced in 17 pigs, followed by 45 min of mechanical CPR using the Lucas device. ETCO2 levels at this point were < 1.3 kPa in all animals. eCPR was then commenced for 4 h. Seven pigs were subjected to NucleoCapture® apheresis using the Terumo Optia system during eCPR for 4 h. Ten pigs were subjected to the same protocol without NucleoCapture® apheresis. cfDNA/NETs were measured using the PicoGreen dsDNA assay (Thermofisher, UK).
Results: The baseline levels of circulating cfDNA/NETs measured in the control and NucleoCapture® treated pigs were 544.8 ng/ml and 485.6 ng/ml, respectively. This level rose to 3162 ng/ml after 45 min mechanical CPR and 4 h eCPR in the control pigs. This rise was attenuated in the NucleoCapture® treated pigs to 1451 ng/ml ($p = 0.013$ vs. controls). Mean (95% CI) values shown in graph. Systemic inflammation as measured by TNF alpha was attenuated in the intervention group vs. control at 3 h (255 pg/ml vs. 491 pg/ml, $p = 0.032$).
Conclusions: NucleoCapture® removed cfDNA/NETs from the circulation of pigs subjected to eCPR. This could lead to reduced cfDNA/NETs related brain and other organ injury. Further work to confirm this hypothesis is underway evaluating blood and brain biomarkers, including complete brain histological analysis.

NucleoCapture reduces cfDNA/NETs during eCPR.

Intensive Care Medicine Experimental 2025,* 13(1)*:001637

Introduction: Infections sustained by *Pseudomonas aeruginosa* are known for their high morbidity and mortality across multiple patient groups.

Objectives: We sought to quantify the incidence and trend of ventilator associated pneumonia caused by *P. aeruginosa* in Italian ICUs over recent years, along with associated patient outcomes.

Methods: We performed a multicentre registry-based analysis, using the Promoting Patient Safety and Quality Improvement in Critical Care (PROSAFE) nationwide ICU clinical quality database. The primary endpoint was the yearly incidence proportion of ventilator-associated-pneumonia sustained by *P. aeruginosa* (PaVAP) from 1 January 2020 to 31 December 2023. Secondary endpoints included patient-centred outcomes and fraction of carbapenem-susceptible, carbapenem-resistant not-DTR, and difficult-to-treat resistance (DTR) *P. aeruginosa*. Patients with PaVAP were compared to those with VAP sustained by other Gram-negative pathogens (otherVAP). Temporal trends were investigated using the Cochrane-Armitage trend test and generalized linear models.

Results: The study involved 133 intensive care units (ICUs) in Italy, with 36,170 patients who were ventilated from more than 48 h. A total of 4853 (13.4%) patients had VAP with 3595 (74.1%) cases sustained by Gram negative pathogens. Of these 1033 (28.7%) were PaVAP, and 2562 (71.3%) otherVAP. No significant demographic differences were observed between groups. The proportion of VAP sustained by Pseudomonas was stable over the study period (Cochrane–Armitage test $P = 0.436$; mean across years 28.7%). The incidence of the DTR PaVAP increased over time (figure). Crude and standardized mortality ratios did not differ between PaVAP and otherVAP groups. However, PaVAP patients required longer duration of mechanical ventilation, longer ICU and hospital stays ($p < 0.001$). Carbapenem-resistant not-DTR PaVAP had the same mortality as carbapenem-susceptible PaVAP. DTR PaVAP had longer duration of mechanical ventilation, ICU and hospital stays.

Conclusions: While overall incidence of PaVAP remained stable from 2020 to 2023, burden of DTR strains is increasing. Patients with PaVAP show a higher resource use as compared to VAPs caused by other gram negatives organisms.

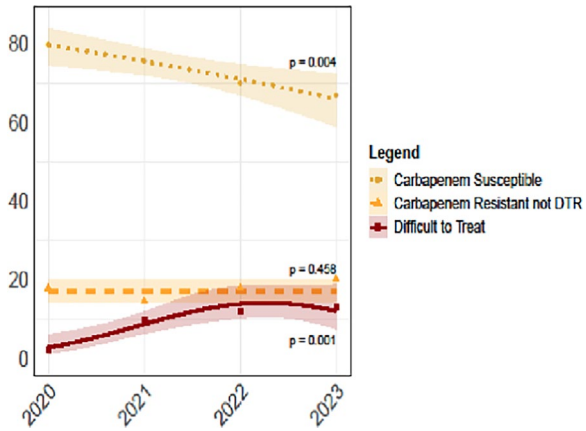

Figure Trends in the proportions of carbapenem-susceptible (CS), carbapenem-resistant not-DTR (CR) and difficult-to-treat resistance (DTR) PaVAP. The lines represent GLM models with corresponding 95% confidence interval, while the points indicate observed yearly proportions. *P* values were calculated using the Cochran–Armitage trend test

Intensive Care Medicine Experimental 2025,* 13(1)*:001638

Introduction: Under Sepsis-3 criteria, septic shock is defined as persistent sepsis-related hypotension requiring vasopressors and a serum lactate > 2 mmol/L —the latter as a metabolic surrogate for global hypoperfusion. A proportion of patients, however, present early in shock with normal—or simply unmeasured—lactate values, and lactate itself can be modulated by non-hypoperfusion mechanisms. Experimental and clinical studies nonetheless demonstrate that micro- and regional perfusion may remain severely impaired even whithout hyperlactatemia. Bedside signs of hypoperfusion—prolonged capillary-refill time (> 3 s) or mottling—have been shown to reflect microcirculatory derangements and may identify high-risk patients despite low lactate. Nevertheless, the prognostic value of these markers in septic patients with shock in the absence of hyperlactatemia remains poorly characterized.

Objectives: To compare 28-day mortality between (1) Sepsis-3–defined septic shock and (2) patients septic shock patients without hyperlactatemia but with clinical signs of hypoperfusion in a large ICU cohort.

Methods: We conducted a retrospective cohort analysis using large ICU database MIMIC-IV v3.1. Adult, non-cardiac-surgery ICU admissions with suspected infection who began norepinephrine (time zero)

were eligible. Two prespecified phenotypes were constructed from data recorded around time zero: "High Lactate Only "(Septic shock by Sepsis-3: lactate ≥ 2 mmol L^{-1}, no abnormal peripheral perfusion) and Low-lactate + hypoperfusion (lactate < 2 mmol L^{-1} or missing, plus capillary-refill time > 3 s or mottled skin). A third group, "High Lactate + Hypoperfusion", was included for secondary analyses. The primary outcome was 28-day all-cause mortality. Adjusted risk ratios (aRR) comparing "Low Lactate + Hypoperfusion" with "High Lactate Only" were estimated with modified Poisson regression with log link and robust (sandwich) standard errors, adjusting for age, BMI, Charlson comorbidity index, SOFA score at diagnosis, invasive mechanical ventilation, and renal replacement therapy. secondary Tukey-adjusted pairwise comparisons included the third phenotype ("Hyperlactatemia + Hypoperfusion"). Statistical significance was set at $p < 0.05$.

Results: Among 2 066 patients included in the primary analysis, 1 862 (90.1%) were "High Lactate Only" and 204 (9.9%) were "Low Lactate + Hypoperfusion." Baseline characteristics were similar between groups (median age 67 [IQR 56–76] vs. 66 [55–75] years; BMI 27.4 [23.7–32.2] vs. 27.6 [24.0–32.5] kg/m^2; median SOFA 8 [6–10] in both; invasive mechanical ventilation 84% vs. 81%; renal-replacement therapy 22% vs. 15%). Crude 28-day mortality was 42% vs. 39%, respectively. In adjusted modified Poisson regression, "Low Lactate + Hypoperfusion" did not significantly differ from "High Lactate Only" (aRR 1.06; 95% CI 0.87–1.28; $p = 0.56$).

In a secondary analysis of all three phenotypes (n = 2580), 514 (19.9%) had both hyperlactatemia and hypoperfusion ("High Lactate + Hypoperfusion"), with a mean 28-day mortality of 58.0%. Secondary pairwise comparisons showed that patients with hyperlactatemia and hypoperfusion signs showed a significantly higher risk of death than dose without hypoperfusion signs ("High Lactate Only") (aRR 1.34; 95% CI 1.06–1.70; $p = 0.011$).

Conclusions: Clinical signs of hypoperfusion identify a subgroup of vasopressor-dependant septic patients without hyperlactatemia whose 28-day mortality is similar of that of Sepsis-3–defined septic shock. These findings highlight that CRT and mottling may provide additional prognostic information beyond lactate alone. Integrating these clinical markers into septic shock definitions could enable earlier identification of at-risk patients, prompt targeted resuscitation, and ultimately improve patient outcomes.

Table 1 Descriptive Statistics. Patients were separated in two distinct phenotypes

Variable	High Lactate Only N = 1,862	Low Lactate + Hypoperfusion N = 204
Age (years)	67.0 [56.0, 76.0]	68.0 [61.0, 80.0]
Females, n (%)	795 (43%)	93 (46%)
Charlson Comorbidity Index	5.0 [4.0, 8.0]	6.0 [4.0, 8.0]
BMI (kg/m²)	27.4 [23.7, 32.2]	27.1 [22.6, 34.0]
SOFA Score at Diagnosis	8.0 [6.0, 10.0]	7.0 [5.0, 10.0]
Vital Support Time (hours)	3.0 [1.0, 7.0]	3.0 [1.5, 6.0]
Invasive Mechanical Ventilation, n (%)	1,436 (77%)	167 (82%)
Renal Replacement Therapy, n (%)	416 (22%)	30 (15%)
Hospital Length of Stay, (days)	12.3 [6.5, 23.5]	11.7 [7.4, 20.1]
ICU Length of Stay, (days)	4.6 [2.5, 9.6]	5.3 [3.0, 9.9]
28-Day Mortality, n (%)	779 (42%)	79 (39%)
ICU Mortality, n (%)	606 (33%)	53 (26%)

Median [Q1, Q3]; n (%).

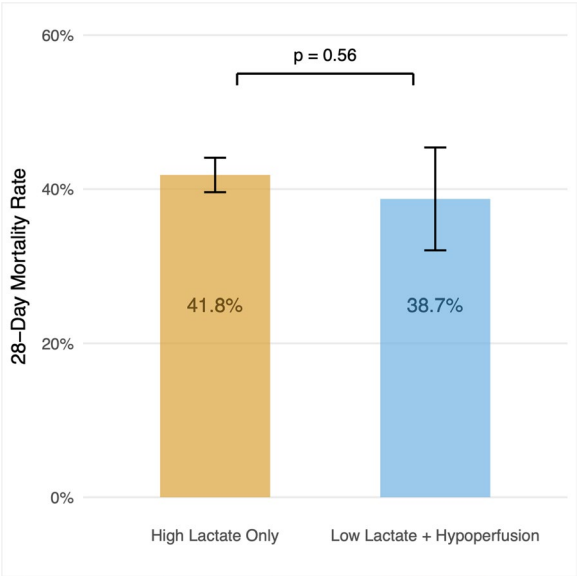

Figure 1 Unadjusted 28-day mortality in the two primary phenotypes. Bars show the proportion of deaths among patients with Sepsis-3 septic shock ("High Lactate Only"; n = 1862) and those with normolactate shock plus bedside hypoperfusion ("Low Lactate + Hypoperfusion"; n = 204). Heights correspond to crude mortality rates (41.8% vs. 38.7%); vertical lines represent 95% confidence intervals. The between-group difference was not statistically significant ($p = 0.56$, modified Poisson regression)

Intensive Care Medicine Experimental 2025,* 13(1)*:001639

Introduction: Early identification of the severity of sepsis can help improve patient outcomes. Current sepsis guidelines divide sepsis and septic shock according to the severity of the disease, and the concept of "severe sepsis" has been eliminated. In clinical practice, there is no way to accurately define the severity of the disease, and it is difficult

to accurately treat and predict the severity of the disease. Here, we applied a novel EVs proteomics method in the large-scale sepsis cohort with different clinical subtypes, which revealed the potential biomarkers and molecular subtypes of the sepsis.

Objectives: The heterogeneity of sepsis presents significant challenges for early diagnosis and effective treatment. In this study, a proteomic examination of serum extracellular vesicles (EVs) was applied to a large cohort of patients with varying sepsis severity, aiming to identify potential biomarkers and uncover molecular subtypes of the condition.

Methods: Peripheral blood samples from patients with sepsis (Sepsis-only, $n = 100$), sepsis complicated with ARDS (*S*-ARDS group, $n = 50$), sepsis complicated with AKI (*S*-AKI group, $n = 50$), sepsis complicated with both ARDS and AKI (S-ARDS&AKI group, $n = 50$), and healthy controls ($n = 50$) were collected. The successful extraction of EVs was confirmed by transmission electron microscopy, nanoparticle tracking analysis, and western blot assays. Proteins were identified by mass spectrometry. Integrated bioinformatics analyses were performed to explore the vital biomarkers and molecular subtypes of sepsis.

Results: EVs were successfully extracted in different clinical groups. A total of 4754 proteins were detected in 279 samples after quality control. The results revealed that the expression level of CD81, FLOT1, FLOT2, HSP90AA1, and HSP90AB1 were gradually up-regulated during the progression of sepsis and may act as the promising biomarker for predicting the onset and severity of sepsis. Consensus clustering divided Sepsis-only group into four molecular subtypes with distinct clinical severity. Finally, the levels of metabolism-related proteins were associated with the severity and prognosis of sepsis.

Conclusions: This study utilized EVs proteomics on large-scale cohorts to establish molecular subtypes of sepsis, uncovering the inter-individual heterogeneity of the condition. In addition, metabolic dysregulation was found to be closely linked to disease severity and patient survival. Targeting metabolic disorders may, therefore, represent a promising therapeutic strategy for sepsis.

Intensive Care Medicine Experimental 2025,* 13(1)*:001640

Introduction: As precursor of nitric oxide (NO) production, *L*-Arginine (*L*-Arg) plays a pivotal role in vascular physiology 1 2. In critically ill patients, especially in sepsis, increased NO production results in abnormal vascular reactivity. Persistently abnormal capillary refill time—CRT—a marker of tissue perfusion and vascular reactivity—has been associated with increased morbidity and mortality 2. Oral use of arginine has been associated with cardiovascular effects (i.e., improved endothelial function) 3, but no studies exist on the potentially beneficial effect of oral *L*-Arginine supplementation in tissue perfusion parameters.
Objectives: We aimed to evaluate the effects of a commercially available oral *L*-Arg-based supplement (*Ammino Alliance—AAS*) on vascular reactivity using non-invasive routinely used tests to assess peripheral microcirculation status in patients.
Methods: A prospective, non-randomized, single center, single-arm, minimal risk, exploratory study was conducted at Catholic University Intensive Care Unit (ICU) of Santiago, Chile. Healthy volunteers (HVs) were asked to take 85 mg and 170 mg of AAS on day 1 and day 2, respectively. Macro- and microcirculatory parameters were collected at baseline (T0), after 1 h (T1) and 3 h (T2) from ingestion on both days. Exclusion criteria included vascularization-affecting comorbidities or drugs. Ethical approval was obtained and all HVs signed an informed consent. A descriptive analysis was performed. The Wilcoxon test was used for the statistical analysis.
Results: Overall, thirteen HVs were enrolled in the study, male 8/13 (61.5%) with an average age of 29 (± 4) years (Table 1). A statistically significant reduction in heart rate was observed (5.1 bpm 3 h after ingestion and 0.9 bpm/day on average on experimental days) between T0-T1 (p-value = 0. 009) and T0-T2 (p-value = 0.002). Systolic, diastolic and mean arterial pressure had increased after 3 h from ingestion (3.4; 2.0; 2.4 mmHg, respectively, with no statistical significance), but decreased from day 1 to day 2 (1.4, 0.2, and 0.3 mmHg, respectively). Capillary refill time (CRT) decreased when measured visually (vsCRT) by 1.18 s after ingestion, and 0.15 s from day 1 to day 2, but did not achieved statistical significance. The magnitude of change did not differ significantly comparing day 1 and day 2 in any variable except for the T0-T2 in peripheral index calculated through vsCRT. No difference for any variable was observed between L-Arg single (day 1) and double (day 2) dose at T0, T1, and T2. No adverse events were observed after ingestion.
Conclusions: Oral L-Arginine AAS seems to produce an immediate and lasting- decrease in heart rate and visually measured capillary refill time values in healthy individuals. Blood pressure also appears to be positively affected by the ingestion of AAS. Further studies with a major sample size are needed to confirm these results.

Table 1 Demographic and parametric features of the 13 healthy volunteers (HVs) included in the study. Read: decreased (+) or increased (-). BMI: body mass index. SD: standard deviation

	All HVs (*n* = 13)
Demographic data	
Male gender (n, %)	8/13 (61,5%)
Age (years, mean ± SD)	29 (± 4)

Virtual reality-based family support system for delirium mitigation in mechanically ventilated ICU patients: an interventional study

Q. Wang[1]; Y. Xue[1]; L. Mi[1]; L. Yun[1]
[1]Department of Intensive Care Unit, Peking Union Medical College Hospital, Beijing, China
Correspondence: Y. Xue
Intensive Care Medicine Experimental 2025,* 13(1)*:001641

Introduction: Delirium is a common acute brain dysfunction characterized by fluctuating mental status with temporal and spatial disorientation, inattention, and disorganized thinking. It is associated with negative impacts on prolonged intensive care unit (ICU) and hospital stay, increased days of mechanical ventilation, short-term or long-term cognitive decline, and excess death. However, common therapeutic methods are often ineffective.
Methods: In this study, we developed a virtual reality (VR)-based family support system (VRFS) for non-pharmacological intervention in delirious patients. The VRFS provides a protective barrier from the ICU ward environment by immersing patients in a simulated natural setting. In this setting, virtual family members offer companionship and soothe patients. We conducted interventions on patients with post-cardiac surgery delirium using VRFS. Quantitative EEG (qEEG) analysis revealed that VRFS intervention, particularly in the "VR-Family" mode, induced changes in qEEG indices of delirious participants toward the mean values observed in non-delirious participants.
Results: Persistent delirium occurred following 35% post-cardiac surgery patients. VR interventions were administered on when delirium happened. EEG data was collected under sedation within VR interventions. Increased slow-wave activity percentage on EEG correlated with reduced sedation depth. With VR intervention, patients decreased agitation and increased responsiveness to family interactions and the post-VR EEG demonstrated marked reduction in slow-wave activity (Δβ/θ ratio + 32%).
Conclusions: This suggests a potential regulatory effect on brain activity. These findings demonstrate the potential of VRFS as a non-pharmacological tool for managing delirium. However, further validation through large-sample studies is necessary to confirm these preliminary results.

Introduction: In many parts of Africa, critically ill children are frequently admitted to adult intensive care units (ICUs) or high dependency units (HDUs), underscoring the challenges of providing pediatric critical care in resource–limited settings.
Objectives: To better understand this issue, we analyzed the demographics, clinical characteristics, and outcomes of critically ill children admitted to adult ICU or HDU in Kenya.
Methods: We conducted a registry-based study in six ICUs and five HDUs in Kenya. We included consecutive patients aged under the age of 18 years, admitted to an ICU or HDU participating in the Kenya

Critical Care Registry [1], between January 2021 and June 2022. The primary outcome was ICU or HDU mortality; secondary outcomes included clinical management, duration of invasive ventilation, and length of stay. Risk factors for mortality were analyzed using multivariable logistic regression.
Results: Of the 5012 ICU or HDU admissions, 455 (9.1%) involved critically ill children. The median age was 2.0 [0.4–8.5] years, with 172 (37.8%) children being under 1 year. Medical admissions accounted for and 346 (76.0%) cases, while 109 (23.9%) were surgical. Almost half of the children received invasive ventilation, whereas noninvasive ventilation was rarely used. The use of cardiovascular support and renal replacement therapy were also limited. Approximately one quarter of children were sedated on admission, and more than 80% received at least one antibiotic. The overall ICU–mortality rate was 34.7%, higher in medical cases than in surgical cases (39.9 vs. 18.3%, $P < 0.01$). Independent risk factors for mortality were medical admission, age under 1 year, invasive ventilation, altered consciousness and a low platelet count (figure).
Conclusions: In Kenya, one out of ten admissions to adult ICUs and HDUs concerns a child, which often receive invasive ventilation and a high mortality rate. Children admitted for medical reasons and under age of 1 year are at high risk of a poor outcome. All risk factors for poor outcome are non–modifiable.

Forest plot of odds ratios for death in ICU for significant factors affecting ICU mortality

Correspondence: L.A. Biesheuvel

Intensive Care Medicine Experimental 2025, **13(1)**:*001643*

Introduction: AmsterdamUMCdb 1.0, released in 2020, consisted solely of ICU data from the VUmc campus of Amsterdam UMC. The forthcoming AmsterdamUMCdb 2.0 combines data from both campuses of the now-merged hospital—VUmc and AMC—and incorporates the Epic EHR, substantially enlarging the cohort and broadening temporal coverage. All tables are converted to the OMOP common data model, making the data set fully FAIR (Findable, Accessible, Interoperable, Re-usable).
Its public release is planned before ESICM LIVES 2025.
Objectives: To describe the architecture, de-identification strategy and preliminary patient characteristics of AmsterdamUMCdb 2.0
Methods: Data sources:
1. Metavision PDMS, VUmc.
2. Metavision PDMS, AMC.
3. Epic EHR at the merged Amsterdam UMC.
A harmonised extract–transform–load pipeline mapped all clinical, device and laboratory tables to OMOP. We reused the risk-based de-identification framework validated for v1.0 ($k \geq 2$, $l \geq 2$ strict average risk, mandatory end-user licence and scientific-integrity training). Anonymisation and final quality-assurance steps are in progress and will follow the same protocol.
Results: Preliminary data at the time of abstract submission includes 23,081 admissions from VUmc (20,081 unique patients), 29,432 admissions from AMC (21,341 unique patients), and 27,538 admissions from Epic (25,381 unique patients). In total, AmsterdamUMCdb 2.0 currently comprises 80,051 ICU admissions from 66,803 unique patients. This represents a more than threefold increase in size compared to version 1.0. The data set contains high-frequency data such as, laboratory measurements, vital signs, and medication administrations. All variables are mapped to OMOP standard concepts. Final risk metrics will be included in the full manuscript.
Conclusions: AmsterdamUMCdb 2.0 will become the largest openly accessible European ICU database to date. It integrates data from three different EHR systems into a single GDPR-compliant and OMOP-mapped data set. By including both campuses of Amsterdam UMC, it significantly increases cohort size and heterogeneity. The resource will enable reproducible machine learning research, cross-center benchmarking, and external validation of clinical AI tools. Final de-identification and public release are expected in Q3 2025. A full description of methods and data characteristics will be submitted alongside the conference.

Introduction: Necrotizing soft tissue infections (NSTI) are rare and life-threatening bacterial infections characterised by necrosis of subcutaneous tissue, fascia or muscle. Few prospective studies have been conducted.
Objectives: The primary objective is to assess the 90-day mortality rate and identify prognostic factors in patients with NSTI in an international setting. Secondary objectives are (i) to characterise the clinical and microbiological presentation and management; (ii) to assess the risk of limb amputation and associated factors; and (iii) to assess functional and health-related quality of life (HRQoL) outcomes and associated factors.
Methods: We conduct a multinational, prospective, non-interventional cohort study (NCT05116956, registered on 2021-11-02). Data have been collected prospectively on a secure web-based server. The primary outcome measure is day-90 mortality. Secondary outcomes include need for limb amputation, the activity of daily living scale and health-related quality of life at day-90 (EQ-5D-5L questionnaire). Baseline characteristics associated with outcomes will be identified by multivariable analyses. Exploratory analyses will be conducted to assess the impact of therapeutic interventions on day-90 mortality and secondary outcomes. A statistical analysis plan has been published listing the variables to be included in the models (1). Analysis will be reported according to STROBE guidelines for observational cohort studies. The flow of patients will be displayed in a Consolidated Standard of Reporting Trials (CONSORT) diagram. The study protocol has been approved by an ethics committee in each participating country.
Results: We enrolled 1033 consecutive patients admitted to 85 hospitals with surgically proven NSTI between November 2021 and December 2024 in 17 countries over three continents. The last patient was enrolled on 31 December 2024 with a last follow-up date of 30 March 2025. Analyses are ongoing and results will be presented at LIVES 2025 according to the previously published protocol and statistical plan (1).
Conclusions: SKIN-ICU aims at being the largest multicentre multinational prospective cohort study on NSTI. A large amount of high-quality prospectively-collected data from multinational centres will allow for filling important gaps in our current knowledge on this devastating disease.

Introduction: Aminoglycosides, such as amikacin and gentamicin, are commonly used in intensive care (ICU) for the treatment of gram-negative bacterial infections in life-threatening conditions such as sepsis and infective endocarditis. Aminoglycosides are hydrophilic drugs which have a low volume of distribution and are renally cleared. Therefore, doses should be calculated based on lean body weight—or corrected body weight if patients are obese—and may require dose adjustment in renal impairment. Furthermore, as these drugs have a narrow therapeutic range and carry a significant risk of nephrotoxicity and ototoxicity at high levels, therapeutic drug monitoring (TDM) is essential. In critically ill patients, correct aminoglycoside dosing to achieve therapeutic concentrations which adequately treat infections is vital, however, appropriate monitoring must also be performed to manage the risk of adverse effects. In practice, aminoglycoside prescribing and monitoring varies widely. This service evaluation aims to assess current practice and identify options to optimise aminoglycoside use.
Objectives: To evaluate whether the correct dose of aminoglycoside was prescribed based on weight and renal function, and to evaluate whether drug levels were taken, when indicated, at the appropriate time.
Methods: Data were retrospectively collected for patients administered an aminoglycoside on ICU at St. Bartholomew's Hospital from 1/9/24 until 12/3/25. A total of 212 patients and 287 doses were included. Data wERE collected using a Microsoft Excel data collection tool, with patient-identifiable data anonymised. Data collected included patient demographics, prescription information, creatinine clearance and timing of levels taken. Levels were deemed appropriate if taken 18–24 h after the previous dose. Levels were not considered necessary for STAT doses as per local guidance.
Results: 287 doses were evaluated with 60% (172) of doses prescribed correctly and 40% (115) prescribed incorrectly based on local hospital guidelines. Among the incorrect doses, 58 were subtherapeutic and 57 were supratherapeutic (Fig. 1). TDM was performed for 94 of the 287 doses. Of these, 29% (27) were taken correctly based on the timing, while 71% (67) were taken incorrectly. Among the inappropriate levels, 34 were not indicated and 33 were taken at the incorrect time (Fig. 2).
Conclusions: Our results show there is significant variation in dosing and monitoring of aminoglycosides in ICU, with only 60% of doses prescribed correctly and 30% of levels taken appropriately at the correct time. To improve practice, a critical care specific guideline detailing dosing and monitoring practices for aminoglycosides should be developed. Furthermore, optimisation of the electronic prescribing system should be considered to guide correct dosing as well as timing of levels.

Prognostic value of severity scores in spontaneous supratentorial intracerebral haemorrhage: a retrospective cohort study

L. Sousa Nanji[1]; M. Franco Carneiro[2]; V. Pereira[1]; D. Luz[2]; A. Fernandes[1]

Intensive Care Medicine Experimental 2025,* 13(1)*:001646

Introduction: Spontaneous supratentorial intracerebral haemorrhage (ICH) remains a devastating neurological emergency with high morbidity and mortality. Accurate early prognostication is critical in guiding treatment intensity, resource allocation, and family counselling. While scoring systems are widely used, their discriminative value in small, focused neurocritical populations remains under-explored.
Objectives: To assess the association between established severity scores and age with hospital mortality in all spontaneous supratentorial ICH patients admitted to an intensive care unit in 2024.
Methods: We conducted a retrospective single-centre analysis of 33 adult patients with spontaneous supratentorial ICH admitted to the ICU. Patients were stratified by age (< 65 vs. ≥ 65 years) and GCS at admission (3–4, 5–12, 13–15). Severity scores (SOFA, APACHE II, SAPS II and ICH) were calculated for each patient based on established criteria. Mortality was defined as death prior to hospital discharge. Univariate analysis with Mann–Whitney *U* and Kruskal–Wallis tests was used to compare continuous variables across groups. We considered statistically significant results with $p < 0.05$.
Results: Among the 33 patients, the hospital mortality rate was 27% (9 out of 33). Mortality was significantly more frequent in patients aged 65 years or older ($p < 0.05$), and in those presenting with a GCS score of 3–4 upon admission ($p < 0.05$). Non-survivors exhibited significantly elevated severity scores compared to survivors: the median APACHE II score was 25 in non-survivors vs. 15 in survivors ($p < 0.05$); the median SOFA score at admission was 12 vs. 6 ($p < 0.05$), and the SAPS II score reached a median of 60 in non-survivors compared to 35 in those who survived ($p = 0.031$). Severity scores were clearly stratified across GCS categories, with patients in the GCS 3–4 group displaying the highest scores across all indices. ICH score distribution ranged from 0 to 4. Higher ICH scores were significantly associated with increased hospital mortality, with a stepwise rise in mortality from 0% in patients with ICH Score 0–100% in those with score 4.
Conclusions: In this focused cohort of 33 spontaneous supratentorial ICH patients, GCS 3–4 and elevated APACHE II, SOFA, SAPS II and ICH Scores were significantly associated with hospital mortality. These findings support the utility of general ICU severity scores alongside disease-specific tools in the neurocritical context. Integration of both physiologic and neurologic markers, including the ICH Score, may enhance early risk stratification and decision-making. Further prospective validation in larger ICH cohorts is warranted.

Intensive Care Medicine Experimental 2025,* 13(1)*:001647

Introduction: Immediate initiation of extracorporeal membrane oxygenation (ECMO) has not shown a consistent benefit in patients diagnosed with cardiogenic shock based on the presence of hypotension and hypoperfusion. In the Extracorporeal Membrane Oxygenation in the Therapy of Cardiogenic Shock (ECMO-CS) trial, tissue hypoperfusion was defined as evidence of either low venous oxygen saturation (SvO2) or elevated lactate levels. However, the relationship between these parameters and clinical outcomes, with or without ECMO, remains incompletely understood.
Objectives: This study aimed to evaluate the effect of immediate ECMO initiation in patients with cardiogenic shock and evidence of low SvO2 or elevated lactate levels.
Methods: In the ECMO-CS trial, 117 patients with cardiogenic shock were randomized to either immediate ECMO initiation or an early conservative strategy. This post-hoc analysis assessed the clinical efficacy of immediate ECMO in subgroups defined by baseline SvO2 < 50% or lactate ≥ 3 mmol/L. The primary endpoint was all-cause mortality at 1 year. The secondary endpoint was a composite of all-cause mortality or hemodynamic deterioration requiring ECMO.

Results: Baseline SvO2 data were available for 95 patients. Among those with SvO2 < 50% (n = 40), immediate ECMO initiation was associated with a significantly lower risk of all-cause mortality (HR 0.35; 95% CI 0.15–0.81; p = 0.014; Fig. 1) and the composite secondary endpoint (HR 0.34; 95% CI 0.15–0.76; p = 0.003). Lactate data were available for all 117 patients. In the subgroup with lactate ≥ 3 mmol/L (n = 92), immediate ECMO did not significantly reduce 1-year all-cause mortality compared to the conservative strategy (HR 0.86; 95% CI 0.53–1.41; p = 0.538; Fig. 1). Similarly, there was no significant difference in the composite secondary endpoint (HR 0.65; 95% CI 0.41–1.05; p = 0.067).
Conclusions: Immediate ECMO initiation was associated with improved clinical outcomes in patients presenting with low SvO2, but not in those with elevated lactate. These findings may help identify patients in cardiogenic shock who might benefit from mechanical circulatory support.

Cumulative incidences of all-cause mortality according to baseline venous oxygen saturation (SvO2) and baseline lactate. CI confidence interval; Cons, early conservative arm; ECMO, immediate extracorporeal membrane oxygenation arm; HR, hazard ratio.

Correspondence: E. Bustamante-Munguira
Intensive Care Medicine Experimental 2025,* 13(1)*:001648

Introduction: The patient in the ICU requiring extracorporeal renal replacement therapy is typically either a patient in shock who develops acute renal failure (ARF), initially requiring hemofiltration and later possibly dialysis, or a patient with chronic kidney disease undergoing dialysis who decompensates and needs to continue dialysis if their hemodynamic status allows or use hemofiltration for a few days until they recover and can return to dialysis.
Objectives: To study over 6 months (July-December 2024) in the ICU of HCUVA all patients admitted who required dialysis and/or hemofiltration and/or both, assessing whether there are differences in the development of catheter-related infections between the two groups, considering that many of them go through an initial phase of hemofiltration followed by dialysis.
Methods: A prospective observational cohort study without intervention, from July to December (current date) 2024. It studies two groups of patients followed throughout their stay in our unit, assessing dialysis or hemofiltration and whether they develop catheter-related infections.
Results: 49 patients were included, of which 17 required dialysis during their entire ICU stay, and 32 required.
hemofiltration, with 12 of them later undergoing several sessions of dialysis before discharge.
Dialysis—17 patients; **hemofiltration**—32 patients.
Dialysis group:- **Sex**: 66.6% male, 33.3% female **Mean age**: 70.83 years.
· **APACHE II**: 21.25, ·
FR: 41.66% chronic kidney disease (CKD) on dialysis 32% diabetes, hypertension, ·
Average stay: 18.3 days.
· **Reasons for admission**: ARF: 41.66%, Septic shock: 25%. CKD complications: 11.76%, admitted with infected catheter.
· **ICU mortality**: 16.6%

Hemofiltration group: Sex: 57.14% male, 42.85% female, Mean age: 68.80 years

- **APACHE II**: 27.90, **FR**: 6.25% CKD on dialysis
- **47%** diabetes, hypertension
- **Average stay**: 11.9 days
- **Reasons for admission**: AKI: 23.80%
  - Septic shock: 37%
  - Medication intoxication: 14.28%
- **CKD complications**: 3.12%
- **ICU mortality**: 28.57%

Conclusions:

- In both groups, the development of catheter-related infection is minimal; only 1 out of 49 patients developed this complication. In the dialysis group, the 2 patients with CKD had their tunneled catheters,
- which were infected and had to be removed after being transferred from the ward.
- Adherence to the Zero projects in the ICU units helps improve and maintain very low catheter-related infection rates.
- The profile of the patient with hemofiltration is more severe, with a higher APACHE score (27.9) and
- higher mortality (28.57%), 10 points above the dialysis group. This severity, combined with a higher prevalence of diabetes, could partly explain the slight increase in infectious complications.

Intensive Care Medicine Experimental 2025,* 13(1)*:001650

Introduction: Extracorporeal membrane oxygenation (ECMO) is a life-saving intervention used for patients with severe cardiac and/or

respiratory failure. This study aimed to analyse patient demographics, clinical characteristics, and outcomes associated with ECMO.
Objectives: The aim of this study was to analyze patient demographics, clinical characteristics, and outcomes associated with ECMO.
Methods: A retrospective analysis of 540 consecutive ECMO patients was conducted. Data on demographics, primary diagnoses, ECMO modalities, length of ECMO support, and mortality were collected. Statistical analysis included ANOVA, chi-square tests, and ROC analysis.
Results: The mean age of patients was 50.4 years (IQR 42–62), with a male predominance (70.9%). The most frequent primary diagnoses were cardiac arrest (20.9%), COVID-19 (17.1%), and post-operative status (12.4%). VV ECMO was the most common modality (44.4%), followed by VA ECMO (30.5%) and DCP (14.8%). The mean duration of ECMO support was 13.3 days. Overall mortality was 33.1% ($n = 179$). Among the patients, 45.7% ($n = 247$) were discharged alive. Post-ECMO mortality (4.1%, $n = 22$), aborted procedures (6.1%, $n = 33$), and cases, where cannulation was not performed (5.2%, $n = 28$). Age differed significantly across ECMO modalities (ANOVA, $F = 4.82$, $p < 0.0001$). No significant association was found between sex and ECMO type ($p = 0.089$). Primary diagnosis and mortality varied significantly across modalities (Chi-square, $p < 0.0001$). ECMO duration also differed significantly by modality ($F = 29.97$, $p < 0.0001$). VV ECMO was the most commonly utilized modality (44.4%, $n = 255$), followed by VA ECMO (30.5%, $n = 175$) and distal perfusion catheter (DCP) (14.8%, $n = 85$). Less frequently used modalities included ECPR (6.1%, $n = 35$) and VVA ECMO (0.7%, $n = 4$). The performance of a logistic regression model for predicting mortality was evaluated using Receiver Operating Characteristic (ROC) analysis. The model, incorporating Age and ECMO Modality as predictors, achieved an Area Under the Curve (AUC) of 0.73 (95% CI 0.66–0.80), indicating fair discriminatory power. These findings suggest the model's moderate ability to distinguish between survival and mortality, highlighting its potential utility in clinical decision-making.
Conclusions: This study provides a comprehensive overview of ECMO utilization, highlighting the variability in patient characteristics and outcomes across different ECMO modalities. Further research is needed to identify predictors of survival and optimize patient selection for ECMO therapy.

Understanding AI acceptance in European critical care: a cross-sectional survey study exploring physician perspectives

I. Ihaddouchen[1]; S. Buijsman[2]; C. Jung[3]; D. Gommers[1]; M. Van Genderen[1]
[1]Department of intensive care, Erasmus MC, Doctor Molewaterplein, Rotterdam, Netherlands, Rotterdam, Netherlands; [2]Faculty of Technology, Policy and Management, Delft University of Technology, Delft, Netherlands; [3]Department of cardiology, pulmonology and angiology, University Hospital of Düsseldorf, Düsseldorf, Germany
Correspondence: I. Ihaddouchen
Intensive Care Medicine Experimental 2025,* 13(1):*001651

Introduction: Artificial intelligence (AI) holds promise for improving patient care and decision-making in intensive care units (ICUs). However, successful adoption remains limited, partly due to a lack of insight into ICU physicians' acceptance and trust in AI. Identifying the factors that shape these attitudes is essential to understand the needs and concerns of ICU professionals and to ensure effective AI integration.
Objectives: This study aims (1) to identify factors influencing ICU physicians' acceptance of clinical AI, (2) to explore ethical considerations relevant to AI implementation based on WHO principles, and (3) to assess specific needs for AI implementation in ICUs.
Methods: A multicenter, cross-sectional survey was conducted among ICU physicians across 20 European hospitals collaborating in the INDICATE consortium. The survey included 51 items based on the Unified Theory of Acceptance and Use of Technology (UTAUT), Status Quo Bias theory, and WHO ethical AI guidance. Constructs included performance expectancy, effort expectancy, social influence, facilitating conditions, behavioral intention, inertia, perceived threat, resistance to change, and ethical principles. In addition, 10 items were included to explore physicians' views on a proposed solution that provides transparency in AI model characteristics, assessing if this matched their professional needs.
Results: In total, 320 ICU physicians responded, comprising 221 consultants (69%) and 99 residents (31%). Respondents represented a diverse European sample, predominantly from Italy (23%), Austria (16%), and the Netherlands (12%). Most were aged 31–40 years (48%) and worked primarily in adult ICUs (86%). Over 60% had less than 10 years of ICU experience. Overall, 67% of respondents believed the benefits of AI outweigh the potential risks, and 71% indicated they would use AI models to support clinical decision-making. Acceptance for administrative tasks was even higher (85%). Resistance to changes in clinical decision support due to AI was limited (19%) and even lower for administrative tasks (12%). However, familiarity with key AI concepts was limited. Forty-three percent were unfamiliar with performance metrics such as accuracy and specificity. Similarly, 37% lacked understanding of generalizability, and 44% were unfamiliar with fairness in AI.
Conclusions: ICU physicians showed a generally positive attitude toward AI, particularly for administrative support. Despite this, knowledge gaps remain regarding essential AI concepts. These findings emphasize the need for targeted education and transparent communication to support successful AI adoption. By identifying barriers, facilitators, and ethical concerns, this study informs strategies to improve AI implementation in intensive care settings.

Intensive Care Medicine Experimental 2025,* 13(1)*:001652

Introduction: Epidemiologically, acute poisoning data vary, directly dependent on cultural, social, and geographic factors, including the type of toxic substances involved.
Despite this, poisonings are a progressively growing public health problem, regardless of the increased referral and management capacity for each of these pathologies. Among the identified causes of acute poisonings admitted to ICUs worldwide are psychotropic drugs, drugs of abuse, alcohol, antidepressants, and analgesics.
Currently, there is no multicenter, practice-based database on poisoned patients admitted to intensive care units (ICUs). However, admission to the intensive care unit due to poisoning is a relevant topic due to the profile of the admitted patient, the length of hospital stay, and the resulting mortality.
Objectives: To evaluate the relationship between the cause of poisoning, the use of CRRT, days of hospital stay and mortality in patients with acute poisoning, adjusting for age, sex, APACHE II and SOFA, to identify factors associated with worse outcomes in the intensive care unit at the Juárez de México Hospital between January 1, 2022 and February 28, 2025.
The sample included patients admitted to the intensive care unit: men and women with suspected poisoning. The study consisted of eight men (50%) and eight women (50%). The total sample included patients between the ages of 16 and 66, with a range of 50 years and a mode of 31 years.
An electronic case report form was used to collect data on demographics, exposure, clinical characteristics, investigations, treatment, and in-hospital mortality of poisoned patients.
Methods: Retrospective cohort study, descriptive statistics and bivariate analysis were performed to detect significant associations, logistic regression for mortality and linear regression for length of stay.
Results: Days of stay: There are no significant differences by CRRT or cause of poisoning.
Mortality: The only death is associated with CRRT and Amanita phalloides, but the low frequency prevents conclusions. The trend ($p = 0.125$) suggests that CRRT may be associated with higher mortality, consistent with studies reporting 50–70% mortality in CRR.
CRRT: Not significantly associated with the cause of poisoning, but use is infrequent.
Cause of poisoning: The diversity of substances limits the analysis; the pharmacological/non-pharmacological grouping showed no differences.
Conclusions: Among the complications analyzed, the most common complication is the need for invasive mechanical ventilation; this is also associated with the need for vasopressor support. Less frequently, it is associated with the need for renal replacement therapy (regardless of whether it is intermittent and/or continuous) in 37.5% of cases. The third decade of life was the most affected population. The mortality observed in the overall population was 6.25%.
No significant differences were found ($p < 0.05$), most likely due to the sample size ($n = 16$) and low frequency of events (1 death, 2 CRRT).

Intensive Care Medicine Experimental 2025,* 13(1)*:001653

Introduction: Pulmonary embolism (PE) is a life-threatening cardiovascular emergency frequently encountered in the ICU. While anticoagulation is the standard treatment, systemic fibrinolysis is indicated for patients with high-risk PE, particularly those presenting with obstructive shock.
Objectives: To compare clinical outcomes between patients treated with fibrinolytic therapy and those receiving standard anticoagulation, focusing on disease severity (PESI classification), right ventricular (RV) dysfunction, hemodynamic instability due to schock, bleeding complications, and short-term recovery.
Methods: A retrospective cohort analysis was conducted at a secondary hospital in Portugal, including adult patients diagnosed with acute PE from January 2023 to December 2024. Diagnosis was confirmed by computer tomography pulmonary angiography. Patients were stratified into two groups: fibrinolysis (IV alteplase 100 mg over 2 h followed by anticoagulation with low molecular weight heparin—LMWH) and standard anticoagulation (LMWH alone, 1 mg/kg every 12 h or 1 mg/kg daily in renal impairment). PESI scores were calculated at admission. RV function was assessed by echocardiography. Obstructive shock was defined as hypotension requiring vasopressors due to RV failure. Primary endpoints were in-hospital and 30-day mortality and major bleeding. Secondary endpoints included ICU admission, hospital length of stay, and 90-day VTE recurrence.
Results: Fifty-four patients were included: 12 received fibrinolysis, and 42 received standard anticoagulation. Fibrinolysis was administered in all patients with obstructive shock, except one due to formal contraindication. Therapy was interrupted in two cases due to suspected hemorrhagic complications. Patients in the fibrinolysis group had higher PESI scores (mostly class IV–V), more RV dysfunction, and greater hemodynamic compromise. ICU admission and hospital stay were significantly longer (mean 4.2 vs. 2.9 days, SD ± 1.5), likely reflecting disease severity and multiorgan dysfunction. In-hospital mortality was 25% in the fibrinolysis group vs. 16% in the anticoagulation group. Major bleeding occurred in 4% of fibrinolysis cases, with no fatal events. No significant difference in 90-day VTE recurrence was observed.
Conclusions: Fibrinolytic therapy was selectively used in patients with high-risk PE and obstructive shock, aligned with international guidelines. While associated with slightly increased bleeding risk and longer hospitalization, it did not significantly reduce short-term mortality. These results support the cautious use of fibrinolysis in critically ill patients and highlight the need for individualized risk–benefit assessment. Long-term follow-up, particularly with RV function monitoring, remains essential to evaluate recovery and prevent chronic complications.

Intensive Care Medicine Experimental 2025,* 13(1)*:001654

Introduction: The assessment of airway may be challenging in neurosurgical patients, because airway assessment test need patients to cooperate and move their necks, which might not be possible with altered mental status or a cervical spine injury.1 Hence, thyromental Height (TMH) may be useful alternative in these challenging subset of patients, which can be measured in neutral head position and does not required patient's co-operation.2
Objectives: The objective of this study was to validate TMH as a predictor of Difficult Laryngoscopic View (DLV) and also to evaluate other routinely practised bedside airway assessment parameters for prediction of DLV in neurosurgical patients.
Methods: A total of 562 Patients aged 18–65 years, either gender, ASA physical status 1–3, who requiring neurosurgical procedures under general anaesthesia were included in this study. The patients were assessed preoperatively after getting written informed consent. TMH was assessed in supine position and head in neutral position. The TMH was measured as vertical distance from the anterior mentum to the thyroid notch using vernier calipers. For conscious and cooperative patient, other airway parameters such as mouth opening (MO), modified Mallampati (MMP), Thyromental distance (TMD), Upper lip bite test (ULBT) and Sternomental diostance (SMD) were also recorded. General anaesthesia was commenced as per institutional protocol. Intubation was done mackintosh blade by an experienced anaesthesiologist who has at least 3 years of anaesthesia experience to omit interobserver bias. Laryngoscopic view will be noted as per Cormack Lehane (CL) grade 1–4 where CL grade 3–4 was defines the difficult laryngoscopic view.
Results: Out of 562 participants, 97 (17%) patients had difficult laryngoscopic view (CL grade 3 & 4) in the study. The cut-off value to predict DLV was 4.9 cm of TMH, 2 FB of MO, 3 & 4 Class of MMT, TMD of ≤ 7 cm, and SMD of ≤ 12.7 cm with various sensitivity, Specificity, Positive predictive value, negative predictive value and diagnostic accuracy (Table 1). For unadjusted odds (univariate analysis), a TMH, hypertension, diabetes mallitus, height, ULBT, MMT, TMD, SMD has a statistically significant odds to predict DLV ($p < 0.05$). Following multivariate regression analysis, only TMH, MMT and TMD were statistically significant to predict DLV ($p < 0.05$). The multivariate adjusted odds of TMH was maximum 5.18 followed by MMT 1.84 and TMD 0.45.

Table 1 Performance metrics of the primary diagnostic parameters

Variable	Sensitivity	Specificity	PPV	NPV	Diagnostic Accuracy
TMH (≤ 4.9 cm)	75.3%	67.1%	32.3%	92.9%	68.5%
MO (2 FB)	10.3%	88.8%	16.1%	82.6%	75.3%
ULBT (Grade 2)	8.2%	97.4%	40.0%	83.6%	82.0%
MMT (Class 3&4)	23.7%	87.7%	28.8%	84.6%	76.7%
TMD (≤ 7 cm)	85.6%	24.1%	19.0%	88.9%	34.7%
SMD ≤ 12.7 cm)	80.4%	37.8%	21.3%	90.3%	45.2%

TMH Thyromental height; MO Mouth opening; ULBT Upper lip bite test; TMD Thyromental distance; SMD Sternomental distance; MMT Modified mallampatti test), FB Finger Bredth; Values expressed as percentage.

Conclusions: Thyromental height had a highest negative predictive value and multivariate adjusted odds to predict DLV in patients undergoing neurosurgical procedures. TMH can be measured in supine postion and hence, can be added to battery of airway assessment tool to get the optimal airway assessment.

Gaps between guidelines and practice: a cross-sectional survey on VAP prevention among Italian ICU nurses

C. Fanelli[1]; M. Crudu[1]; D. Pasero[1]; I. Maida[1]
[1]Department of Medicine, Surgery and Pharmacy, Italy, University of Sassari, Sassari, Italy
Correspondence: C. Fanelli

Intensive Care Medicine Experimental 2025,* 13(1)*:001655

Introduction: Ventilator-associated pneumonia (VAP) incidence is estimated as 5–40% with attributable mortality of 10% 1. Nurses have a pivotal role in their prevention, but no data on their current adherence to latest guidelines are available in Italy.

Objectives: We aimed to assess Italian ICU nurses' adherence to recommended hygiene practices to prevent VAP development mentioned in the latest ERS/ESICM/ESCMID/ALAT guidelines of 2017 for VAP management.

Methods: A cross-sectional study was conducted using an auto-administered, online, and anonyme questionnaire elaborated and distributed to ICU nurses of Italy. Participants agreed freely to join the survey. An observational analysis was performed.

Results: Of 53 ICU nurses who completed the survey (37/53; 70% females), 18/53 (34%) had more than 10 years of experience working in ICU with a good representation of the Italian country (North 14 (26.4%); Center 19 (35.8%); South 9 (17.0%); Islands (20.8%)).

In the Real-Life section of the survey, only 54.7% (29/53) of ICU nurses reported not wearing jewelry during clinical practice, neglecting its role in infection transmission. Despite the 71.7% being aware about the latest ERS/ESICM/ESCMID/ALAT guidelines (2017) on VAP management and prevention, the 60.4% (32/53) had never read, and institutional updates were offered in only 4/53 (7.5%) of cases.

Regarding WHO's "Five Moments for Hand Hygiene," high adherence was reported after exposure to body fluids (53/53, 100%), after patient contact (52/53, 98.1%), and before aseptic procedures (48/53, 90.6%). However, only 62.3% (33/53) of nurses performed hand hygiene before patient contact, and just 67.9% (36/53) did so after touching the patient's surroundings.

Considering VAP prevention-specific measures, 49/53 (92.4%) confirmed proper head-of-bed elevation (30–45°), and 49/53 (92.4%) used 0.12% chlorhexidine for oral hygiene. However, only 30/53 (56.6%) consistently performed antiseptic handwashing before oral care. Routine oral care three times per day was reported by 21/53 respondents (39.6%). Bronchial suctioning practices were mostly aligned with standard recommendations: 43/53 (81.1%) performed it only when necessary, 41/53 (77.3%) limited the duration to ≤ 15 s, and 46/53 (86.8%) applied aseptic technique. Use of closed suction systems was reported by 39/53 nurses (73.6%), though only 21/53 (39.6%) performed hand hygiene before closed-circuit suctioning. Finally, 44/53 (83.0%) maintained tracheostomy cuff pressures at 20–25 cmH_2O, and 48/53 (90.6%) managed endotracheal cuff pressures at 25–30 cmH_2O. Cuff pressure monitoring every 8 h was performed by just over half of respondents (28/53, 52.8%). In the Propositive Section, an 'obligatory course about VAP prevention at hiring' was rated as 'best solution', a 'trimestral refresh course' was considered as the 'most effective solution' by respondents.

Conclusions: Hands hygiene compliance remains fairly limited as long as awareness and knowledge of current guidelines among ICU nurses in Italy. Nurses' proposals on how to improve adherence to guidelines should be taken into consideration for future educational efforts to be implemented.

Intensive Care Medicine Experimental 2025,* 13(1)*:001656

Introduction: Acute kidney injury (AKI) is a frequent and serious complication in critically ill patients. Despite the availability of guidelines, the implementation and monitoring of AKI-related quality indicators remain limited.

Objectives: The aim of this study was to develop and to evaluate the use of automated quality indicators (AQI) based on variables obtained from the clinical information system (CSI) to measure compliance with clinical practice guidelines in the field of intensive care nephrology.

Methods: A multidisciplinary team (intensivists and biomedical engineers) developed the indicators based on the 2012 KDIGO guidelines and the 2017 SEMICYUC quality indicators. The AQI were then applied in a retrospective, single-centre analysis in a 30-bed general ICU. All adults patients with an ICU stay > 48 h were included. Patients with chronic renal failure (CRF according to ICD-9/10) were excluded.

AKI was diagnosed and staged according to KDIGO criteria based on daily serum creatinine and diuresis assessed at 6-h intervals. In the absence of pre-admission laboratory values, baseline creatinine was estimated using the age- and sex-adjusted MDRD formula for the Caucasian population.

Results: Ten AQIs were selected (Table 1), six AQIs were outcome-related, assessing the diagnosis, progression, and recovery of AKI and renal function, and four AQIs were process-related, assessing compliance with international recommendations.

Of the 7661 patients included, 1239 for CRF were excluded. The final cohort was 6422 patients with baseline characteristics detailed in Table 2.

In the whole population AKI developed in 32.2% of patients during their stay in the ICU. Among them, 26.9% presented with persistent AKI for more than 7 days. 27.3% of patients progressed to AKI stages II-III, 17.95% required continuous renal replacement therapy (CRRT) and 77.4% recovered baseline renal function.
13.5% of patients spent more than 17% of their time in the ICU with a mean arterial pressure (MAP) below the recommended target, and this rose significantly to 81.2% in patients with a history of hypertension. Only 49.0% had early glycaemic control, only 33.2% had nephrotoxic drugs discontinued within the first 24 h alone, and only 6.6% had creatinine clearance measured to adjust drug doses.
Conclusions: The application of the AQI made it possible to identify low compliance with international recommendations. Having quality indicators in this area has helped to identify areas for improvement and will make it possible to assess the impact of the measures implemented.

Table 1 Automated quality indicators for acute kidney injury

	Indicator Name	Formula	Results
1	ICU-Acquired Acute Kidney Injury Rate (%)	Number of patients who developed AKI[1] during ICU stay / Total number of ICU-admitted patients without AKI on admission[2] × 100	32.21
2	AKI Diagnosis Documentation Rate (%)	Number of patients with ICD-9/10 coded AKI in the discharge report / Total number of patients with AKI × 100	17.76
3	Progression from AKI to Acute Kidney Disease (AKD) (%)	Number of patients with AKI lasting > 7 days during ICU stay / Total number of patients with AKI x 100	26.95
4	Progression from AKI to KDIGO Stage II/III (%)	Number of patients with AKI stage I progressing to stage II–III [1] / Total number of patients with AKI stage I x 100	27.33
5	Renal Replacement Therapy (RRT) Requirement (%)	Number of patients undergoing hemodialysis or RRT / Total number of AKI patients without limitation for RRT x 100	17.95
6	Renal Function Recovery (%)	Number of AKI patients who return to baseline [3] < baseline creatinine before ICU discharge / Total number of AKI patients × 100	77.49
7	Hemodynamic Monitoring in AKI (%)	Number of AKI patients with MAP below target [4]>17% of ICU stay / Number of AKI patients with continuous BP monitoring and no treatment limitations ×100	13.59 (non- hypertensive) 81.21 (hypertensive patients)
8	Correction of Hyperglycemia (%)	Number of episodes with 2 consecutive glucose peaks >180 mg/dL followed by insulin initiation or dose increase / Number of episode with 2 consecutive glucose peaks >180 mg/dL ×100	49.06
9	Nephrotoxic Drug Discontinuation Rate (%)	Number of nephrotoxic drugs[5] discontinued within 24 h of AKI diagnosis / Total number of nephrotoxic drugs prescribed in AKI patients ×100	33.23
10	GFR Estimation via Creatinine Clearance (%) (%)	Number of AKI patients with measured creatinine clearance) / Total number of AKI patients ×100	6.63

(1) AKI diagnosis and staging were based on the 2012 KDIGO criteria, using daily serum creatinine and urine output normalized for ideal body weight in 6-hour intervals. (2) AKI on admission was defined as serum creatinine within 24 hours of ICU admission ≥150% of the estimated baseline value. (3) Baseline creatinine was estimated using the MDRD formula, adjusted for age and sex, in the Caucasian population. (4) Target mean arterial pressure (MAP) was >65 mmHg in the general population and >80 mmHg in hypertensive patients. (5) Nephrotoxic drugs included NSAIDs, metamizole, ACE inhibitors, ARBs, vancomycin, amphotericin B, and aminoglycosides.

Table 2 Baseline characteristics of general population

Age, median [Q1,Q3]	61 [48-71]
Male sex, n (%)	5511 (63.8)
ICU days, median [Q1,Q3]	4 [2-9]
Mortality, n (%)	1256 (14.5)
Chronic cardiac failure, n (%)	431 (5.0)
Liber cirrrhosis, n (%)	755 (8.7)
diabetes, n (%)	1754 (20.3)
Arterial hypertension, n (%)	3856 (44.6)
Chronica anemia, n (%)	1473 (17.0)
Dehydratation, n (%)	15 (0.2)
Sepsis, n (%)	1179 (13.6)
APACHE II, median [Q1,Q3]	19 [14-25]
Charlson index, median [Q1,Q3]	3 [1-5]
SOFA, median [Q1,Q3]	2 [1-4]
Coronari, n (%)	92 (1.1)
Mèdic (%)	6111 (70.7)
Quirùrgic n (%)	2298 (26.6)
Traumàtic n (%)	110 (1.3)
imv DAYS, median [Q1,Q3]	0 [0-4]
Vasoactive drugs, n (%)	86 (1.0)

Status epilepticus severity score a tool to predict mortality in status epilepticus

I. Sdiri[1]; S. Charfi[2]; I. Klai[3]; S. Blonco[1]; Y. Garbaa[1]; S. Ines[3]; N. Falfoul Borsali[4]
[1]Réanimation médicale, Habib Thameur Hospital, Tunis, Tunisia; [2]Intensive care unit, Habib Thameur Hospital, Tunis, Tunisia; [3]ICU, Hôpital Habib Thameur, Tunis, Tunisia; [4]Intensive care, Hôpital Habib Thameur, Tunis, Tunisia
Correspondence: I. Sdiri
Intensive Care Medicine Experimental 2025,* 13(1)*:001657

Introduction: Status epilepticus (SE) treatment ranges from small benzodiazepine doses to coma induction. For some SE subgroups, it is unclear how the risk of an aggressive therapeutic approach balances with outcome improvement. We recently developed a prognostic score (Status Epilepticus Severity Score, STESS), relying on four outcome predictors (age, history of seizures, seizure type and extent of consciousness impairment), determined before treatment institution.
Objectives: Our aim was to assess whether the score might have a role in the treatment strategy choice.
Methods: We conducted a retrospective observational study over 3 years, from January 2022 to December 2024. All consecutive patients aged more than 18 years admitted to the medical ICU of Habib Thamer University hospital for a status epilepticus were included. We collected baseline demographics and clinical characteristics. Therapeutic management and ICU stay related complications were recorded. The primary outcome was the correlation between STESS and the prognosis of SE.
Results: During the study period, we included 80 patients with a median age at 52 [18–90] years. Mainly males (62 patients) with a genre ratio at 3.4. Patients had a known epilepsy in 37.5% of cases (n = 30). Major other comorbidities were hypertension 23.8% and diabetes 22.5%. The median of STESS score at 3 [2–4]. Status epilepticus was caused by an acute stroke in 30.4% of cases followed by poor controlled epilepsy due to medicine withdrawl in 24.1%, meningoencephalitis in 8.9%, metabolic disorder and acute intoxication in 3 cases each. No specific etiology was found in 20.3% of cases. Invasive mechanical ventilation was required in 74.7% of the cohort and the mortality rate was 31.3% (n = 25).
The analysis of the curve ROC demonstrates a STESS score higher than 2 correlated with mortality with aire under curve at 0.67, p = 0.004, 55% of sensibility and 60% of specificity. We noted 23/25 of died patients with a STESS score > 2 points.
Conclusions: STESS can represent a useful tool in assessing the gravity of SE episodes and that immediate aggressive treatment, might possibly be avoided in the majority of patients with a low score, who will almost certainly survive their SE episode, and likely return to clinical baseline.

Efficacy of subcutaneous sumatriptan in post-craniotomy pain: a systematic review and meta-analysis

MD. Balsells[1]; TLM. Lopes[1]; JMS. Treigher[1]; FB. Mendes[1]; HFL. Filho[1]; MAODM. Cavalcante[1]; IFDM. Pereira[2]; ISBD. De Melo[3]; MVF. Messias[4]; AB. De Lucena[2]; LRCC. Da Silva[5]; ÁM. Soares[6]; LAF. De Albuquerque[6]

Correspondence: I. Fernandes de Melo Pereira
Intensive Care Medicine Experimental 2025,* 13(1)*:001660

Introduction: Post-craniotomy pain (PCP) remains a significant clinical challenge. Subcutaneous sumatriptan (SC-SMT) has emerged as a potential non-opioid alternative for PCP management, with promising results in reducing pain scores. Despite these findings, no meta-analysis has exclusively evaluated SC-SMT for PCP management. To address this gap, we conducted a systematic review and meta-analysis to evaluate the role of SC-SMT in PCP after an elective craniotomy procedure.
Methods: We performed a systematic review and meta-analysis of studies retrieved from PubMed, Embase, Cochrane Library, and Web of Science. Studies were included if they assessed SC-SMT in the intervention group. Trials without a control group or with incompatible outcome measures were excluded. The outcomes analyzed were changes in the Numeric Pain Rating Scale at 12 and 24 h postoperatively, postoperative opioid consumption at 6 and 24 h, and scores in the Pain domain of the Quality of Recovery-40 (QoR-40) questionnaire. Statistical analyses were performed using Review Manager version 5.4.1. Heterogeneity among studies was assessed using the I^2 statistic.
Results: Two randomized controlled trials (RCTs) and two observational studies were included, totaling 423 patients, of whom 201 take SC-SMT alone or with opioids, and in the rest were administered placebo or opioids. The mean age in all patients was 55.74 years. The included populations comprised individuals undergoing craniotomy for a range of conditions, including trigeminal neuralgia, intracranial aneurysms, tumors, cerebrovascular diseases, and other neurosurgical indications. Studies follow-up periods ranged from 24 h to 3 months, and they were conducted in North America. Compared to control groups (placebo or opioid-based analgesia), SC-SMT was associated with a statistically significant reduction in pain scores at 12 h (MD = − 0.59; 95% CI − 0.89 to − 0.30; $p < 0.0001$) and at 24 h (MD = − 1.18; 95% CI − 2.06 to − 0.29; $p = 0.009$). Postoperative opioid consumption was significantly reduced in the SC-SMT group at 6 h (MD = − 4.34; 95% CI − 6.76 to − 1.91; $p = 0.0005$). However, the opioid consumption was not significant at 24 h (MD = − 1.40; 95% CI − 5.27–2.48; $p = 0.48$). QoR-40 scores in the pain domain were significantly higher in the SC-SMT group (MD = 6.02; 95% CI 0.14–11.90; $p = 0.04$).
Conclusions: Our systematic review and meta-analysis indicate that SC-SMT is an effective intervention for the management of PCP, with additional benefits observed in the reduction of opioid consumption and enhancement of postoperative recovery quality. However, these findings should be interpreted with care due to limitations in the included studies. We strongly recommend the conduction of further RCTs to more comprehensively assess the efficacy of SC-SMT in the management of PCP, thereby allowing for more definitive conclusions regarding this therapeutic approach.

Topic: Neurointensive care.

Induction teaching on attending emergencies as part of the ITU team for non-anaesthetist resident doctors

M. Mahr[1]; AX. Huang[2]
[1]Emergency Department, ESNEFT, Colchester, United Kingdom; [2]Anaesthetics, Colchester Hospital, Colchester, United Kingdom
Correspondence: M. Mahr
Intensive Care Medicine Experimental 2025,* 13(1)*:001661

Introduction: Resident doctors (SHOs) from non-anaesthetic backgrounds rotating onto Colchester Hospital Critical Care Unit (CCU) are expected to support CCU registrars in emergencies, by drawing up anaesthetic drugs and gathering intubation equipment. Anaesthetics forms only a small part of undergraduate medicine courses; a 2024 review of SHOs shows that 38.5% agreed their undergraduate anaesthetics teaching was sufficient, and only 6% of Foundation Programme jobs include anaesthetics [1]. This means most are not familiar with these roles and in turn, mistakes can occur, in addition to delaying time-critical management of unwell patients. SHOs have expressed anxiety over this, and CCU registrars have reported feeling distracted having to supervise and dictate drug/equipment preparation as well as resuscitation management.
Objectives: To increase the average self-assessed confidence and knowledge scores of non-anaesthetist Resident Doctors at Colchester Hospital when attending CCU emergencies by 25% by August 2025 to optimise the delivery of care to patients.
Methods: We held teaching sessions at every CCU SHO induction since August 2024. We used pre- and post- session surveys on a five-point scale from "not confident" to "confident", to assess level of comfortability in attending arrest calls as part of the CCU team; assisting intubations; recognising CCU candidates; knowledge of anaesthetic equipment, induction and emergency drugs. We also created and distributed quick reference lanyard cards for drug preparations (Fig. 1).
Results: We had eleven and twelve responses for the pre and post surveys, respectively. Scoring the scale between one to five, pre teaching ($n = 11$) trainees generally felt unfamiliar and unconfident with all examined aspects, ranging from average score of 1.9–2.36 out of 5. In the post teaching survey ($n = 12$), an improvement is noted with the score ranging between 3.4 and 3.83, with no participant answering "not confident" to any domain.
Conclusions: Our survey confirms the idea that intensive care medicine is a daunting rotation for resident doctors from a non-anaesthetic background. Many key concepts and procedures are primarily used only in anaesthetics, thus SHOs often feel ill-prepared for the challenges of managing unwell patients, especially those needing emergency intubations. We developed a programme that starts with an induction taught session, supplemented by quick recall lanyard cards, both designed to minimise cognitive overload at the learning stage and in an acute setting. Our post-course survey shows that following our programme, SHOs feel more comfortable and knowledgeable when participating in emergencies as part of the CCU team.

Topic: Health Services Research and Outcome.

Author contributions

KG and IIS had full access to all of the data and take responsibility for the integrity of the data and the accuracy of the analyses. EC, KG, and IIS conceived and designed the study. EC, KG, EP, SO, ID, AK, and IIS acquired and/or interpreted the data. KG performed the statistical analyses. EC and KG drafted the manuscript. EP, SO, ID, AK, and IIS critically revised the manuscript for important intellectual content. IIS supervised the study. All authors read and approved the final manuscript.

Data availability

This secondary analysis used de-identified participant-level data from the LOTUS FRUIT, VIOLET, CLOVERS, and ASTER PETAL trials, obtained from the National Heart, Lung, and Blood Institute's Biologic Specimen and Data Repository Information Coordinating Center (BioLINCC). These datasets are available to qualified researchers upon application and approval through BioLINCC, in accordance with NHLBI data-use

policies. Additional information is available from the corresponding author upon reasonable request.
