Introduction: Hallucinations are perceptual disturbances frequently occurring in critically ill patients, often alongside disturbed behaviour, potentially reflecting neurocognitive dysfunction associated with critical illness. ICU research on hallucinations has previously examined relatively small patient cohorts and utilised post-discharge recall, which is prone to inaccuracies. Natural language processing (NLP) offers a novel, unbiased method for real-time detection by analysing contemporaneously recorded clinical notes.
Objectives: This study aimed to use NLP to determine the incidence of hallucinations in ICU patients, characterise their clinical trajectory, and assess associations with behavioural disturbances, medication use, patient characteristics, and outcomes.
Methods: We conducted a non-interventional, observational study in three medical-surgical ICUs, including adult patients admitted from July 2016 to May 2022. NLP was employed to detect hallucinations and disturbed behaviour (NLP-Dx-BD) [1][2] from clinical progress notes. We conducted a nested cohort analysis of patients with available electronic medication records. Patient demographics, clinical data, and outcomes were sourced from the Australian and New Zealand Intensive Care Society Adult ICU Patient Database. Statistical analysis involved logistic regression and Cox proportional hazards models, adjusted for age, type of admission and ANZROD mortality prediction model [3].
Results: Of 7,525 ICU patients, 625 (8.31%) experienced hallucinations, nearly all (99.7%) having NLP-Dx-BD, compared with 47.4% without hallucinations ($p < 0.001$). Hallucinations typically emerged within the first three ICU days, resolving after a median of 15 h. Patients with hallucinations were younger, had greater acute illness severity, and more frequently had cirrhosis, hepatic failure, acute kidney injury, or psychiatric histories. Visual hallucinations predominated (69.1%), followed by auditory (14.1%), and combined (16.8%). In the nested cohort (n = 2,904), hallucinations occurred in 252 (8.7%) patients, with antipsychotic medications administered to 23.8%, compared with 5.5% without hallucinations ($p < 0.001$). Ketamine use was significantly higher in patients with hallucinations (25.4% vs 6.9%, $p < 0.001$), 96.9% received ketamine before their first hallucination episode. Despite these associations, there were no significant differences in hospital mortality (6.9% vs 9.3%) or 28-day mortality (4.5% vs 8.3%).
Conclusions: Hallucinations affect approximately one in 12 ICU patients and typically occur early during ICU admission. They correlate with subsequent disturbed behaviour and increased antipsychotic medication use. Hallucinations may represent a distinct phenotype of neurocognitive dysfunction associated with critical illness. NLP provides an effective and scalable method for real-time detection, facilitating future research and early interventions aimed at preventing or reducing hallucinations and limiting progression to behavioural disturbance.

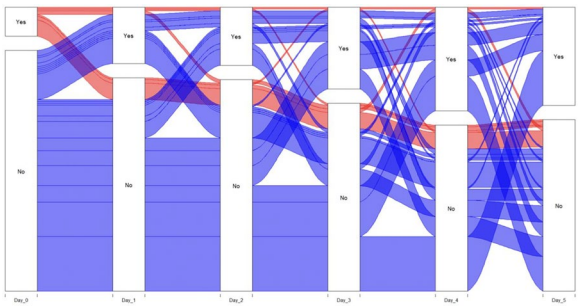

Fig. 1 (abstract 000132) Alluvial plot illustrating the trajectory of hallucinations in ICU patients. Patients without hallucinations on day 0 are shown in blue, and patients experiencing hallucinations on day 0 are shown in red.

Intensive Care Medicine Experimental 2025 **13(1)**:***000311***

Introduction: Intraoperative hypotension (IOH) is a significant risk factor for severe postoperative organ dysfunction [1]. However, the individual patient characteristics contributing to an increased risk of IOH remain insufficiently understood, particularly with regard to sex differences [2]. Previous studies have already highlighted the importance of incorporating sex-specific factors into therapeutic decision-making [3, 4]. The aim of this systematic review is to identify sex as a potential risk factor for IOH and to assess its impact on the incidence of IOH.
Methods: The protocol for this systematic review was registered on PROSPERO [5]. A systematic literature search was conducted in the following databases from inception until March 2, 2024: Embase, MEDLINE (via Ovid), and the Cochrane Library. Additionally, relevant references and newly published studies after the screening period were manually included.
Odds ratios (OR) for the incidence of IOH were pooled using a random-effects model. Whenever available, ORs were extracted directly from the studies. If ORs were not reported, they were independently calculated based on individual patient data, provided that sufficient information was available.
Subgroup analyses were conducted for studies that exclusively investigated either general anesthesia or spinal anesthesia. Studies that included both anesthetic techniques or focused solely on regional anesthesia were categorized as 'Other'.
Inter-study heterogeneity was assessed using the I^2 statistic. Statistical significance was defined as $p < 0.05$.
Results: Of the 6,575 screened studies, 65 met the inclusion criteria and were included in the statistical analysis.
Sex-specific analysis revealed that women had a 15% higher likelihood of developing IOH (OR 1.15; 95% CI 1.07–1.23) (see Fig. 1). This association remained significant in the subgroup analysis of studies focusing on general anesthesia (OR 1.14; 95% CI 1.02–1.28; 40 studies). Overall heterogeneity was classified as high, with an I^2 value of 83%.
Conclusions: Female sex was identified as a relevant risk factor for the occurrence of IOH. Further research is needed to evaluate whether sex-specific therapeutic strategies can reduce the incidence of IOH in women and thereby improve patient outcomes.

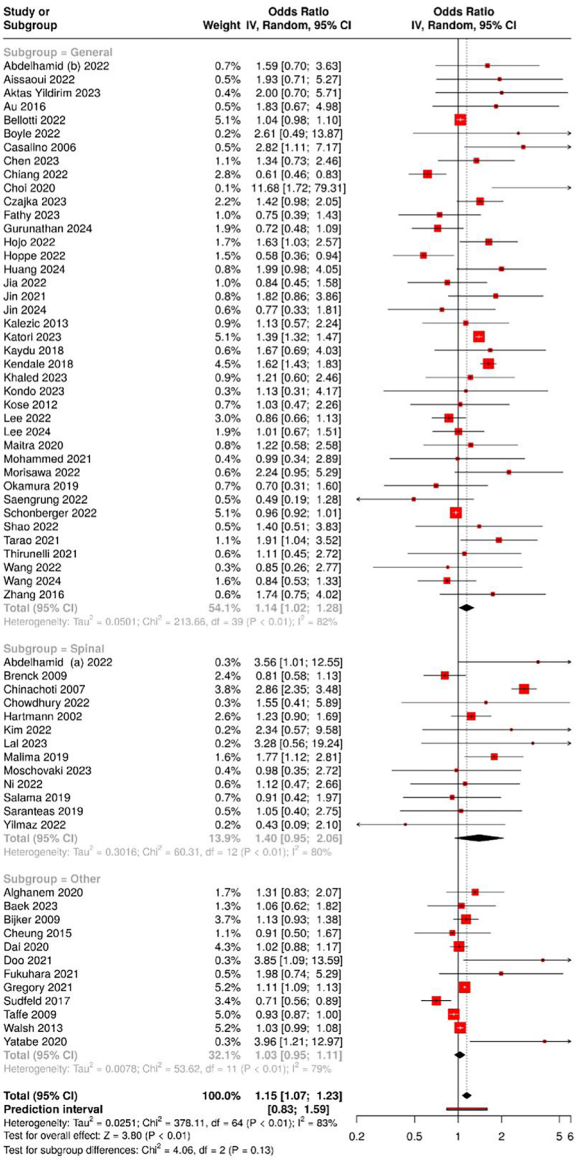

Fig. 1 (abstract 000311) Influence of sex on the probability of intraoperative hypotension occurrence Subgroups were defined as studies that exclusively investigated general anesthesia, those that focused solely on regional anesthesia, and studies that included both anesthesia techniques or purely regional procedures. The latter were categorized under "Other".

Introduction: To extend the evidence base on family-focused ICU care, we developed and tested a multicomponent family support intervention (FSI) that combined family engagement and coordinating practices with nurse-therapeutic family conversations in addition to structured, interprofessional communication (Naef et al., 2022). These intervention components are delivered by dedicated ICU family nurses in close collaboration with the ICU team from patient admission through to the post-ICU phase. The FSI was introduced on ICUs using a trailed implementation strategy (Verweij et al., 2023).
Objectives: To examine the effectiveness of the FSI on family satisfaction, quality of communication, and cognitive/emotional support provided to families of critically ill adults
Methods: Multicenter, cluster-randomized trial with 1:1 assignment of 16 Swiss ICUs to intervention (= implementation of FSI) and control arm (= usual care) (Naef et al., 2022). Participants were family members of critically ill adults with an expected ICU stay of ≥ 48 h and high risk of an adverse course of illness, enrolled between May 2022 and January 2024. The quality of care outcomes were assessed once after discharge (-1 / + 90d), namely family satisfaction as the primary outcome (FS-ICU-24R, 0-100 = high satisfaction), quality of clinician-family communication (QQPPI, 1-5 = high quality), and cognitive/emotional nurse support to family (FPSQ, 14-70 = high support). Linear mixed-effects models were used to analyze data of all participating family members (von Felten et al., 2024
Results: A total of 885 family members (n = 412 intervention, n = 473 control) were enrolled (42.7 enrollment rate), and 91% completed the follow-up. Almost half (48%) were partners of patients with a median SAPS-2 score of 55.8, and 64% were women. Fidelity to the pre-specified minimal intervention dose ranged between 90.8% (patient admission) and 43.9% (follow-up care within 4 weeks, 92.0% if no time limit was applied). The intervention improved family satisfaction with care by a mean difference (MD) of 2.39 (95% CI: 0.31 to 4.47, p = 0.024). Sensitivity analyses adjusting for ICU, patient, and family member baseline characteristics and with multiple imputation confirmed this result. A strong intervention effect was noted for satisfaction with involvement in decision-making (MD: 2.84, 95% CI: 0.71 to 4.98, p = 0.0090), communication (MD 0.37, 95% CI: 0.16 to 0.58, p = 0.0019), and cognitive/emotional support (MD 8.71, 95% CI: 4.71 to 12.71, p = 0.00034).
Conclusions: A nurse-led, interprofessional family support intervention in adult ICU increased family satisfaction to a small extent. A relevant improvement was found for family satisfaction with involvement in decision-making, communication, and cognitive/emotional support to families. The intervention's effectiveness on family functioning and family mental health is still under investigation. Nonetheless, incorporating the intervention as standard component of ICU care seems to be of value.

Intensive care Medicine Experimental 2025* 13(1):*000349

Introduction: Nosocomial lower respiratory tract infections (NLRTIs) are among the most frequent infectious complications in Intensive Care Unit (ICU) patients. Ventilator-associated pneumonia (VAP), ventilator-associated tracheobronchitis (VAT), ICU-acquired pneumonia (ICU-HAP), and hospital-acquired pneumonia (HAP) remain persistent public health challenges despite widespread preventive measures. Gram-negative bacteria, especially *Pseudomonas aeruginosa* (PA), are the predominant causative agents of NLRTIs. However, accurately identifying patients who require empirical antipseudomonal treatment remains a clinical challenge.
Objectives: To identify risk factors associated with PA-related NLRTIs and describe the affected patients' main clinical outcomes.
Methods: This prospective cohort study included ICU-admitted patients with confirmed NLRTIs across 12 countries on two continents, from May 9, 2016, to August 16, 2019. Clinical and microbiological data were collected per local protocols. Patients were categorized based on the isolation of PA or non-PA pathogens. A Random Forest algorithm and LASSO (Least Absolute Shrinkage and Selection Operator) regression were applied to determine variable importance, followed by multivariable logistic regression. Results are reported as odds ratios (ORs)

with 95% confidence intervals. Analyses were conducted in R Studio (version 2023.09.1 + 495).

Results: 1,059 patients were included; 74% were male, with a median age of 64 years (IQR 49–73). The most frequent comorbidities were diabetes, heart disease, and COPD. PA was isolated in 14.4% of patients. Differences in comorbidities, complications, and outcomes were observed between PA and non-PA groups (Table 1). The predominant pathogens were *P. aeruginosa*, *Staphylococcus aureus*, and *Klebsiella spp*. Among PA cases, VAP was the leading NLRTI diagnosis. Notably, 64.6% of non-PA patients received antipseudomonal therapy unnecessarily, while 28.8% of PA-infected patients were not treated with antipseudomonal agents. PA resistance to carbapenems was observed in 11.1% of cases (Fig. 1). The machine learning models demonstrated > 80% accuracy in predicting PA-related NLRTIs. The final multivariable analysis identified the following factors independently associated with PA NLRTI: COPD Gold D (OR 3.44, 95% CI 1.37–8.15, p = 0.01), active autoimmune disease (OR 2.58, 95% CI 1.35–4.72, p < 0.01), acute kidney injury on day 1 (OR 1.95, 95% CI 1.23–3.05, p < 0.01), and renal compromise (OR 1.89, 95% CI 1.10–3.19, p = 0.01)(Fig. 2).

Conclusions: Over half of the patients without PA infection received unnecessary antipseudomonal treatment, while a substantial proportion of PA-infected patients did not receive adequate therapy. COPD Gold D, active autoimmune disease, early acute kidney injury, and renal compromise were significantly associated with PA-related NLRTIs. Interestingly, standard severity scores were not predictive. These findings underscore the need for improved clinical tools to guide empirical therapy and reduce inappropriate antimicrobial use.

Introduction: Ultra-low tidal volume ventilation, by reducing tidal volume (VT) at or below 4 ml/kg predicted body weight (PBW) has potential to minimize ventilator-induced lung injury in patients with acute respiratory distress syndrome (ARDS), but may be associated with an increase in arterial carbon dioxide (PaCO2) without extracorporeal CO2 removal (ECCO2R) techniques. We recently published the short-term results of the VT4-COVID trial, a randomized controlled trial comparing ultra-low tidal volume ventilation with protective ventilation in COVID-19 ARDS.
Objectives: The aim of this study was to evaluate whether ultra-low tidal volume ventilation without ECCO2-R impacts long-term secondary outcomes at day-365 from inclusion.
Methods: VT4-COVID was an open labelled multicentric randomized controlled study performed in 10 French intensive care units. Eligible patients were ARDS patients with COVID-19 pneumonia and a PaO2/FiO2 ratio ≤ 150 mmHg, and were randomized in two arms: an ultra-low tidal volume arm ventilated with VT 4 ml/kg PBW, and a control arm under protective ventilation with VT 6 ml/kg PBW. The following outcome criteria were evaluated at day-365 from inclusion: all-cause mortality, cognitive status assessed with the MOCA-5 min score, quality of life assessed with the SF-36 score, and post-traumatic stress disorder assessed with the IES-R score. Scores were presented as median [interquartile range], and a hazard ratio with its 95% confidence interval (CI95%) was computed to evaluate the impact of study arm on mortality. The study was referenced at clinicalTrial.gov under the reference NCT04349618.
Results: Two hundred and fifteen patients were included and randomized in the ultra-low tidal volume arm (n = 106) or in the control arm (n = 109) between April, 2020 and April, 2021. Four patients were lost to follow-up at day 365. Mortality at day 365 was not significantly different between arms (47/102[46%] vs. 44/106[42%], hazard ratio 1.194 (IC95%: 0.79 à 1.80). The others secondary outcomes were evaluated in 39/55 [71%] patients in the ultra-low tidal volume arm, and in 44/62 [71%] patients in the control arm. The MoCA 5-min score was significantly lower in the ULTV arm (26 [20-28] vs. 28 [25-29], p < 0.05), with a median difference amounting to -1 [CI95%:-4-0]. This difference was related to a significant decrease of the memory-learning component of the score (4 [4-5] vs 5 [5-5], median difference -1 [CI95%: -1-0], p < 0.05). There was no significant difference between groups regarding the 9 domains of the SF-36 score. The IES-R score was not statistically different between groups (19 [9 – 35] in the ULTV arm vs. 15 [8 – 36] in the control arm (p = 0.35), with a median difference amounting to 4 [CI95%: -4-12].
In univariate analyses, the MOCA 5-min score was significantly associated with maximal PaCO2 during ARDS management (p < 0.01), but not with minimal PaO2/FiO2 (p = 0.48).
Conclusions: Ultra-low tidal volume ventilation without ECCO2R has no detectable impact on mortality at day-365 in COVID-19 ARDS patients, but is associated with a small but significant decrease in cognitive status possibly related to increased PaCO2.

Intensive care Medicine Experimental 2025* 13(1):*000602

Introduction: Critically ill patients requiring mechanical ventilation often need sedation to alleviate discomfort. Current sedatives carry risks like hypotension and respiratory depression. Ciprofol (HSK3486), a propofol analog and GABA receptor agonist, shows comparable short-term efficacy to propofol with fewer side effects, as evidenced by prior studies. However, evidence regarding its suitability for prolonged sedation in intensive care settings remains limited. This study aimed to evaluate the efficacy, safety, and hemodynamic effects of ciprofol compared with propofol for long-term sedation in mechanically ventilated patients.
Methods: We conducted a single-center, retrospective cohort study of mechanically ventilated patients admitted to the ICU of the First Affiliated Hospital of Sun Yat-sen University between January 2022 and September 2024 who received continuous sedation with either ciprofol or propofol for > 24 h. The primary outcome was the achievement of target sedation (RASS score + 1 to -4). Secondary outcomes included safety parameters (hepatic/renal function biomarkers, oxygenation index) and hemodynamic stability (MAP, SBP/DBP, HR, and vasopressor requirements). Continuous variables were analyzed using t-tests or Mann–Whitney U tests, while categorical variables were assessed with Fisher's exact test (P < 0.05 considered statistically significant).
Results: The study included 302 patients (ciprofol: n = 188; propofol: n = 114) with comparable baseline characteristics (mean SOFA: 8.67 ± 3.96; APACHE II: 20.43 ± 7.54). Sepsis/septic shock was the primary admission diagnosis (63.6%). Both agents demonstrated equivalent sedation efficacy at all time points (6 h, 24 h, 48 h, and 72 h; P > 0.05), with no differences in ICU and hospital length of stay or ICU mortality. Notably, ciprofol required significantly lower initial doses (0.18 [0.11-0.28] *vs.* 1.18 [0.66-1.72] mg/kg/h; P < 0.001) and demonstrated superior early hemodynamic stability (ΔMAP: + 3.67 *vs.* -3.5 mmHg; ΔSBP: + 7 vs. -4 mmHg; both P < 0.001) with reduced vasopressor requirements (P = 0.012). At 72 h, while blood pressure parameters were comparable between groups, ciprofol maintained significantly lower vasopressor needs (0.14 [0.02-0.5] *vs.* 0.3 [0.07-0.75] mcg/kg/min; P = 0.019). Subgroup analysis of vasopressor-dependent patients revealed ciprofol's advantages in maintaining higher MAP (84.00 ± 10.87 *vs.* 79.85 ± 14.31 mmHg; P = 0.036) and SBP (129.62 ± 15.24 *vs.* 121.62 ± 23.30 mmHg; P = 0.017) while reducing vasopressor demand (P = 0.019).
Conclusions: In critically ill patients undergoing mechanical ventilation, ciprofol demonstrated comparable sedation success rates to propofol while requiring significantly lower initial doses to achieve ICU sedation targets and exhibiting a superior safety profile. Notably, in critically ill patients requiring vasopressor support, ciprofol showed distinct advantages over propofol in maintaining hemodynamic stability and reducing vasopressor demand. The findings support further prospective investigation of ciprofol in critical care sedation protocols.

Intensive care Medicine Experimental 2025* 13(1):*000673

Introduction: Oliguria is a key indicator in the diagnosis of acute kidney injury (AKI), yet the consensus definition of < 0.5 ml/kg/hour is increasingly questioned(1, 2). Recent studies suggest that the risk of AKI and increased mortality occurs at lower urine output thresholds than previously recognized(3, 4). However, to our knowledge, no study has evaluated the optimal threshold in relation to chronic kidney

disease (CKD). Moreover, existing studies evaluating the association between oliguria, AKI and mortality vary widely in methods, study population and population size.

Objectives: We aimed to determine the optimal threshold of minimal average urine output (mUO) associated with subsequent AKI, CKD and death using a large, high-quality, retrospective ICU dataset.

Methods: We included adult patients (≥ 18 years) admitted to the general ICU at Uppsala University Hospital between 2017 and 2024. Hourly urine output and clinical characteristics were extracted from electronic medical records. Patients with preexisting CKD were excluded. For each patient, mUO was calculated over 3, 6, 12 and 24 h (mUO3h, mUO6h, mUO12h, mUO24h) in accordance with previous publications(4). Multivariable logistic regression models were fitted for each time window, adjusting for SAPS 3 estimated mortality ratio and sex. Outcomes were: (1) AKI within 7 days of mUO, based on the KDIGO creatinine criteria; (2) CKD after ICU discharge; and (3) mortality following ICU care. We then fixed all covariates except mUO and visualized the multivariable models to determine a threshold for mUO in the range 0.0-1.0 ml/kg/h.

Results: 5006 patients were included in the analysis. mOU3h was not associated with mortality ($p < 0.156$). All other mOU time frames were significantly associated with AKI, CKD and death (mOU6h with mortality $p = 0.011$, all other models $p = < 0.0001$). In the visualized models with fixed covariates, the lowest risk of AKI, CKD and death was observed at mOU at 0.5 ml/kg/h or above. The mOU thresholds for a significant increased risk of AKI compared to the point of lowest risk were 0.54 (mUO3h), 0.48 (mUO6h), 0.41 (mUO12h), and 0.54 (mUO24h) (Fig. 1). For CKD, the corresponding thresholds were 0.20 (mUO3h), 0.24 (mUO6h), 0.31 (mUO12h) and 0.43 (mUO24 h), respectively (Fig. 2). For mortality, no significant thresholds were identified for mUO3h or mUO6h, while thresholds of 0.32 (mUO12h) and 0.21 (mUO24h) were observed (Fig. 3).

Conclusions: Although the current oliguria threshold of ≤ 0.5 ml/kg/h appears to align with the estimated AKI threshold in our models, more restrictive limits may offer improved prediction of long-term kidney outcomes, as suggested by associations with CKD and mortality. Our findings indicate that lower oliguria thresholds could be considered when the objective is to identify patients at risk of sustained kidney injury.

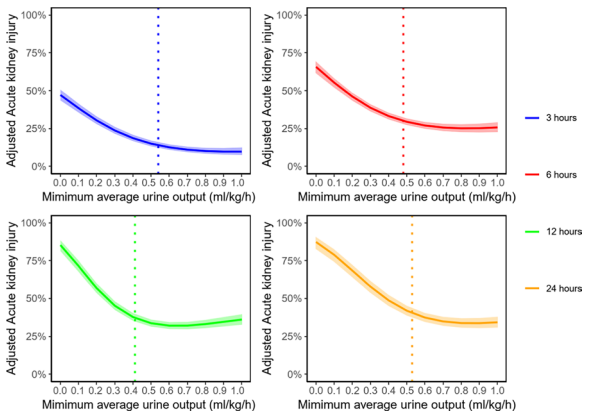

Fig. 1 (abstract 000673) Adjusted risk of acute kidney injury as a function of minimum average urine output over 3, 6, 12, and 24 h. Plot showing regression line, with 95% confidence intervals. Different colors represent different time windows as shown on the graph. The dashed line represents a statistical difference from minimal risk. Regression carried out with fixed predictors at median (i.e., male, and SAPS 3 estimated mortality ratio of 27.6).

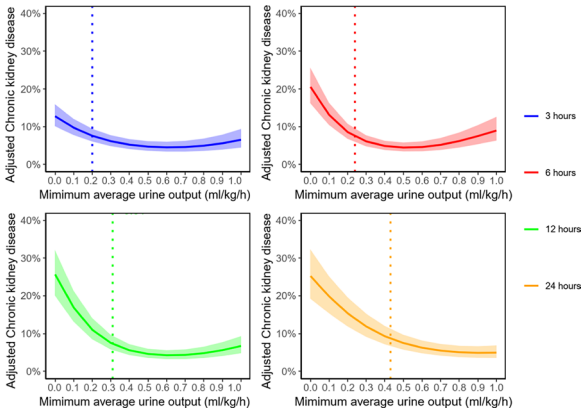

Fig. 2 (abstract 000673) Adjusted risk of chronic kidney disease after ICU-care as a function of minimum average urine output over 3, 6, 12, and 24 h. Plot showing regression line, with 95% confidence intervals. Different colors represent different time windows as shown on the graph. The dashed line represents a statistical difference from minimal risk. Regression carried out with fixed predictors at median (i.e., male, and SAPS 3 estimated mortality ratio of 27.6).

TREM-1 causes sepsis-associated acute kidney injury by mediating NLRP3 inflammasome activation to inhibit autophagy

X. Chen[1]; X. Liu[2]; X. Xu[2]; Y. Long[1]; L. Su[1]

Introduction: Sepsis triggers a rapid pathophysiological cascade leading to multiorgan failure, with the kidney often being the first affected organ. Epidemiologic data show sepsis-associated AKI (SA-AKI) occurs in 30-70% of critically ill patients, with mortality rates reaching 40-60%. Early detection and mechanistic understanding of SA-AKI are crucial for improving outcomes.
The inflammatory cascade and immune dysregulation drive sepsis pathogenesis. As a metabolic, excretory, and immunomodulatory organ, the kidney plays a central role in sepsis-induced multiorgan failure. Triggering receptor expressed on myeloid cells-1 (TREM-1) amplifies inflammation via the TREM-1/DAP12 pathway upon LPS stimulation. Soluble TREM-1 (sTREM-1) in urine shows diagnostic potential for SA-AKI, though its exact mechanisms remain unclear.
SA-AKI pathophysiology involves tubular injury, vascular dysfunction, and programmed cell death (apoptosis, pyroptosis, autophagy). While autophagy maintains renal homeostasis, TREM-1 appears to suppress autophagy while promoting apoptosis via NF-κB. Pyroptosis—mediated by caspase-1 and NLRP3 inflammasome activation—releases proinflammatory cytokines (IL-1β, IL-18). We hypothesize TREM-1 exacerbates tubular damage by activating NLRP3 while disrupting autophagy balance, creating a vicious cycle of inflammation and kidney injury.
Methods: To investigate the role of TREM-1 in sepsis-associated kidney injury, we generated TREM-1 knockout mice using CRISPR/Cas9 technology targeting the functional coding region of the TREM-1 gene. Twelve-week-old male C57BL/6J mice were subjected to cecal ligation and puncture (CLP) to establish a sepsis model, with experimental groups including wild-type controls, CLP-only, CLP with NLRP3 inhibitor (MCC950), TREM-1 knockout controls, knockout CLP, and knockout CLP with NLRP3 activator (nigericin).
We cultured HK-2 human renal tubular epithelial cells and manipulated TREM-1 expression using siRNA knockdown and cDNA overexpression, followed by LPS stimulation to mimic septic conditions. Kidney tissues from experimental mice were analyzed through histopathological scoring of tubular injury, while molecular analyses included qRT-PCR for TREM-1 expression, Western blotting for NLRP3 inflammasome components (caspase-1, gasdermin D) and autophagy markers (LC3B, Atg5, beclin-1), and ELISA for inflammatory cytokines. Serum creatinine and BUN levels were measured to assess renal function. Statistical analysis of triplicate experiments was performed using ANOVA with SPSS software, with $p < 0.05$ considered significant.
Results: We observed that TREM-1 deficiency alleviated kidney damage, as evidenced by reduced tubular injury, lower serum creatinine and blood urea nitrogen levels, and decreased proinflammatory cytokine expression. Moreover, TREM-1 activation was associated with enhanced NLRP3 inflammasome activity, promoting pyroptosis and apoptosis, while inhibiting autophagy.
In vitro, HK-2 renal tubular epithelial cells treated with lipopolysaccharide (LPS) demonstrated that TREM-1 upregulation increased inflammasome activation and cytokine release, suppressing autophagy and exacerbating apoptosis. Conversely, TREM-1 silencing reversed these effects, suggesting a regulatory role for TREM-1 in balancing inflammasome activity and autophagy. The interplay between NLRP3 and autophagy was further validated through pharmacological manipulation with MCC950 (inhibitor) and nigericin (activator).
Conclusions: In summary, TREM-1 may mediate the inflammatory response caused by the NLRP3 inflammasome by reducing the level of autophagy and kidney damage. This study provides a theoretical basis for sTREM-1 as a marker for the early diagnosis of AKI and for the use of TREM-1 as a new target in the treatment of AKI, which will help direct the study of new interventions and treatments of AKI in the future.

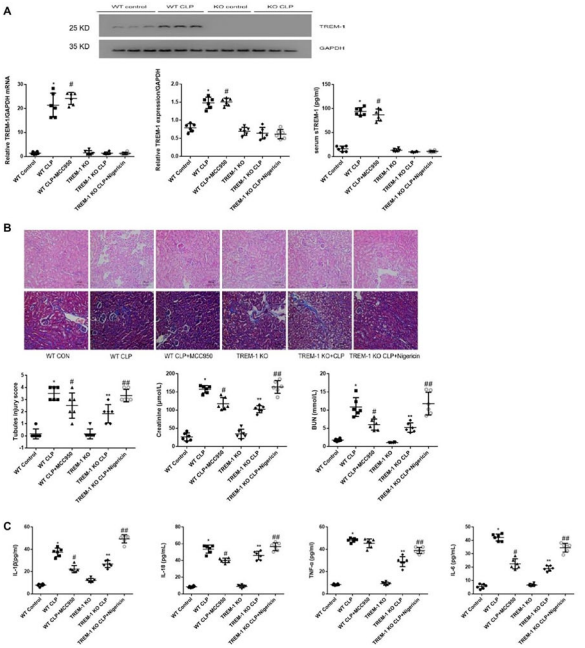

Fig. 1 (abstract 000901) AKI model, established by CLP, in TREM-1-KO and WT control mice. The effects of NLRP3 deletion (MCC950) and activation (nigericin) on the NLRP3 inflammasome in CLP-AKI mice were also examined. A Kidney TREM-1 protein and mRNA expression and serum sTREM-1 concentration in the different groups determined by Western blotting, PCR and ELISA (n = 6 per group). B Effect of renal injury after CLP on renal morphology. Representative micrographs showing kidney injury in the different groups of mice (original magnification is × 200). The kidney sections were subjected to HE and Masson staining. The kidney injury scores were quantitatively determined. The effect of renal injury on serum creatine and BUN levels was assessed (n = 6 per group). C TREM-1 mediates the production of inflammatory cytokines (IL-1β, TNF-α, and IL-6) in the different groups (n = 6 per group). The data are presented as the means ± SDs. Introduction: Heterogeneity of the host response in sepsis presents major challenges to finding effective treatments.[1] Several immunobiologically distinct subgroups (i.e. subphenotypes or endotypes) have been identified over the past decade, most commonly through data-driven analyses of single-timepoint biomarker data.[2] However, the dynamic biology of sepsis, together with methodological limitations of unsupervised clustering approaches, raises concerns regarding the temporal stability of these subphenotypes and their potential as therapeutic targets.
Objectives: This study investigates the temporal robustness of subphenotypes derived through biomarker-based clustering approaches in critically ill patients with sepsis.
Methods: We analyzed high-resolution longitudinal biomarker data from 345 sepsis patients enrolled in two Dutch ICU cohorts. Thirty biomarkers related to inflammation, endothelial injury, and coagulation were measured in plasma every 8 h for up to day 7 (3852 samples total). Latent profile analysis was used to identify immunobiological subphenotypes upon admission, and subsequently re-classify patients at later timepoints. Temporal stability was assessed by (1) between-subphenotype transition rates over time, and (2) subphenotype cohesion (regardless of label) as quantified by the Rand index.
Results: At ICU admission, three subphenotypes were identified: Profile A (128 patients, 37%) represented T-cell activation with high IL-4, IL-5, IL-7, IFN-γ, and GM-CSF); Profile B (92 patients, 27%) represented a hyperinflammatory profile with high IL-6, IL-8, IL-10, IL-1Ra, and low protein C; and Profile C (125 patients, 36%) exhibited overall suppressed levels of inflammation (Fig. 1). Within 48 h, the relative prevalence of profiles A and B declined to 29% and 10%, respectively, while C increased to 61%. Group reassignment occurred at least once in 82% of patients initially classified in profile A, 71% in profile B, and 43% in profile C. On average, across all successive time intervals, Profile A showed the highest rate of reassignment, followed by Profiles B and C (Fig. 2A). Lastly, an average of 55% of patients remained consistently grouped together or apart at later timepoints, as measured by the Rand index (Fig. 2B).
Conclusions: Sepsis patients assigned to biologically plausible subphenotypes based on latent profile analysis of comprehensive biomarker data at ICU admission were frequently reclassified at subsequent closely spaced time points, and overall, only about half of patients remained consistently grouped together over time. This instability raises concerns about the robustness and clinical applicability of such biomarker-derived endotypes.

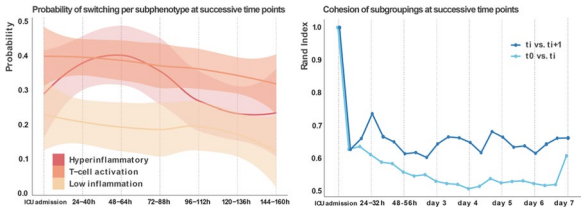

Fig. 2 (abstract 000994) Panel A. Probability of subphenotype transitions at successive time points. Lines represent locally estimated smoothing curves (LOESS), with shaded ribbons indicating the standard error. Transition probabilities were averaged across three consecutive time points prior to plotting. Panel B. Proportion of patients consistently grouped together or apart at each time point, as measured by the Rand index.

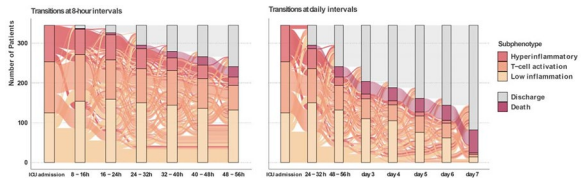

Fig. 1 (abstract 000994) Subphenotype transitions over time. Alluvial plots depicting patient subphenotype allocations at each time point based on a latent profile analysis (LPA) model derived at ICU admission (t0) using 30 biomarkers and a posterior probability cutoff of 0.5. Lines represent individual patient trajectories, with line colors indicating the subphenotype assigned at t0. Stacked bars reflect the proportion of patients assigned to each subphenotype at the respective time points. ICU: intensive care unit

Tissue inhibitor of metalloproteinase-2 (TIMP2) drives cellular senescence and maladaptive repair in the AKI-CKD transition through Wnt/β–catenin axis

Introduction: Acute kidney injury (AKI) frequently progresses to chronic kidney disease (CKD), yet the underlying mechanisms driving this transition remain largely unclear. Here, we investigated the role of tissue inhibitor of metalloproteinase-2 (TIMP2), an established AKI biomarker, in the AKI-to-CKD transition.
Methods: We utilized mouse models of AKI-CKD induced by ischemia–reperfusion (IR), unilateral ureteral obstruction (UUO), or cisplatin (CP). Conditional renal tubule-specific TIMP2 knockout mice and AAV-mediated TIMP2 overexpression were employed in vivo. In vitro studies used primary tubular cells and HK-2 cells with TIMP2 knockdown or treatment with recombinant wild-type or MMP-inactive mutant TIMP2. Analyses included histology, molecular biology (Western blot, IHC, IF,

qPCR), protein interaction assays (Co-IP, molecular docking), and Wnt/β-catenin signaling assessment (luciferase reporter assays).
Results: TIMP2 expression was significantly upregulated in renal tubules across diverse AKI-CKD models. Tubule-specific TIMP2 deletion attenuated cellular senescence, maladaptive repair processes, and tubulointerstitial fibrosis following AKI. Mechanistically, TIMP2 promoted senescence and dedifferentiation independent of its MMP-inhibitory activity. We discovered that TIMP2 directly interacts with the Wnt co-receptor LRP6, enhancing LRP6 phosphorylation and activating downstream β-catenin signaling. Consequently, TIMP2 deficiency inhibited Wnt/β-catenin activation in vivo and in vitro. Conversely, TIMP2 overexpression in vivo exacerbated cellular senescence, maladaptive repair, and kidney injury in an IR model.
Conclusions: TIMP2 promotes the AKI-to-CKD transition by directly activating Wnt/β-catenin signaling through interaction with LRP6, independent of its MMP-inhibitory function. Our findings establish TIMP2 as a key mediator in kidney disease progression and identify it as a potential therapeutic target to prevent CKD following AKI.

Schematic diagram of TIMP2-mediated pathways in tubular epithelial cell injury and repair
Following AKI, there is loss of tubule epithelial cells by cell death followed by adaptive dedifferentiation and proliferation of the surviving cells. Once the surviving cells divide to repair the damaged epithelium, they dedifferentiate into a normal epithelium. TIMP2 interacts with the Wnt coreceptor low-density lipoprotein receptor-related protein 6 (LRP6), which enhanced LRP6 phosphorylation and mediated β-catenin activation. TIMP2 exacerbate cellular senescence and maladaptive repair through β-catenin signaling, thereby worsening kidney disease.

Introduction: Mean systemic pressure (MSP) plays a crucial role in venous return. Traditionally, MSP has been assessed using two methods: (1) via radial artery catheterization, where the pressure is measured at the nadir after a rapid occlusion of the humeral artery (MSPa), and (2) through a complex mathematical equation (MSPeq).
We propose a simpler method to estimate MSP using central venous pressure (CVP) combined with Doppler flow assessment of the superior vena cava (SVC). By analyzing SVC flow, we measured the mean pressure gradient (MPGsvc), which we assume to represent the pressure gradient between MSP and CVP.
Methods: We conducted this study in ICU patients under mechanical ventilation with shock. CVP was measured, and MSP was assessed using the two conventional methods (MSPa and MSPeq). Additionally, using a supraclavicular window, we evaluated SVC flow with color Doppler and recorded it using pulsed Doppler with a sample volume placed in the SVC near the right atrium. The mean pressure gradient (MPGsvc) of this flow was measured, allowing us to calculate MSP using the following equation:
$MSPsvc = CVP + MPGsvc$
Results: Thirteen patients were included (age: 55 ± 17 years, mean arterial pressure: 75 ± 11 mmHg).
The measured values were:
CVP: 10 ± 5 mmHg
MSPa: 17 ± 6 mmHg
MSPeq: 19 ± 5 mmHg
MSPsvc: 15 ± 5 mmHg
Correlation analyses showed:
An excellent correlation between MSPa and MSPeq ($r^2 = 0.82$, $p < 0.01$).
A good correlation between MSPa and MSPsvc ($r^2 = 0.40$, $p < 0.01$).
A strong correlation between MSPeq and MSPsvc ($r^2 = 0.63$, $p < 0.01$).
Conclusions: MSP can be accurately estimated using CVP measurement combined with the mean pressure gradient of SVC Doppler flow. This novel and simplified method may provide a practical alternative for bedside hemodynamic assessment in critically ill patients.

Introduction: Reproducibility remains a recognized challenge in research [1]. Generating robust evidence from real-world clinical data requires both high-quality data and international collaboration. Seven open-access intensive care unit (ICU) databases—AmsterdamUMCdb [2], eICU-CRD [3], HiRID [4], MIMIC-III [5], MIMIC-IV [6], NWICU [7], and SICdb [8]—have each facilitated the development of clinical prediction models. Yet, heterogeneity in data structures, terminology, and clinical practices across sources limits generalizability. BlendedICU [9] and ricu [10] have harmonized subsets of these databases, while INDICATE [11] targets pan-European standardization. However, a fully integrated, harmonized, and internationally representative ICU database remains unavailable.
Objectives: The objective of this study was to develop a harmonized database from seven public ICU databases to support

reproducible observational research in critical care and facilitate collaboration between clinicians and researchers.

Methods: The reprodICU database was built by harmonizing 136 time series variables and 153 active drug ingredients from seven ICU databases (Fig. 2). Established clinical vocabularies—SNOMED [12], LOINC [13], RxNorm [14], and OMOP [15]—were used for standardization aligning broadly with modules from the German Medical Informatics Initiative [16,17], ensuring architectural consistency and interoperability. Minimal preprocessing was applied to preserve source fidelity. Variables were selected to enable rapid application of complex cohort definitions, and a replication pipeline currently under development supports reproducible study designs.

Results: The reprodICU database encompasses 469,822 ICU admissions from 2001 to 2022, spanning four countries across Europe and the United States. Substantial variation was observed in data collection practices, drug exposures, and outcomes. ICU mortality ranged from 3.6% (SICdb) to 22.7% (NWICU). Additional heterogeneity was identified in unit types, admission categories, and case mix.

Time series granularity varied considerably: mean vital sign measurement rates ranged from 26.1 (NWICU) to 2093.9 (HiRID) per day, while mean lab value availability ranged from 14.7% (eICU-CRD) to 98.8% (AmsterdamUMCdb).

Our pipeline replicated the cohort from Lam et al. [18] in under 5 min on a standard workstation, demonstrating rapid external validation potential.

Conclusions: The reprodICU database provides an open, harmonized, international resource to enhance reproducibility and generalizability in critical care research. Leveraging established standards, the framework preserves source-level fidelity while supporting rapid replication of study designs.

While heterogeneity across databases highlights the importance of external validation, potential biases introduced by the harmonization process warrant further investigation.

Code, accompanying tools, and documentation are publicly available [19], offering a foundation for future robust, reproducible research in critical care.

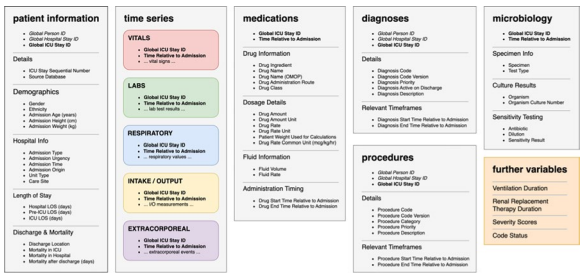

Fig. 1 (abstract 000012) Database overview showing the contents of the harmonized reprodICU dataset

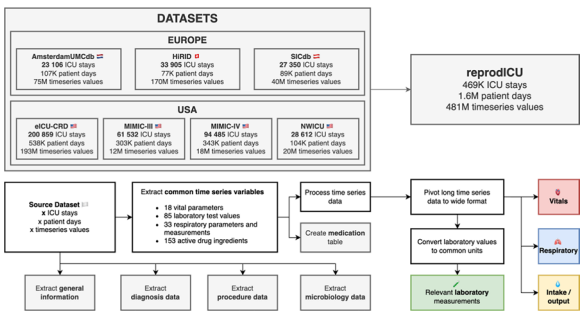

Fig. 2 (abstract 000012) Database creation pipeline overview showing the transformation flow from raw source databases to the harmonized reprodICU database

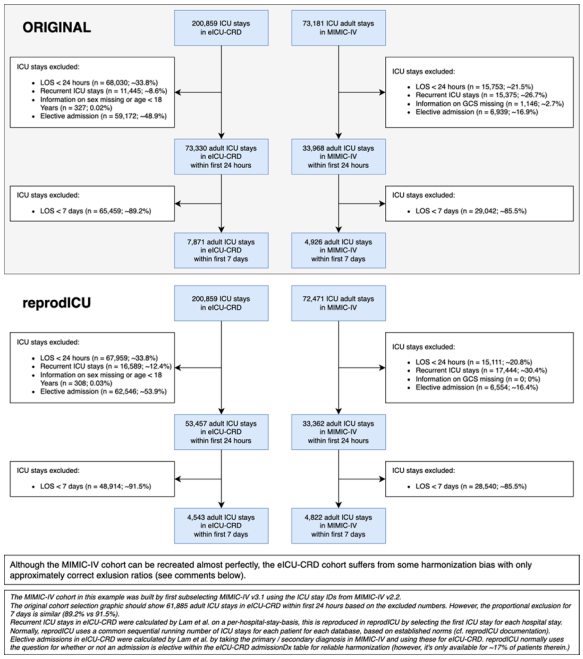

Fig. 3 (abstract 000012) Study replication overview demonstrating the framework's ability to efficiently reproduce complex patient selection criteria across multiple databases. (Cohort selection from Lam et al. [18])

Intensive care Medicine Experimental 2025* 13(1)**: ***000014

Introduction: Septic shock, a life-threatening condition characterized by systemic inflammation and multi-organ dysfunction, remains a significant challenge in postoperative patients, particularly in the elderly. The management of septic shock requires timely intervention and effective antimicrobial treatment. Toraymyxin®, a polymyxin B-based hemoperfusion therapy, has emerged as a promising therapeutic option for the removal of endotoxins in sepsis, potentially improving outcomes in critically ill patients. This study aims to evaluate the effectiveness of Toraymyxin® in 12 postoperative patients aged 58 to 78 years old diagnosed with septic shock.
Objectives: The primary objective of this study was to assess the safety and efficacy of Toraymyxin® in reducing endotoxin levels and improving clinical outcomes in postoperative patients with septic shock. Secondary objectives included evaluating the impact of Toraymyxin® on vital signs, organ function, and overall survival rates.
Methods: This prospective observational study included 12 postoperative patients (aged 58–78 years) diagnosed with septic shock, who received Toraymyxin® treatment as part of their standard care. Inclusion criteria were patients experiencing septic shock after surgery, with endotoxin levels above 0.6 EU/mL and failure to respond to conventional antibiotic therapy. Toraymyxin® was administered via hemoperfusion for 2 to 4 h. Clinical data, including vital signs (blood pressure, heart rate, respiratory rate), organ function (renal, hepatic, cardiovascular), and endotoxin levels, were recorded before, during, and after treatment. The primary endpoint was the reduction in endotoxin levels, and secondary endpoints included improvement in hemodynamic stability, organ function, and 30-day mortality.
Results: Of the 12 patients, 10 experienced a significant reduction in endotoxin levels within 24 h of Toraymyxin® treatment. The mean endotoxin reduction was 75% ($p < 0.05$). Clinically, 9 patients showed marked improvement in hemodynamic parameters, including a significant increase in mean arterial pressure and a reduction in lactate levels. Organ function, particularly renal and hepatic, improved in 8 patients, with a 50% reduction in renal replacement therapy requirements post-treatment. The overall 30-day survival rate was 83%, with 10 patients surviving and 2 experiencing fatal outcomes due to multi-organ failure despite treatment. Adverse events associated with Toraymyxin® were minimal, with no major complications reported during or after therapy.
Conclusions: Toraymyxin® appears to be a promising adjunctive therapy for the management of septic shock in postoperative patients, demonstrating significant reductions in endotoxin levels and improvements in clinical outcomes, including hemodynamic stability and organ function. The treatment was well-tolerated, with a favorable safety profile. Further large-scale randomized controlled trials are warranted to confirm these findings and establish more comprehensive guidelines for its use in septic shock.

Intubated patients with chronic obstructive pulmonary disease with and without ventilator-associated pneumonia: why early prediction of risk factors are important for patient outcomes?

A. Sadigov[1]
[1]pulmonary and critical care, Azerbaijan Medical University, Baku, Azerbaijan
Correspondence: A. Sadigov
Intensive care Medicine Experimental 2025* 13(1)**:000015***

Introduction: Chronic obstructive pulmonary disease (COPD) is a major risk factor for the development of nosocomial lower respiratory tract infections, as the patient's immune system may be weakened by prolonged corticosteroid use and reduced microbial clearance. During the natural course of the disease, exacerbations and infections are common in patients with COPD, the management of which requires assisted ventilation and hospitalization. Patients requiring prolonged duration of mechanical ventilation in the intensive care unit (ICU) have a particular risk of developing ventilator-associated pneumonia (VAP). Since both COPD and VAP adversely affect lung function, a combination of both disorders may have serious impact on patient outcomes
Objectives: The purpose of the present study was to evaluate the influence of VAP to the patient outcomes in intubated patients with COPD and early prediction of risk factors and their modification for improving patient outcomes.
Methods: Our study was retrospective and we have conducted the electronic based medical history data of 159 patients with COPD who have been intubated due to failure of non-invasive mechanical ventilation and severe hypercapnic respiratory failure, at the department of pulmonary and critical care medicine of university hospital from January 2016 to December 2024.
Results: In 57 of 159 (35.8%) patients have developed VAP after 48 h of mechanical ventilation. The results of our retrospective analysis indicated that the presence of VAP significantly increased the mortality of patients with COPD (risk ratio[RR]:2.14,95%CI:1.11-2.98;$p = 0.003$). The duration of intensive care unit (ICU) stay was significantly longer in patients with COPD and VAP as compared with that of patients with COPD without VAP (mean difference MD:3.46,95%CI:0.69-7.24,$p = 0.01$). Our study also indicated that the presence of VAP in patients with COPD significantly increased the duration of

mechanical ventilation (MD:7.24, 95%CI:2.46-13.65,p < 0.001). Independent risk factors for mortality in patients were: presence of septic shock at ICU admission (3.49[0.84-7.54];p < 0.001); higher SOFA score > _8(2.82[0.81-5.40]; p < 0.004); the presence of acute respiratory distress syndrome (ARDS) (3.14[1.14-5.47];p < 0.001); and VAP due to MDR Acinetobacter baumannii bacteria (2.02[0.89-4.14];p < 0.01).
Risk factors associated with development of VAP in intubated COPD patients were: kidney failure (2.48[0.91-4.88]'p < 0.004); use of steroids prior to intubation (2.86[0.85-5.16]; p < 0.002); use of antibiotics prior to intubation (3.41[1.25-7.21]; p < 0.001); presence of shock before admission to ICU department (4.25[1.12-7.56]; p < 0.001); PaO2/FiO2 ratio < 250 at the time admission to ICU department (2.76[0.84-5.16]; p < 0.003);previous history of lung tuberculosis (2.08[0.77-3.88]; p < 0.01); and concomitant to COPD bronchiectasis (2.17[0.81-4.16]; p < 0.007).
Conclusions: Our study indicated that the development of VAP in COPD patients is associated with significantly increased patient mortality, duration of mechanical ventilation and the duration of ICU stay. Several independent risk factors may predict mortality in these patients. Early identification of such risk factors predicting development of VAP in COPD patients and evaluation of independent risk factors for morality may be useful in term on the possibility their modification and improving of patient outcomes.

Intensive care Medicine Experimental 2025* 13(1)**: ***000016

Introduction: Incidence of medical device-related pressure injuries (MDR-PI) related to nasogastric tubes (NGT) is under-investigated. This is particularly significant in Intensive Care Units (ICUs) and internal wards because those patients are highly susceptible to MDR-PI development.
Objectives: To conduct ongoing monitoring of patients with NGT in ICU and internal ward to ascertain the incidence of NGT MDR-PI in both settings.
Methods: Prospective cohort study. Inclusion criteria: adult ICU/internal ward patients with NGT inserted during ICU/internal ward stay or shortly before the admission. Exclusions: patients with facial injuries/wounds/ulcers. Research team conducted daily monitoring for the NGT-MDR-PI. Upon PI detection, its location and stage documented.
Results: Data collection conducted from July 2022 to July 2024 in an 18-bed general ICU and a 30-bed internal ward of a large medical center resulted in the recruitment of 136 patients (88 from the ICU and 48 from the internal ward). The incidence of NGT-MDR-PI was 4.5% (4/88) in the ICU and 27% (13/48) in the internal ward. No correlation was found between the development of NGT-MDR-PI and factors such as albumin levels at admission, patient age, gender, or the number of follow-up days (total of 1288). The regression model (p < 0.0001) revealed statistically significant associations with the hospitalization site (ICU vs. internal ward, p < 0.001) and Charlson comorbidity score at admission (p = 0.022). The model explained 19.3% (R^2 = 0.193) of the variance in NGT-MDR-PI development.
Conclusions: To the best of our knowledge, this is the first prospective long-term study dedicated solely to the incidence of NGT-MDR-PI in both the ICU and internal ward. The incidence of NGT-MDR-PI is lower in the ICU compared to the internal ward. This may be due to several factors: more intensive nursing care in the ICU, and a higher Charlson comorbidity score in the internal ward, which indicates that more chronically ill patients are hospitalized there rather than in the general ICU. Another possible explanation is the different types of fixation used: simple plaster in the ICU and special plaster for NGT fixation in the internal ward. Further research is needed to clarify these findings.

[1]Department of Anesthesia and Intensive Care, Hospital G. Tatarella, Cerignola (FG) ASL Foggia, Foggia, Italy; [2]Department of Anesthesia and Intensive Care, AST Ancona, Fabriano, Italy
Correspondence: D. Galante
Intensive care Medicine Experimental 2025* 13(1)**:000017***

Introduction: Intensive Care Units (ICUs) are pivotal in the management of critically ill patients, and their design plays a crucial role in optimizing patient outcomes. Traditionally, ICUs consist of multiple beds within a shared space, which can contribute to the risk of cross-contamination and hospital-acquired infections (HAIs). Recent trends emphasize the need for innovative ICU designs that prioritize both patient care and infection control. Our ICU, consisting of eight beds, is uniquely organized with individual rooms for each patient. This configuration aims to reduce the transmission of infections, enhance privacy, and improve overall clinical care. This study explores the impact of this design on patient outcomes, infection rates, and staff efficiency.
Objectives: This study aims to:

- Evaluate the effect of individual patient rooms on the incidence of hospital-acquired infections.
- Assess patient outcomes, including length of stay, mortality rates, and recovery times, in comparison to traditional open ICUs.
- Investigate staff satisfaction and workflow efficiency in a critical care unit with a design that offers greater patient separation.

Methods: A retrospective cohort study was conducted in our eight-bed ICU, which is designed with separate individual rooms, each equipped with specialized monitoring and ventilation systems. Data on infection rates (both HAI and ventilator-associated pneumonia), patient outcomes (mortality rates, length of stay, discharge status), and staff workflow were collected over a 12-month period. Comparisons were made with data from two traditional open ICUs within the same hospital network, with similar patient demographics and severity of illness. Statistical analysis was performed to determine the significance of observed differences using Chi-square tests for categorical variables and t-tests for continuous variables.
Results: Preliminary results indicate a significant reduction in the incidence of hospital-acquired infections in the single-room ICU compared to the traditional open-ward design (p < 0.05). Specifically, the rates of ventilator-associated pneumonia and central-line-associated bloodstream infections were lower by 30% in the individual-room ICU. Mortality rates, while not significantly different, showed a trend toward improved outcomes in the individual room cohort, with a slightly lower average length of stay (2.5 days fewer). Staff surveys indicated increased satisfaction with the workflow, citing improved privacy for patients and better management of clinical tasks.

Conclusions: The design of an ICU with individual rooms offers significant advantages in terms of infection prevention and control, supporting a safer environment for critically ill patients. While patient outcomes, including mortality and length of stay, did not show drastic differences, the reduction in infection rates was substantial. Staff satisfaction was also notably higher, suggesting that the organizational structure of the ICU contributes to a more efficient and effective care environment. Future studies should explore long-term clinical outcomes and the financial implications of such ICU designs.

The use of dexmedetomidine in the intensive care unit: efficacy, safety, and strategies to mitigate hypotension and bradycardia

G. Montenero[1]; G. Sfregola[1]; A. Ragone[1]; M. Ciuffreda[2]; C. Piangatelli[2]; D. Galante[1]
[1]Department of Anesthesia and Intensive Care, Hospital G. Tatarella, Cerignola (FG) ASL Foggia, Foggia, Italy; [2]Department of Anesthesia and Intensive Care, AST Ancona, Fabriano, Italy
Correspondence: D. Galante
Intensive care Medicine Experimental 2025* 13(1)**: ***000018

Introduction: Sedation in the Intensive Care Unit (ICU) is essential for patient comfort, compliance with mechanical ventilation, and overall management of critical conditions. Dexmedetomidine, a selective alpha-2 adrenergic agonist, has emerged as a preferred sedative due to its unique pharmacological profile, offering sedation without respiratory depression. Despite its benefits, the drug is associated with adverse effects such as hypotension and bradycardia, which can complicate patient management, particularly in critically ill populations. Understanding how to balance these benefits and risks is crucial for its optimal use in the ICU.
Objectives: This study aims to evaluate the efficacy of dexmedetomidine compared to other sedative agents in the ICU, focusing on its impact on sedation quality, duration of sedation, and the management of undesirable side effects, particularly hypotension and bradycardia. Additionally, we seek to identify strategies for mitigating these adverse effects during dexmedetomidine administration.
Methods: A retrospective cohort study was conducted in a mixed ICU setting, reviewing patient data from January 2023 to December 2024. Patients were stratified based on the sedative agent used: dexmedetomidine, propofol, or benzodiazepines. Primary outcomes included the incidence of hypotension and bradycardia, as well as the duration of mechanical ventilation and the need for vasopressor support. Secondary outcomes included sedation depth (measured by Richmond Agitation-Sedation Scale scores), duration of ICU stay, and the occurrence of any other adverse effects. Data were analyzed using multivariate regression to adjust for potential confounders.
Results: Among the 162 patients analyzed, dexmedetomidine was associated with a significantly higher incidence of bradycardia (25%) and hypotension (19%) compared to propofol (bradycardia 10%, hypotension 12%) and benzodiazepines (bradycardia 8%, hypotension 10%). However, when managed with careful titration and the use of vasopressors in the event of hypotension, these adverse effects were largely mitigated, with no significant differences in the duration of mechanical ventilation or ICU stay between groups. The sedation quality, as measured by Richmond Agitation-Sedation Scale, was comparable across all agents, but patients receiving dexmedetomidine showed a shorter median time to extubation and a lower incidence of delirium.
Conclusions: Dexmedetomidine provides effective sedation in the ICU with a favorable impact on delirium and extubation time. However, it is associated with an increased risk of hypotension and bradycardia compared to other sedative agents. These side effects can be managed with careful titration, close monitoring, and the strategic use of vasopressors. Clinicians should be aware of these risks when choosing dexmedetomidine for sedation in critically ill patients and should have protocols in place to address these potential complications.

Decoding neurogenic biomarkers for the differentiation between septic patients with or without encephalopathy: an updated meta-analysis

J. Hu[1]; S. Xie[1]; L. Ya[1]; C. Tao[1]; Z. Qian[1]; L. Zhang[1]
[1]Department of Critical Care Medicine, Xiangya Hospital, Central South University, Chang Sha China
Correspondence: J. Hu
Intensive care Medicine Experimental 2025* 13(1)**:000020***

Introduction: Sepsis-associated encephalopathy (SAE) is characterized by brain dysfunction in the context of sepsis and frequently leads to significant cognitive and neurological impairments, as well as an elevated risk of mortality. Accurate diagnosis of SAE is crucial for the timely initiation of optimal treatment and appropriate patient management. Neurogenic biomarkers hold promise as reliable serum diagnostic tools for the detection and longitudinal monitoring of SAE. This meta-analysis seeks to evaluate the diagnostic and prognostic utility of serum neurogenic biomarkers in patients with SAE.
Methods: The study protocol was registered in the PROSPERO database (CRD42023408312) and conformed to the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines. A meta-analysis was conducted to comprehensively and critically evaluate the existing body of evidence regarding the use of serum neurogenic biomarkers: neuron-specific enolase (NSE), ubiquitin C-terminal hydrolase-L1 (UCH-L1), Tau, S100 calcium binding protein β (S100β), and glial fibrillary acidic protein (GFAP) for the diagnosis and risk assessment of fatality in SAE. We conducted a systematic search of electronic bibliographic databases, including PubMed, Web of Science, Embase, Cochrane databases, CNKI, CQVIP, and WFSD. The quality and risk of bias of the selected studies were assessed using the QUADAS-2 tool. For biomarkers reported in two or more studies, pooled standardized mean differences and 95% confidence intervals were calculated. Heterogeneity among the included studies was examined using the I^2 statistic and random-effects model was applied owing to large heterogeneity.
Results: Forty-two studies were included in our meta-analysis. As showcased in Figure, the levels of serum neurogenic biomarkers were significantly higher in patients with SAE as compared to septic patients with no-encephalopathy (NE): NSE [standardized mean difference (SMD) 1.98 (95% CI 1.55–2.42), $P < 0.00001$]; UCH-L1 [SMD 1.75 (95% CI 0.90–2.59), $P < 0.0001$]; Tau [SMD 1.14 (95% CI 1.01–1.28), $P < 0.00001$]; S100β [SMD 1.82 (95% CI 1.45–2.19), $P < 0.00001$] and GFAP [SMD 3.63 (95% CI 1.85–5.41), $P < 0.0001$]. In addition, the

significantly lower serum neurogenic biomarkers levels were noted in septic patients with survivors as compared to non-survivors (Figure not shown): NSE [SMD -1.87 (95% CI -2.43– -1.32), $P < 0.00001$]; UCH-L1 [SMD -1. 71 (95% CI -2.24– -1.19), $P < 0.00001$]; Tau [SMD -0.57 (95% CI -0.79– -0.35), $P < 0.00001$]; S100β [SMD -1.34 (95% CI -1.88– -0.80), $P < 0.00001$]. However, no significant differences in serum GFAP levels [SMD -7.98 (95% CI -22.23–6.27), P = 0.27] were found between the surviving and non-surviving groups.
Conclusions: The increased serum neurogenic biomarkers may be predictive of SAE and mortality for septic patients, which are expected to be applied as a reliable blood-based diagnostic tool for detection and longitudinal monitoring in SAE patients. However, results should be interpreted with caution due to the high heterogeneity among studies.

Forest plot evaluating the association between serum neurogenic biomarkers levels and SAE (A: NSE; B: UCH-L1; C: Tau; D: S100β; E: GFAP).

Creating a prediction model for invasive candidiasis in the intensive care unit using a case control design: a European multicentre approach
P. Benders[1]
[1]Anesthesiology and Intensive Care Medicine, Radboud University Medical Center, Nijmegen, Netherlands
Correspondence: P. Benders
Intensive care Medicine Experimental 2025* 13(1):*000022

Introduction: Invasive candidiasis (IC) has a high attributable morbidity and mortality in patients in the intensive care unit (ICU). Current diagnostic tools lack sensitivity, introduce delay or have not been validated for regular use. As early treatment has proven vital for survival, multiple prediction models have been proposed, but have not been validated for multinational implementation. In this study we propose to find factors predisposing the ICU patient to develop IC. We hope to develop an alternative prediction model using a large international dataset.
Methods: Using ICU-acquired IC as primary endpoint we retrieved retrospective information about 285 cases and 285 matched controls from the EUCANDICU database. Data about comorbidities, severity of illness and known risk factors for IC were available. We identified 31 independent risk factors using univariate analysis. A random subset of 80% of the observations were used to find the optimal prediction model. The selection of predictors was done using the LASSO technique, using λ = 1SE as regularization parameter. This choice for λ implies that a small amount of precision of the prediction is sacrificed to improve the external validity. The remaining 20% of cases were used to assess the predictive performance of the model.
Results: Among other factors SAPS II score, SOFA score, past infection, renal impairment and the presence of multiple *Candida* colonization sites were all independently associated with an increased risk of developing IC. We incorporated 22 of 31 variables in a LASSO regression analysis which showed an AUROC of 0.7433.
Conclusions: Predicting which ICU patient will develop invasive candidiasis remains challenging, despite using an alternative methodology in a large multinational database. The performance of this prediction model is not good enough to be used in clinical practice. Therefore, early diagnosis with subsequent early treatment is still a clinical case-by-case decision and of utmost importance.

Intensive care Medicine Experimental 2025* 13(1):*000023

Introduction: According to some authors, sepsis in surgical patients is different from those in non-surgical patients because of the immune function modulation that occurs as a result of surgery and anesthesia applied. We consider important to characterize surgical sepsis in order to have a better undertanding.
Objectives: To know differential characteristics between medical sepsis and surgical sepsis.
Methods: Retrospective study of patients with sepsis admitted to the ICU from May 2021 to April 2024. Sepsis was defined according to the Sepsis-3 definitions. Variables collected included age, sex, comorbidities, number of organ failures, pathogens isolated, anatomic focus of infection, the use of adjunctive therapies such as mechanical ventilation and renal replacement techniques, patients´ severity at admission as APACHE II score and SOFA score. Continuous variables are expressed as means and standard deviations and categorical variables as percentages. The Mann–Whitney U test was used to compare quantitative variables and Chi-square test for categorical variables.
Results: During the study period, 182 patients were admitted to the ICU with sepsis, 67,7% (122 patients) were medical sepsis. The mean age of patients with surgical sepsis was higher than patients with medical sepsis [79,9 years (SD 10,6) vs 68 years (SD 11,6), p = 0,007]. 66,6% were male. 62,5% were medical sepsis in male sex and 75,8% in female sex; p = 0,032. Atrial fibrillation (25%) and hypertension (65%) were more common in surgical sepsis. The most common site of infection causing medical sepsis was the genitourinary (36,9%) while the intraabdominal (85%) was more frequent in surgical sepsis; p < 0,001. Respiratory dysfunction was predominant in both of them, especially in medical sepsis (37,7% vs 29,1%; p < 0,001). Gram-negative were the pathogens more frequent in medical sepsis and negative culture in surgical sepsis (46,7%); p < 0,001. In most cases the antibiotic was appropriate in medical sepsis (71,3% vs 53,3% in surgical sepsis; p = 0,01. Bacteremia was predominant in medical sepsis (42,6% vs 13,3%; p < 0,001). Septic shock was more frequent in surgical sepsis (83,3% vs 64,8%; p = 0,01). The proportion of patients receiving mechanical ventilation was higher in surgical sepsis (81,7% vs 36,9%; p < 0,001) as well as renal replacement therapy (23,3% vs 9%; p = 0,01). The mortality in the ICU was higher in surgical sepsis (33,3% vs 14,8%; p = 0,004)
Conclusions: Our analysis shows that surgical sepsis occur in older people and patients have more comorbidities. The main focus of infection in surgical sepsis is the intraabdominal. Although APACHE II and

SOFA score at admission did not differ between groups, patients with surgical sepsis had septic shock more frequent, and they also required invasive mechanical ventilation and renal therapy more often than patients with medical sepsis. Finally, the mortality was higher in surgical sepsis.

ICU admission characteristics and mortality among elderly and very elderly patients

AB. López Pérez[1]; R. Jerez Sánchez[1]; C. Ochoa Sangrador[2]; C. Tarancón Maján[1]
[1]Intensive Care Unit, Hospital Virgen De La Concha, Zamora, Spain; [2]Pediatrics, research support unit, Hospital Virgen De La Concha, Zamora, Spain
Correspondence: A.B. López Pérez
Intensive care Medicine Experimental 2025* 13(1):*000024

Introduction: There is a growing population of older adults requiring admission to the ICU. In addition, their remaining life expectancy is often limited. So, elderly patients have less to gain from ICU treatment thann young patients. It is therefore important to carefully consider the proportionality of ICU treatment. On the other hand, the effect of advanced age on the short survival of older patients remains unclear.
Objectives: To analyze the characteristics of elderly patients admitted to the ICU.
Methods: A retrospective study was carried out from January 2022 to May 2024. Patients were divided into two groups: 75-80 years and > 80 years. Variables collected included age, sex, reason for ICU admission, severity at ICU admission, therapeutic procedures, in addition to the limitations of care.
Results: During the study period, 274 patients were admitted to the ICU (65,3% male and 34,7% female). 55,8% were 75-80 years and 44,2% were above 80 years. The most common indications for ICU admission were: 20,4% sepsis, 10,6% polytraumatism, 7,3% cardiac disorders and 61,7% others. Vasopressors were used in 43,4%, mechanical ventilation in 42%, dialysis machine in 7,3% and 4,4% tracheostomy. APACHE II at admission was 19,5 (SD 7,9). The length of ICU stay was 5,1 days (SD 8,7) and the hospital stay was 16,7 days (SD 19,4). Treatment limitations were performed in 21,2% of cases. The mortality in the ICU was 20,4% and the hospital mortality was 6,9%. When patients were divided into 75-80 years and over 80 years, there was no difference in sex between the two groups. Male sex was predominant in both of them. Neither the reason for admission nor the use of vasopressors, mechanical ventilation or renal therapy differed between groups. Nevertheless, the proportion of patients who received tracheostomy was significantly lower in patients over 80 years (1,7% vs 6,5%; p = 0,05). There was no difference in ICU-mortality, but the hospital mortality was higher in patients over 80 years (11,6% vs 3,3%; p = 0,007).
Conclusions: Elderly patients are admitted to ICU in most cases for sepsis. Patients are mainly male. Taking into account the age, there was a higher conservative management in the very old patients. Some interventions such as tracheostomy was less common in patients above 80 years. All in all, older adults might benefit from life-sustaining treatment. Patients older than 75 should be regarded as a risk factor for mortality.

Introduction: Hospital-acquired bloodstream infections (HA-BSIs) are severe and require antibiotic therapy. While adequate early antibiotic therapy improves outcomes, unnecessary antibiotic use is frequent and exposes to complications.
Several studies and meta-analyses showed that in non-complicated BSIs in hemodynamically stable patients, shortened therapy reduces side effects without compromising efficacy. Recently, a large international randomized controlled trial (RCT) showed the safety of a short treatment in BSIs, however, ICU patients represented only a half of the studied population and difficult-to-treat (DTR) microorganisms were poorly represented. Therefore, the impact of shortened antibiotic therapy in HA-BSI critically ill patients without indication of prolonged therapy requires further evaluation.
Objectives: We conducted this study including a population with higher severity of illness to investigate the impact of the antibiotic therapy duration on treatment failure in ICU patients with HA-BSI.
Methods: Using the international prospective EUROBACT-2 cohort, we compared shortened (7–10 days) versus long (14–21 days) treatment durations in ICU patients eligible for shortened therapy. Patients without antibiotic therapy within 3 days after HA-BSI occurrence or requiring prolonged therapy (due to infection source, microorganism, or clinical deterioration) were excluded.
Treatment failure, defined as death, persistent infection, or subsequent infectious complications by Day 28, was assessed using an inverse-probability of treatment weighted (IPTW) logistic regression. We performed a sensitivity analysis with a PS-matched population, several explanatory subgroup analyses (according to immune status, microorganisms (*Staphylococcus aureus* vs. other microorganisms), antimicrobial resistance (DTR); source of infection (catheter vs. others); delta SOFA score between days 1 and 7), and lastly, an a posteriori analysis on subgroups of hemodynamically stable and unstable patients.
To minimize center effect bias, we excluded centers that only used long antibiotic courses, as the large number of countries and centers made mixed effects analysis not statistically valid.
Results: Among 2600 patients, 550 were eligible for shortened treatment and with a reliable treatment's duration calculation. Among them, 213 received short, and 337 received long treatment (Fig. 1). The most common infection source was intravascular catheters (n = 180, 33%), most common microorganisms were *Enterobacterales* (n = 212, 39%).
Patients with long treatment were more frequently infected with *Staphylococcus aureus* (11% vs. 5.6%, p = 0.025) or difficult-to-treat microorganisms (23% vs. 7%, p < 0.001), and received more commonly combination therapy (46% vs. 30%, p < 0.001).
Short treatment reduced 28-day treatment failure (OR 0.64, 95% CI 0.44–0.93, p = 0.019), mainly due to reduction in subsequent infectious complications (OR 0.58, 95% CI 0.37–0.91, p = 0.018). Mortality (OR 0.92 [95% CI 0.59, 1.43], p = 0.7) and persistent infection rates (OR 0.47 [95% CI 0.17, 1.14], p = 0.12) were similar (Fig. 2).
The benefit of short therapy was more pronounced in non-immunocompromised patients (OR 0.51 [95%IC 0.33, 0.79], p = 0.003), in HA-BSIs other than SAB (OR 0.57 [95%IC 0.38, 0.85], p = 0.006), and in patients with a decreased SOFA score at day 7 (OR 0.39 [95%IC 0.23, 0.65], p < 0.001).

Conclusions: In selected critically ill patients with HA-BSI without indication of prolonged therapy, a shortened therapy (7-10 days) reduced 28-day treatment failure as compared to prolonged therapy (14-21 days) mostly due to a reduction of subsequent infectious complications.

Intensive care Medicine Experimental 2025* 13(1)*:000027

Introduction: The 2011 Accreditation Council of Graduate Medical Education (ACGME) has laid the requirement of hand-off communication as a residency skill.1 In US, the Joint Commission has emphasized on the role of standardization of handover in improving quality of communication.2
Objectives: Primary objective
To assess adequacy of patient handover (PHO) by anaesthesia resident to healthcare worker (HCW) in post-anaesthesia care unit (PACU) using a pre-defined checklist including 31 parameters (7 preoperative, 15 intraoperative and 9 postoperative).
Secondary objectives
To compare the adequacy of PHO in patients belonging to ASA physical status I and II, in patients undergoing surgery under general anaesthesia to those undergoing surgery under neuraxial block and in first fifty patients with last fifty patients enrolled in the study.
Methods: After approval from IEC (IEC-INT/2023/MD-953) and written informed consent, a prospective observational study was conducted two hundred patients over a period seven months. Using computer randomization, two days of each week were randomly selected and divided into four slots of 2 h each. One patient handover was observed in each of the slots and a total of four patients were enrolled on each observation day.
In PACU, the process of PHO by anaesthesia resident to HCW was directly observed for the parameters in checklist. Documentation in anaesthesia chart and recovery room proforma was verified. If any parameter was not communicated in any form, it was considered to have been missed. To avoid bias, all anaesthesia residents and HCWs in PACU were blinded to the observation process and the content of checklist.
Results: Any parameter for which this adequacy percentage was less than 85% was considered inadequate handover. The data of adequacy of PHO (in percentage) were compared between ASA I and II patients, in patients receiving GA with those receiving neuraxial block and between the first fifty and last fifty patients was compared using Chi-square and Fisher exact test.
The preoperative parameters included patient name, age and gender (100%), underlying diagnosis (99.5%), ASA physical status (94.5%), allergies (85.7%), airway details (96%), past medical history (88.7%) and past surgical history (39.4%). The intraoperative parameters included name of procedure (99.5%), duration of surgery (78%), anaesthesia technique (99.5%), anaesthesia drugs administered (91%), airway management (96.8%), haemodynamic fluctuation (98.5%), IV fluids given (96%), blood loss (82%), blood and blood product transfusion (58.9%), IV access (99.5%), urine output (73.5%), drains/catheters in situ (91.7%), drug infusions on flow (81.6%), intraoperative events (98.9%), any blood investigations done (100%). The postoperative parameters included monitoring required (99.5%), oxygenation (99.5%), IV fluids (99%), drug infusions (87.5%), plan of analgesia (98.5%), oral intake (100%), investigations required (63.6%) and disposition details (100%).
No statistically significant difference was found when comparing adequacy of PHO between ASA I and II patients. When comparing PHO

between patients receiving GA with those receiving neuraxial, a statistically significant difference was found for drug infusions on flow (P value 0.0067). The comparison of PHO between first fifty and last fifty patients showed statistically significant difference for handover of past surgical history (P value 0.01), duration of surgery (P value 0.04), intraoperative blood loss (P value 0.04), urine output (P value 0.03) and drains/catheters in situ (P value 0.04).
Conclusions: The adequacy of PHO observed in 200 patients undergoing elective surgery showed more than 85% adequacy in majority of parameters except past surgical history, duration of surgery, intraoperative urine output, blood loss, blood and blood product transfusion, drug infusions on flow and postoperative investigations. A significant improvement in adequacy was observed in all these parameters except blood and blood product transfusion.

Impact of oral MIDODRINE to liberate ICU patients from vasopressor infusion in septic shock: a prospective randomized controlled trial

V. Saini[1]; A. Vp[2]
[1]Anaeasthesia and Intensive Care, Postgraduate Institute of Medical Education and Research, Chandigarh, India; [2]ANAESTHESIA AND INTENSIVE CARE, Post Graduate Institute of Medical Education & Research, Chandigarh, Chandigarh, India

Intensive care Medicine Experimental 2025* 13(1)*:000029

Introduction: Septic shock remains a leading cause of morbidity and mortality in critically ill patients worldwide, with vasopressors often required to maintain adequate mean arterial pressure. However, prolonged vasopressor therapy can be associated with adverse effects including vasopressor-related complications and delayed mobilization. Midodrine, an oral alpha-1 agonist, has shown promise in reducing intravenous vasopressor requirements, potentially facilitating earlier transfer out of intensive care units (ICUs).
Objectives:

- **Primary outcome:** Time taken to de-escalate to a single low-dose vasopressor (noradrenaline ≤ 0.15 μg/kg/min).
- **Secondary outcomes:** VIS trend (recorded every 6 h), maximum VIS during ICU stay, time taken for complete vasopressor weaning, length of ICU stay, ICU mortality, and incidence of bradycardia (heart rate < 50/min). Laboratory values such as serum cortisol and thyroid function tests (T3, T4, TSH) were also recorded.

Methods: In this prospective randomized controlled trial, 102 adult patients (aged > 18 years) with septic shock requiring vasopressors were enrolled. Participants were allocated equally into two groups: midodrine (n = 51) or placebo (n = 51). The primary endpoint was the time taken to de-escalate to a single low-dose vasopressor (defined as noradrenaline ≤ 0.15 μg/kg/min). Secondary endpoints included the Vasoactive Inotropic Score (VIS) trend, maximum and mean VIS, time to complete vasopressor wean, length of ICU stay, and ICU mortality. Statistical analyses included t-tests, Mann–Whitney U tests, Chi-square/Fisher's exact tests, and Kaplan–Meier survival analysis. A p-value < 0.05 was considered statistically significant.
Results: Both groups were comparable in baseline demographics, illness severity scores (APACHE II and qSOFA), and comorbidities. The mean time to single low-dose vasopressor was 17.80 ± 7.09 h in the Midodrine group vs. 19.33 ± 9.13 h in the Placebo group (p = 0.347). No significant differences were found in maximum VIS or overall mortality rates. However, the Midodrine group had a significantly higher incidence of bradycardia episodes (33.3% vs. 17.6%) and a longer ICU stay (7.94 ± 5.59 vs. 6.08 ± 3.02 days, p = 0.039).
Conclusions: Oral midodrine did not significantly reduce the time to de-escalate to a single low-dose vasopressor in patients with septic shock. Although there was a transient reduction in VIS at one time point, the Midodrine group experienced more frequent bradycardia and longer ICU stays. Larger, multi-center trials are warranted to better delineate midodrine's role in vasopressor weaning for septic shock.

Intensive care Medicine Experimental 2025* 13(1)*:000030

Introduction: The hypotension prediction index (HPI) is a predictive model derived from arterial pressure waveform for predicting future hypotension. The HPI provides good performance for predicting hypotension in intraoperative surgical patients, however, limited study in critically ill patients admitted in the ICU.
Objectives: To evaluate the performance of HPI for predicting hypotension as original study and modify MAP gray zone (65-75 mmHg) was included in the non-hypotensive group.
Methods: This is a prospective observation study in septic shock patients admitted in ICU. The area under the receiver-operating characteristic curve (AUC) was used to evaluate the performance of HPI. Hypotension defined as MAP < 65 mmHg for at least 1 min. Non-hypotensive events included MAP > 75 mmHg for primary outcome as original study and all MAP value (> 65 mmHg) for secondary outcome. A positive event was chosen for the sample at 5, 10 and 15-min before the hypotensive events.
Results: A total of 30 septic shock patients with 293,315 data points were included. There were 645 hypotensive events with a median of 14.5 [8-31] events per patient and the median time was 3.2 [2.5-4] mins. The receiver operating characteristic curve (ROC) of the HPI at 5, 10 and 15 min before events for predicting hypotension are shown in Fig. 1. The AUC of HPI at 5 and 10 min before hypotensive event was significantly higher than that of HPI at 15 min before the event (Table 1, p = 0.002 and p = 0.01, respectively). However, the predictive ability of HPI 5 min was not differ from HPI 10 min before hypotensive event (p = 0.05). HPI for all time points had a significant higher ability for predicting hypotension than other hemodynamic variables (MAP, SBP, CI, SVV, PPV, HR, CVP, Eadyn, dP/dtmax). However, when included MAP gray zone in the non-hypotensive events, the ability of HPI declines as Table 1 and Fig. 2 and was not differ from MAP for predicting hypotension for all time points (AUC 0.817 vs. 0.786, p = 0.28 for 5 min before event, 0.787 vs. 0.761, p = 0.4 for 10 min before event and 0.753 vs. 0.720, p = 0.31 for 15 min before event).

Table 1 (abstract 000030) The performance of the hypotension prediction index

	Time to event (min)	AUC	Sensitivity (%)	Specificity (%)	Cutoff
Primary outcome (non-hypotensive events included MAP > 75 mmHg)					
HPI	5	0.953 (0.936–0.956)	89.4	89.1	37

	Time to event (min)	AUC	Sensitivity (%)	Specificity (%)	Cutoff
	10	0.934 (0.913–0.956)	87.2	85.8	36
	15	0.919 (0.895–0.942)	85.4	84.3	35
Secondary outcome (non-hypotensive events included MAP > 65 mmHg)					
HPI	5	0.817 (0.782–0.852)	71.9	71.9	58
	10	0.787 (0.748–0.825)	70.1	70.4	56
	15	0.753 (0.713–0.794)	66.1	66.8	53

Conclusions: HPI presents excellent performance for predicting future hypotension in septic shock patients in the ICU. However, the ability of HPI decreased when all MAP values were included in non-hypotensive events. HPI algorithm needs further revisions to improve predictive ability.

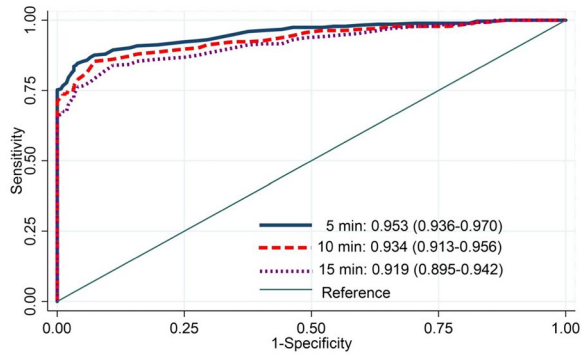

Fig. 1 (abstract 000030) The ROC of HPI for predicting hypotension in primary outcome

Intensive care Medicine Experimental 2025* 13(1):*000032

Introduction: The use of extracorporeal membrane oxygenation (ECMO) could be associated with systemic inflammatory response syndrome (SIRS) at the time of ECMO initiation or decannulation.(1)
Objectives: There is existing evidence to state that clinical criteria of SIRS accompany decannulation. We aim at finding if the SIRS state in this scenario has a concomitant change in the pro-inflammatory cytokines' levels.
Methods: A prospective observational pre–post study in a single tertiary academic center. Thirty consecutive patients with SIRS after successful decannulation of veno-arterial (VA)-ECMO. Levels of interleukins (ILs), IL-1α, IL-1β, IL-6 and tumor necrosis factor-alpha (TNF-α) were measured at 1 h before and at 1, 12, and 24 h(s) after decannulation
Results: One hundred and ten patients who were on VA-ECMO were screened and of them, a total of 30 (27.3%) patients with post-ECMO-decannulation SIRS were recruited during the study period. The mean age of patients was 48.80 ± 10.91 years. One hour prior to VA-ECMO decannulation, the blood levels of IL-1α, IL-1β, IL-6, and TNF-α were 6.68 ± 10.99 pg/mL, 0.28 ± 0.21 pg/mL, 18.21 ± 55.76 pg/mL, and 5.62 ± 5.89 pg/mL, respectively. There were not statistical differences between the pre-cannulation blood levels of all the cytokines and their respective blood levels at 12 and 24 h post decannulation except for the 24-h post-decannulation level of TNF-α (4.15 ± 4.65 pg/mL) which showed significant reduction compared with the pre-decannulation level ($p = 0.044$).
Conclusions: In patients with SIRS at the time of ECMO decannulation, there were no significant changes in the blood levels of the pro-inflammatory cytokines pre- and post-ECMO decannulation.

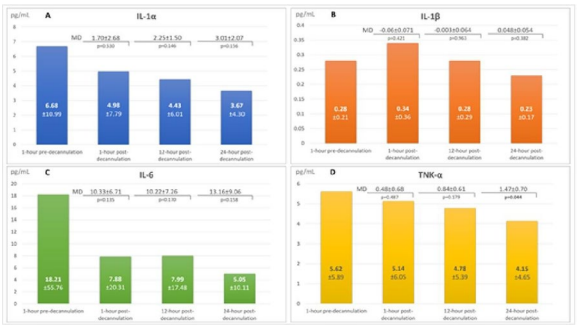

Fig. 1 (abstract 000032) Pro-inflammatory cytokines blood levels. Panel A. interleukin-1α (IL-1α); Panel B. interleukin-1β (IL-1β); Panel C. interleukin (IL-6); Panel D. tumor necrosis factor-alpha (TNF-α)

Pediatric intensivist coverage and outcomes in critically ill pediatric patients: A

JN. KIM[1]; JW. Hwang[1]
[1]Anesthesiology and Pain Medicine, Seoul National University Bundang Hospital, Seongnam-si, Republic of Korea
Correspondence: J.N. KIM
Intensive care Medicine Experimental 2025* 13(1):*000034

Introduction: The impact of trained intensivist staffing on critically ill pediatric patients requiring intensive care unit (ICU) admission is not clear.
Objectives: This study aimed to examine whether trained intensivist coverage is associated with improved survival outcomes in critically ill pediatric patients.
Methods: Our analysis included all pediatric patients hospitalized in ICUs in South Korea between 2017 and 2021. The intensivist and non-intensivist groups included pediatric ICU patients in hospitals with and without trained intensivists, respectively
Results: This study included 28,047 critically ill pediatric patients. Among them, 9,909 (35.3%) were admitted to ICUs of hospitals where trained intensivists were dedicated to patient management and were subsequently assigned to the intensivist group. After propensity score matching, 16,992 critically ill pediatric patients (8,496 in each group) were included in the final analysis. The all-cause mortality rates for 90 days and one year were 6.7% (566/8,496) and 8.3% (709/8,496) in the intensivist group, and 8.6% (732/8,496) and 9.8% (835/8,496) in the non-intensivist group, respectively. In the Cox regression analysis, the intensivist group showed 24% (hazard ratio [HR]: 0.76, 95% confidence interval [CI]: 0.68–0.85; $P < 0.001$) and 17% (HR: 0.83, 95% CI: 0.75–0.92; $P < 0.001$) lower 90-day and 1-year all-cause mortality rates, respectively, than the non-intensivist group.
Conclusions: The presence of pediatric intensivists in the ICU substantially reduced the mortality of critically ill pediatric patients. Our findings highlight the significant role of pediatric intensivists in reducing long-term mortality among critically ill pediatric patients.

Table 2 (abstract 000034) Survival analyses using multivariable Cox regression

Variable	HR (95% CI)	*P*-value
90-day mortality (model 1)		
Non-intensivist group	1	
Intensivist group	0.85 (0.78, 0.93)	<0.001
90-day mortality (model 2)		
Non-intensivist group	1	
Type I Intensivist group	0.91 (0.82, 0.99)	0.044
Type II Intensivist group	0.74 (0.65, 0.85)	<0.001
1-year all-cause mortality (model 3)		
Non-intensivist group	1	
Intensivist group	0.93 (0.83, 0.98)	0.021
1-year all-cause mortality (model 4)		
Non-intensivist group	1	
Type I Intensivist group	0.92 (0.83, 0.99)	0.046
Type II Intensivist group	0.82 (0.73, 0.91)	<0.001

Comparison of motor subtypes of delirium in critically ill patients: a retrospective study

C. Tanaka[1]; T. Tagami[2]; K. Junya[1]; M. Kuno[1]
[1]Emergency and critical care medicine, Nippon Medical School Tama Nagayama Hospital, Tama, Japan; [2]Department of emergency medicine, Jikei university school of Medicine, Kanagawa, Japan
Correspondence: C. Tanaka
Intensive care medicine experimental 2025* 13(1):*000036

Introduction: Delirium is a common problem in critically ill patients and it can increase mortality; however, the epidemiology of delirium, especially based on motor subtypes, is not fully understood.
Objectives: The aim of this study was to evaluate demographics, treatments, and outcomes for critically ill patients with an accurate diagnosis of delirium by consultation liaison psychiatry (CLP).
Methods: This single-center, retrospective cohort study was carried out from January 1, 2021, to December 31, 2022. All adult patients who were admitted to the intensive care unit (ICU) or high care unit (HCU) and who had been diagnosed with delirium by CLP were enrolled. The main outcome measure was all-cause in-hospital mortality. The subjects were assigned to either the hyperactive delirium group or the hypoactive/mixed delirium group and backgrounds, treatments, and outcomes were compared between the groups.
Results: Among 1,910 patients admitted to the ICU and HCU during the study period, 82 adult patients were included in this study. Of these, 62.2% had hyperactive delirium and 37.8% had hypoactive or mixed delirium. The diagnosis and vital signs at admission and psychotropic drugs for delirium did not differ between groups. In-hospital mortality was higher in the hypoactive/mixed delirium group than in the hyperactive delirium group (16.1% vs. 2.1%; $p = 0.027$).
Conclusions: Most patient characteristics, diagnoses, severity of vital status, and medications for delirium prescribed by CLP were similar between the two groups. However, in-hospital mortality was higher in the hypoactive/mixed delirium group than in the hyperactive delirium group.

Prognosis prediction for post-cardiac arrest patients using images of waveforms of somatosensory evoked potential manipulated by machine learning: a single-center retrospective cohort study

C. Tanaka[1]; T. Tagami[2]; K. Junya[1]; M. Kuno[1]
[1]Emergency and critical care medicine, Nippon Medical School Tama Nagayama Hospital, Tama, Japan; [2]Department of emergency medicine, Jikei university school of Medicine, Kanagawa, Japan
Correspondence: C. Tanaka
Intensive care Medicine Experimental 2025* 13(1):*000037

Introduction: Somatosensory evoked potentials (SSEP) are part of the multimodal approach for neurological prognostication after cardiac arrest (CA). Previously reported that the lack N20 wave strongly suggested poor outcome; however, there was no established evidence about the predictive ability of SSEP for favorable outcome.
Objectives: This study aimed to make several machine learning models to predict neurological outcome after CA using images of SSEP waveforms, and to validate the predictive ability of them.
Methods: This was a single center retrospective cohort study. We analyzed SSEP images which were performed for post-CA patients who admitted to our hospital from 2016 January to 2024 December. The outcome was neurological outcome judged with cerebral performance category (CPC): favorable outcome (CPC1 and 2) or poor outcome (CPC 3, 4,and 5). Firstly, we collected the raw image of SSEP, then adjusted them as the same size and resize them for easy manipulation

by machine learning. Next, we classified the images into favorable or poor group, and assigned them into train, validation and test data. Thirdly, we performed several machine learning methods (K-nearest neighbor algorithm, conventional neural network, feature extraction, principal component analysis, autoencoder, siamese network, prototypical networks and Model-agnostic Meta-learning [MAML]).
Results: We collected 173 images from 89 patients. The accuracy of each models ranges from 0.64 to 0.89. The area under the curve of receiver operating characteristic (roc-auc) of each models ranges from 0.54 to 0.83. Autoencoder (the accuracy 0.71, roc-auc 0.88), and MAML (the accuracy 0.78, roc-auc 0.83) were reliable models.
Conclusions: Using images of waveforms of SSEPs, we could make machine leaning models which showed the accuracy over 0.7 and the roc-auc over 0.8. These methods might help using the small number of images with simple lines in critical care field.

Nutrition support and adequacy in stunted critically ill children

N. Knebusch[1]; P. Hong-Zhu[2]; M. Mansour[1]; T. Fogarty[1]; F. Stein[1]; JA. Coss-Bu[1]
[1]Department of Pediatrics, Division of Critical Care, Baylor College of Medicine, Texas Children's Hospital, Houston, United States of America; [2]Department of Pediatrics, Texas Tech University Health Sciences Center, Lubbock, United States of America
Correspondence: J.A. Coss-Bu
Intensive care Medicine Experimental 2025* 13(1):*000038

Introduction: Nutritional support for children in the pediatric intensive care unit (PICU) is influenced by disease severity, baseline nutritional status, and invasive therapeutic interventions. In the first week of admission, a survival benefit is associated with achieving 60% enteral adequacy for calories and protein. We hypothesize that malnourished children will achieve > 60% calorie and protein adequacy compared to children with a normal nutritional status at baseline during their first week of admission to PICU.
Objectives: To evaluate nutrition support adequacy in malnourished children during their first week of admission to the PICU.
Methods: Retrospective cohort study of children admitted (index) to Texas Children's Hospital PICU between Jan 2016 to Dec 2017. Inclusion criteria included mechanical ventilation (MV) > 48 h., PICU length of stay (LOS) > 7 days, and > 2 yrs. of age. Nutritional status evaluated by CDC growth charts (Height for Age [HFA] z-scores, stunting defined as HFA z-score < -2). Nutrition support included enteral and parenteral nutrition and propofol if on TPN, and adequacy was defined as (intake/prescription × 100). All calculations used dietitians' prescriptions and actual body weight. Optimal adequacy was defined as ≥ 60%. Comparison analysis by Mann–Whitney test.
Results: Of 4199 patient admissions, 164 children (45% female) met inclusion criteria. Anthropometric evaluation on admission was an HFA z-score of -1.15 ± 1.92 [SD], with 75% normal nutritional status and 25% stunted. Patient characteristics are included in Table 1. Malnourished children vs. nourished children on day 7 had a median caloric intake (kcal/kg/day) of 37 (24-52, IQR) vs. 24 (13-40); p = 0.0032 and a protein intake (g/kg/day) of 1.56 (0.99-2.24) vs. 1.21 (0.63-2.10); p = 0.1233. Total calorie adequacy (%) in malnourished vs nourished children for days 1, 3, 5 and 7 were: 0 (0-0) vs. 0 (0-0), p = 0.48; 22 (0-77) vs. 25 (0-69), p = 0.78; 70 (28-129) vs. 76 (26-122), p = 0.99; and 105 (62-132) vs. 85 (45-118), p = 0.0362; respectively. Total protein adequacy (%) in malnourished vs nourished children for days 1, 3, 5 and 7 were: 0 (0-0) vs. 0 (0-0), p = 0.62; 21 (0-82) vs. 15 (0-75), p = 0.59; 76 (40-107) vs. 74 (20-132), p = 0.95; and 104 (66-149) vs. 81 (42-141), p = 0.12; respectively. For both groups, calorie and protein adequacy of ≥ 60% was reached on day 5.

Table 1 (abstract 000038) Patient

Characteristics	All	Nourished at baseline (n = 122)	Malnourished at baseline (n = 42)	P value
Age (years)	11.7 (7.7–15)	11.7 (7.4–15)	12.5 (8–16)	0.3472
Weight (kg)	37 (23–55)	39 (25–62)	30.6 (21–41)*	0.0004
PIM2 ROM (%)	3.7 (2.8–6.3)	3.7 (2.8–6.3)	3.8 (2.8–6.3)	0.8329
PSOFA score day 1	7.5 (5–10)	8 (5–10)	6.5 (4–9)	0.0635
PSOFA score day 3	7 (5–9)	7 (5–10)	6 (5–8)*	0.0126
MV (days)	9.3 (6.5–16)	9.3 (6.5–16)	9.4 (6.5–21)	0.6363
PICU LOS (days)	12 (9–20)	12 (9–18)	12 (10–28)	0.3163
Hospital LOS (days)	30 (19–53)	30 (19–51)	29 (20–58)	0.6283
Chronic condition n (%)	109 (66.4)	70 (64.2)	39 (35.8)**	< 0.0001
Mortality n (%)	20 (12.2)	16 (80)	4 (20)	0.5396

Values are median (IQR 25th–75th). PIM 2 ROM: Pediatric Index of Mortality, Risk of Mortality; PSOFA: Pediatric Sequential Organ Dysfunction; MV: mechanical ventilation; LOS: length of stay. * Comparison analysis by Mann–Whitney and ** Chi-square tests.

Conclusions: In this cohort of critically ill children, 1 out of 4 were stunted, and malnourished children had lower organ dysfunction scores on day 3. Optimal nutrition delivery was reached on day 5, and malnourished children reached higher caloric intake and adequacies than nourished children on day 7. Nutrition support teams should enact prompt nutritional support to stunted critically ill children.

Intensive care Medicine Experimental 2025* 13(1):*000039

Introduction: The approach to pericardial effusion in Intensive Care Medicine has always been controversial. Traditionally, this procedure has been reserved for other specialties. The often urgent need for pericardial drain placement and the lack of 24-h availability of some specialists (mainly in lower-level hospitals) can pose a problem that cannot always be resolved quickly and effectively. Furthermore, the traditional subxiphoid approach, in our opinion, does not always offer guarantees of success or safety for various reasons: obesity or morphological abnormalities, abdominal pathology (ascites, hepatomegaly), loss or lack of complete vision of the procedure. We propose a different approach, performed by the intensivist (a specialist available 24 h a day) at the bedside, under ultrasound guidance and with direct vision throughout the procedure.
Objectives: To analyze the management, approach and safety of the pericardial drainage technique performed (in cases eligible for drainage) in patients admitted to the ICU of a regional hospital with a diagnosis of pericardial effusion over a period of 6 years. Comparison between the classic subxiphoid approach vs. the anterior ultrasound-guided puncture under direct vision.
Methods: Retrospective, single-center observational study. The data have been obtained from the database of the Intensive Care Medicine service of the Hospital General de Granollers over a period of 6 years (2018-2024). All patients diagnosed with pericardial effusion, drained or not, are included.
Results: Final cohort: 50 patients. Mean age 63 years, 58% men. GMA (adjusted morbidity group) average of 4 (range 0 to 5). Apache average income of 14. The causes of effusion include paraneoplastic (32%), pericarditis (16%), autoimmune pathology (14%), congestive heart failure (CHF) (8%), idiopathic (18%) and others (12%). In terms of severity: 11% non-severe, 14% pre-tamponade (RV collapse, without hypotension), 64% cardiac tamponade. Drainage was indicated in 80% of cases, being successful in 95% of these.
Regarding the approach, it was anterior ultrasound-guided in 62.5% and subxiphoid in 37.5%. Of those performed via anterior ultrasound-guided route, 100% were successful. With the subxiphoid approach, the drain was not correctly placed in 14.3% of cases.
The rate of complications associated with drain placement was 7.5%. A 100% in cases with subxiphoid approach. The observed complications were: right ventricular puncture, wall hematoma and malposition of the drain. None of the cases was death as a consequence of the placement of the drainage.
Conclusions: The ultrasound-guided anterior approach is highly effective and safe. No complications of any kind were observed with the anterior approach during the data collection period. Greater drainage failure and a greater number of complications were observed in cases where a subxiphoid puncture was performed. The ultrasound-guided anterior approach allows drainage in the region with the greatest volume of effusion, under direct vision during all the procedure. It is a technique that requires training, but provides autonomy to the intensive care physician.

Intensive care Medicine Experimental 2025* 13(1):*000040

Introduction: Sepsis patients are becoming progressively older and frailer, and often require chronic medication. Comorbidities and long-term pharmacological treatments may influence survival outcomes in sepsis. This study aimed to assess the impact of baseline health status and chronic medication on sepsis-related mortality.
Objectives: The aim of this to study the relationship between pre-existing comorbidities, chronic medication use, and sepsis-related mortality in critically ill patients.
Methods: Retrospective population-based cohort study of ICU patients diagnosed with sepsis. The influence of baseline health status, measured using the adjusted morbidity group (GMA) score and the Queralt index, along with the effect of chronic pre-admission medication on post-sepsis survival was analysed.
Results: A total of 12,095 ICU-admitted patients with a diagnosis of sepsis were identified in the Catalan population database for 2018-2019. The cohort had a mean age of 68.2 years; high comorbidity burden (Queralt index: 52.9; GMA: 33.2), high dependency on health services; and elevated baseline health expenditures. In 73.5% of cases infection was present at admission. The overall mortality rate was 36.4%. Non-survivors exhibited higher comorbidity levels and greater medication use, particularly of statins, antiplatelet agents, beta-blockers, benzodiazepines, but lower use of corticosteroids, non-steroidal anti-inflammatory drugs and sulphonylureas. In multivariate analysis, prior statin use was the only pharmacological factor associated with reduced mortality (OR 0.803, 0.731, 0.883).
Conclusions: This population-based study highlights the significant role of age, comorbidities, and chronic medication in sepsis survival. Statin use was associated with reduced mortality, whereas corticosteroid use correlated with worse outcomes. The GMA score and Queralt index may enhance predictive models, improving resource allocation and clinical decision-making in hospitals.

Multivariate analysis of patients discharged from hospitals with a diagnosis of sepsis, showing risk factors, origin of infection, comorbidities, chronic medication and organ failure at admission. OR: odds ratio.

Intensive care Medicine Experimental 2025* 13(1):*000042

Introduction: Following right hemicolectomy, patients at University Hospital Southampton (UHS) NHS Foundation Trust are often admitted to the intensive care unit (ICU) or high dependency unit (HDU). This decision is based on patients' underlying co-morbidities and surgical complexity. Pain management here consistently features strong opioids (fentanyl, morphine, oxycodone) and adjuvant agents (paracetamol, regional anaesthesia) [1]. Postoperative opioid exposure and its associated risk factors are important to establish given opioids' safety profile. There is a potential risk of relative overdose in ICU where mechanical ventilation precludes titration to effect, though this has not yet been examined rigorously.
Objectives: To compare patients' opioid consumption within 24 h of admission to an ICU or HDU following right hemicolectomy and identify clinically relevant factors associated with opioid use.
Methods: This retrospective cohort study was registered and approved by the University of Southampton's ethics service (ERGO reference 88350.A1). It included adult patients admitted to the ICU or HDU at UHS (between 2017 and 2024) following right hemicolectomy that received opioids within 24 h of admission. Clinical data were manually extracted from a local clinical information system (MetaVision) and opioid doses were converted into IV morphine milligram equivalents (MMEs) [2]. Multiple linear regression (MLR) analysis was then conducted. The dependent variable was log-transformed opioid consumption in IV MMEs within 24 h of admission and the independent variables were demographic characteristics (gender, age, weight), history of substance dependence (alcohol, smoking, pre-hospital opioids), unit admitted to (ICU or HDU), mechanical ventilation and Sequential Organ Failure Assessment (SOFA) score.
Results: A total of 254 patients were included: 57 were admitted to ICU and 197 to HDU. Median (IQR) opioid consumption in IV MMEs within 24 h of admission was 68 (32-124) in ICU and 39 (20-70) in HDU patients ($p = 0.002$). The MLR model explained 24% of the variance in opioid consumption (adjusted R2 = 0.24) and was statistically significant ($p = < 0.001$). Age (B = 0.97, $p = < 0.001$) and history of alcohol dependence (B = 1.98, $p = 0.038$) were significant predictors of opioid consumption, while pre-hospital opioid exposure (B = 1.50, $p = 0.054$) was marginally significant. In contrast, gender, weight, history of smoking, unit admitted to, mechanical ventilation and SOFA score did not reach statistical significance.
Conclusions: Opioid consumption was significantly greater in patients admitted to ICU compared to HDU following right hemicolectomy. Younger age and history of alcohol dependence (> 14 units per week) both positively predicted opioid consumption. Adequately powered research is needed to confirm these findings and should assess the clinical impact of ICU opioid consumption excess to pain requirements.

BMSCs-Exos promotes M2 polarization of mouse alveolar macrophages by delivering miR-137-3p

Y. Cao[1]
[1]Deparment of critical care medicine, Shanghai Tenth People's Hospital, Tongji University, Shanghai, China
Correspondence: Y. Cao
Intensive care Medicine Experimental 2025* 13(1):*000045

Introduction: Acute lung injury (ALI) is a common problem in the critically ill population with a high mortality rate, phenotypic transformation of alveolar macrophages (AMs) plays a crucial role in the progression of ALI [1]. AMs account for over 90% and they are the main body of cells involved in the regulation of inflammation and immune imbalance in lung tissue of ALI patients [2]. Research has shown that in the progression of ALI, AMs can be activated into classically activated M1 macrophages and alternative activated M2 macrophages based on different lung microenvironments [3]. The main function of M2-type AMs is to release anti-inflammatory factors and promote the repair of diseased tissues. Up to now, multiple studies have confirmed that the M2 polarization of AMs can improve lung tissue damage and fibrosis progression caused by ALI by effectively inhibiting the pulmonary inflammatory cascade and cytokine storm [4].
Mesenchymal stem cells (MSCs) are a type of adult stem cells derived from bone marrow, with high self-renewal ability and multi-directional differentiation potential [5]. Research has shown that MSCs can colonize the lung tissue of ALI mice to exert immune regulatory effects and improve the survival rate of model mice [6]. Independent studies have also shown that human bone marrow-derived mesenchymal stem cells (BMSCs) have a significant protective effect on lipopolysaccharide (LPS) induced lung tissue damage in ALI mice [7]. Studies have shown that extracellular vesicles derived from MSCs can participate in M1/M2 polarization of macrophages through microRNAs (miRNAs) delivery [8]. This suggests that exosomes derived from BMSCs may participate in the M1/M2 polarization regulation of AMs through miRNAs delivery and thereby improving pulmonary inflammatory injury and delaying fibrosis progression through M2 polarization of AMs.

Objectives: To clarify the role of exosomes derived from bone marrow mesenchymal cells (BMSCs-Exos) in promoting M2 polarization of mouse alveolar macrophages and elucidate the mechanism.
Methods: BMSCs isolated from 8-week-old male mice and were used to prepare BMSCs-Exos. The mouse alveolar epithelial cells (MH-S) were induced with bacterial lipopolysaccharide (LPS) and INF-γ and were then treated with gradient BMSCs-Exos. A co-culture system was established with mouse BMSCs and MH-S cells, after treatment with exosome inhibitor GW4869 and LPS + INF-γ, the relative content of miR-137-3p in MH-S cells was detected by RT-qPCR, the proteins expression of TRIM24 and p-STAT6 in MH-S cells was detected by western blotting, and the intracellular ROS activity in MH-S cells was detected by using fluorescence probe method. The binding sites between miR-137-3p and TRIM24 mRNA 3′-UTR was predicted by using database and confirmed by luciferase assays. Furthermore, Co-IP was used to detect and evaluate the effect of BMSCs-Exos addition on the binding of CREB-binding protein (CBP) and STAT6 proteins in MH-S cells.
Results: Induction of LPS (100 ng/ml) + IFN-γ(20 ng/ml) for 48 h significantly upregulated the contents of inflammatory factors (TNF-α, IL-1β and IL-10) in the supernatants, and significantly upregulated the expression of M1 macrophage marker CD86 in MH-S cells. Treatments of BMSCs-Exos (1-10 mg/ml) could significantly inhibit LPS + IFN-γ induced increase in TNF-α and IL-1β contents and further upregulate the IL-10 level in the supernatants, and inhibited the expression of M1 polarization marker CD68 but upregulate the expression of M2 type marker CD163 in MH-S cells in a gradient dependent manner(Fig. 1). Co-culture of BMSCs upregulated the content of miR-137-3p, inhibited the protein expression of TRIM24, promoted phosphorylated STST6 protein expression and inhibited the enhanced ROS activity in MH-S cells induced by LPS + INF-γ(Fig. 2). Moreover, the aforementioned effects of BMSCs could be blocked by 20 μM exosome inhibitors. MiR-137-3p can bind to the 3′UTR of TRIM24 mRNA and inhibit its protein expression. Treatment of BMSCs-Exos inhibits the binding of CBP and STAT6 proteins in MH-S cells (Fig. 3)
Conclusions: BMSCs-Exos carrying miR-137-3p can promote M2 polarization and inhibit M1 polarization of mouse alveolar macrophages by activating the miR-137-3p/TRIM24/STAT6 axis, suggesting that it has broad application prospects in the biological therapy of acute lung injury patients.

Intensive care Medicine Experimental 2025* 13(1)*:000046

Introduction: Aging is posing a threat to the healthcare system globally. One of the biggest challenges the elderly facing is the infection of various sites. The elderly is vulnerable to infections, such as urinary tract, respiratory tract, and gastrointestinal tract[1], as a result of immune system dysfunction and accompanied chronic diseases, such as cardiovascular diseases and diabetes. These comorbidities further weaken the function of the immune system and increase the risk of infection[2]. As the population get older, there is an increasing incidence of elderly patients with sepsis[3, 4]. As a result of their relatively reduced immunity, elderly individuals are inclined to develop a quicker disease progression and higher mortality[5, 6]. Consequently, early identification, clinical intervention, and managing the infection progression are of paramount importance for the prognosis of patients.
Methods: A total of 775 patients were admitted into this study, who were diagnosed as infections and critical state. Firstly, using association rule mining methods, the mortality rates were obtained in the different combinations of abnormal indicators, which were compared with the baseline. Indicator was divided into quartiles and the mortality rate was calculated to figure out the threshold and different critical indicators were combined in different ways to form a specific marker for predicting the prognosis. Moreover, the association between biomarkers and prognosis was analyzed by multivariable Cox proportional hazard models, and the predictive value was determined by a receiver-operating characteristic curve.
Results: Firstly, we identified five indicators, including interleukin-10 (IL-10), activated partial thromboplastin time (APTT) and thrombin time (TT), alanine aminotransferase (AST), and monocyte, resulting in a significant increase of mortality. Further data mining revealed IL-10 alone as a valid predictor (AUC = 0.68, 95%CI 0.64-0.74). More importantly, when the value of IL-10 exceeds 2.73 pg/ml, the mortality risk rises significantly (OR = 2.70, 95%CI 1.80-4.15). The dynamic changes of IL-10 reflected the changes of infections and critical state in the elderly population. Furthermore, IL-10/lymphocytes ratio (ILR) (AUC = 0.70, 95%CI 0.63-0.76) acts as an effective predictor of prognosis in the elderly with infections. Patients with ILR at 0.63 and higher would be at a relatively higher risk of mortality (OR = 2.96, 95%CI 1.96,4.49).

Table 1 (abstract 000046) Mortality rates of six groups of patients for training cohort

		Deaths (mortality rate)	
Group	**Indicator combinations and ranges**	**Derivation cohort**	**Validation cohort**
1	All-cause deaths (All-cause mortality rate)	107(30%)	70 (17%)
2	IL-10 (pg/mL) > 12.9	71 (54%)	33 (31%)
3	IL-10 (pg/mL) > 12.9 & APTT (s) > 43	11 (91%)	12 (55%)
4	IL-10 (pg/mL) > 12.9 & ALT (U/L) > 50	25 (72%)	11 (61%)
5	IL-10 (pg/mL) > 12.9 & PT(s) > 16	20 (70%)	18 (53%)
6	IL-10 (pg/mL) > 12.9 & Monocyte (%) < 3	24 (75%)	17 (42%)

Table 2 (abstract 000046) The optimal cutoff value of IL-10 in all cohorts

Cohort	IL-10	OR	95% CI	p-value
Derivation cohort	IL-10 > 2.73	2.70	[1.80, 4.15]	$p < 0.005$
West China & Huashan	IL-10 > 2.36	2.36	[1.29, 4.30]	$p < 0.05$
Peking Union	IL-10 > 5.0	1.90	[1.25, 2.87]	$p < 0.005$

Table 3 (abstract 000046) The optimal cutoff value of ILR in all cohorts except for Peking Union hospital

Cohort	ILR	OR	95% CI	p-value
Derivation cohort	ILR > 0.63	2.96	[1.96, 4.49]	$p < 0.005$
West China & Huashan	ILR > 0.63	2.40	[1.32, 4.36]	$p < 0.005$

Conclusions: IL-10 alone predicts the prognosis and risk of death in the elderly with infections and critical state, and ILR showed a better performance. Clinicians are supposed to pay more attention to the high IL-10 and especially high ILR in the elderly with infections.

Introduction: Acute respiratory distress syndrome (ARDS) is a critical condition with high mortality, frequently complicated by acute kidney injury (AKI). Despite the substantial impact of AKI on ARDS outcomes, its inclusion and definition in randomized controlled trials (RCTs) of ARDS remain inconsistent. This study systematically reviews the definition and inclusion of AKI in ARDS RCTs over time and analyzes trends in mortality among these patients
Methods: A systematic search was conducted in PubMed, Embase, Cochrane Library, and ClinicalTrials.gov from 2000 to 2025, following PRISMA guidelines. We included RCTs assessing interventions in ARDS that reported AKI as an outcome. Data extraction included study year, AKI definition used (RIFLE, AKIN, KDIGO, or study-specific criteria), inclusion criteria, AKI incidence, and mortality rates. Meta-regression was performed to assess trends in mortality over time.
Results: A total of 68 RCTs, involving 24,315 patients with ARDS, were included in the analysis. Among these trials, 47 (69%) reported on AKI as an outcome, with the inclusion of AKI patients increasing significantly over the years. The inclusion rate rose from 36% in trials published between 2000 and 2010 to 89% in studies published between 2011 and 2025. The definition of AKI varied across studies: the KDIGO definition became predominant, used in 58% of studies after 2015, compared to the RIFLE and AKIN definitions, each used in 21% of studies. In 22 studies (32%), patients with severe AKI or those requiring renal replacement therapy (RRT) were excluded, potentially leading to selection bias. The incidence of AKI in ARDS patients varied widely between studies, ranging from 19 to 72%. Higher incidences of AKI were observed in trials focused on lung-protective ventilation strategies (53%) compared to those assessing pharmacological interventions (38%). Regarding mortality, the overall mortality rate for ARDS patients across all studies was 41% (95% CI: 37–45%). Patients with AKI had significantly higher mortality, with a rate of 58%, compared to 33% in those without AKI ($p < 0.001$). Over the years, the mortality rate of ARDS patients with AKI demonstrated a modest decline. In studies conducted between 2000 and 2005, the mortality rate in AKI patients was 63%. This decreased to 53% in trials published between 2011 and 2015 and further to 50% in the most recent studies (2016–2025). However, the mortality gap between AKI and non-AKI patients persisted throughout the years, with AKI remaining a strong predictor of poor outcomes. Meta-regression analysis showed that while the overall mortality rate of ARDS patients decreased over time ($\beta = -0.34$, $p = 0.047$), the mortality in AKI patients did not show a comparable decrease. The persistent higher mortality in AKI patients underscores the ongoing need for better management strategies targeting renal dysfunction in ARDS.
Conclusions: The inclusion of AKI in ARDS RCTs has significantly increased over the past two decades, with a shift towards the use of the KDIGO definition. Despite improvements in ARDS management and a decline in overall mortality, patients with AKI continue to experience substantially higher mortality rates, and this disparity has not decreased significantly over time. Standardized definitions of AKI and its inclusion in RCTs are critical for improving the comparability of study findings and optimizing outcomes for critically ill patients

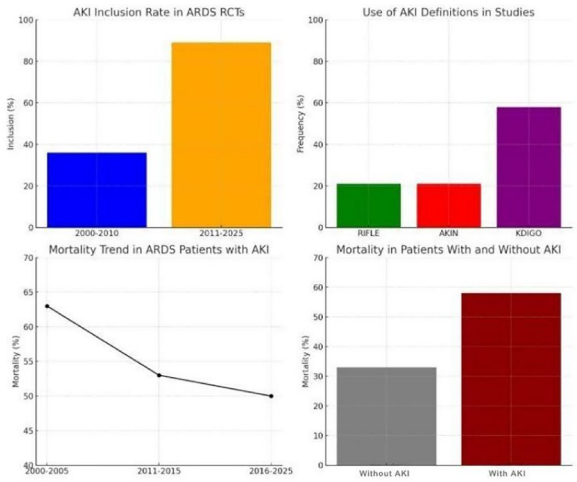

Fig. 1 (abstract 000048) The graphs illustrate: (I) the inclusion rate of patients with AKI in randomized controlled trials on ARDS across the periods 2000–2010 and 2011–2025; (II) the frequency of use of different AKI diagnostic criteria (RIFLE, AKIN, and KDIGO); (III) the temporal trend in mortality among patients with both ARDS and AKI; and (IV) the comparison of mortality between ARDS patients with and without AKI

Intensive care Medicine Experimental 2025* 13(1)*:000049

Introduction: Endotoxin, a component of lipopolysaccharide (LPS) from bacteria, disrupts the immune system, potentially leading to multiorgan failure. Unlike previous studies that used endotoxin activity (EA) levels, this study involved patients with relatively mild clinical conditions after major abdominal surgery and assessed the predictive value of EA levels for postoperative complications. We also evaluated the differential diagnostic value of EA in a subgroup of patients with abnormal liver function during the immediate postoperative period.
Methods: Patients admitted to the surgical ICU of our institution following major abdominal surgery were included in this study. Participants were classified into low and high postoperative EA groups based on EA cutoff values for predicting complications. Additionally, participants were categorized based on liver function assessed at ICU admission using total bilirubin (TB) levels after surgery. Abnormal liver function was defined as a TB level > 1.2 mg/dL.
Results: The study included 86 patients. The EA cutoff for postoperative complications was 0.485, with 49 patients (57%) categorized in the low EA group (EA levels < 0.485) and 37 patients (43%) in the high EA group (EA levels ≥ 0.485). The high EA group experienced statistically worse clinical outcomes, including longer ICU stays and higher mortality rates. Logistic regression analysis confirmed that EA levels and SOFA scores were significant predictors of postoperative complications. For patients with elevated TB, the EA cutoff value for postoperative complications was 0.515, which is higher than those obtained for the total patient cohort.
Conclusions: EA level is a viable surveillance tool for detecting postoperative complications in the acute period among ICU patients undergoing major abdominal surgery, and must be interpreted carefully considering the patient's liver function.

Placenta accreta spectrum (pas): data review of pas cases successfully managed by a trained multidisciplinary team in our tertiary referral hospital

T. Palladino[1]; P.S. Mariotti[1]; P. Vaira[1]; P. Ricciardi; A. Maglione[2]
[1]Anesthesia and intensive care unit 1, Casa Sollievo della Sofferenza, San Giovanni Rotondo, Italy; [2]Gynecology and obstetrics care unit, Casa Sollievo della Sofferenza, san Giovanni Rotondo, Italy, san giovanni rotondo, Italy
Correspondence: P.S. Mariotti
Intensive care Medicine Experimental 2025* 13(1):*000051

Introduction: Placenta accreta spectrum (PAS), is frequently associated with severe obstetric haemorrhage, anaesthesia risks and high mortality. We present a data review of PAS cases successfully managed by a trained, comprehensive, multidisciplinary team in an Italian Tertiary referral hospital.

Objectives: To validate the necessity of a trained, comprehensive, multidisciplinary team.
Methods: The analysis includes all PAS cases which have been managed between 2020 and 1st semester of 2024 at Casa Sollievo della Sofferenza (CSS), city of San Giovanni Rotondo, Italy.
Results: During the study period, 19 women underwent caesarean section for PAS-related reasons. More than half women were preterm at time of delivery and almost 100% had almost one previous caesarean section (CS) in their obstetric history. Regarding obstetric management during pregnancy, 66.7% were placenta praevia major cases. MRI was performed in 3 cases. Regarding multidisciplinary management at time of delivery, almost half CS were performed in hybrid operating room; more than half were conducted under regional anaesthesia and for all of them interventional radiologic procedures with preoperative placement of catheters were carried out; iliac arteries occlusion was necessary for half of them. Ureteral stents were placed in 2 cases. Peripartum hysterectomy was performed in 4 cases and one-third of them were admitted to the ICU. More than half newborns were admitted to the NICU. No maternal or neonatal deaths occurred.
Conclusions: CSS has developed an internal protocol for managing PAS cases. We presented our cases successfully managed by a trained, comprehensive, multidisciplinary team, composed of Gynaecologists, Obstetricians, Sonographers, Anaesthesiologists, Urologists and Interventional Radiologists. A careful antepartum diagnosis by ultrasound imaging is critical to get ready for surgery; surgical and anaesthetic skills are significant to reduce risk of injury; interventional radiologic technique is fundamental to minimise high risk of intraoperative haemorrhage. These skilled facilities are fundamental for optimal management of these increasingly frequent cases.

Table 1 (abstract 000051) Maternal features

TOTAL	19 Patients	
AGE	35 ys	
BMI	24,6	
ART	4/19	21.1%

Ventilator high and low alarms that received intervention: an analysis in respiratory care center

C. Yujen[1]; SH. Chi[2]
[1]Adult Respiratory Care, Changhua Christian Hospital, Changhua City, Taiwan; [2]RespiratoryTherapy Section for Adults, Changhua Christian Hospital, Changhua City, Taiwan

Intensive care Medicine Experimental 2025* 13(1):*000052

Introduction: Ventilator alarms are a critical built-in safety feature designed to detect changes that may require immediate attention to the patient and/or ventilator. Alarms are capable of identifying faulty equipment, leakage, patient disconnection, and alerting a trained clinician when important changes such as compliance or airway resistance occur. Data describing ventilator high and low alarm management in respiratory care center (RCC) are limited. Effective high and low alarm management is an important goal for patient safety and avoid respiratory therapists burnout.
Objectives: This study wanted to evaluate the selection of intervention ventilator high and low alarm settings, determine agreement to current recommendations. This study wanted to evaluate the selection of intervention ventilator high and low alarm settings, determine agreement to current recommendations.
Methods: This was a retrospective review of electronic medical records (EMR) of subjects admitted to the RCC and placed on a mechanical ventilator during the month of Oct. 2024 in Taiwan middle medical center. We retrospectively gathered ventilator alarm and event data without patient identifiers, for ventilator with a Drager Evita 4、Savina300 and PB840. The measured values recorded were peak inspiratory pressure (PIP), respiratory rate (RR), and exhaled minute ventilation (MV). The alarm settings selected for analysis were high peak inspiratory pressure (HI PIP), high respiratory rate (HI RR), and high and low minute volume (HI MV, LOW MV).The data were analyzed for event, priority, date, time, and duration of alarm using Microsoft access and Excel
Results: Data were collected from 242 subjects. The mean recorded measured values were: RR = 15.54 (± 4.63), PIP = 26.70 (± 6.45), MV = 8.18 (± 2.00). Discrepancies between recorded patient parameter and alarm limits ranged ranging from 63 to 94%. The mean percentage change between measured PIP and the high-pressure alarm was 53.52 ± 25.26%; while between measured total respiratory rate and the high-rate alarm was 80.82 ± 23.67%. The difference between mean measured minute ventilation and low minute ventilation alarm was 53.18 ± 6.59% and between measured minute ventilation and high minute ventilation alarm was 93.92 ± 30.56%. The three most common ventilator alarms, comprising more than 70% of all high priority alarms, were compared. Alarm that were not followed by an any intervention than 1 min were reported as average time in second and number of alarm events.
Conclusions: Ventilators alarms are created and set to signify a change in a patient condition that requires the attention of the clinician in our population, high peak inspiratory pressure and high respiratory rate alarms are the largest high priority alarms that received intervention. Alarm limits in the RCC were not selected in accordance with current recommendations and appear to be poorly individualized. Airway pressure high alarms are the shortest alarms with interventions and were common especially in the RCC. Alarms with interventions contribute to alarm fatigue and noise. There is a clear need to review the practice of ventilator alarm selection in the RCC and to evaluate the potential impact of alarm selection on clinical outcomes.

Intensive care Medicine Experimental 2025* 13(1):*000053

Introduction: Current guidelines for mechanical ventilation (MV) recommend targeting tidal volumes (Vt) normalized to predicted body weight (PBW) to prevent ventilator-induced lung injury [1]. The calculation of PBW aims to account for smaller lung sizes of females by applying a correction factor [2]. However in critically ill patients, the functional lung size often deviates from actual lung size, and the validity of the sex-correction factor has not been assessed.
Objectives: To assess whether the PBW equation used since the ARDSnet ARMA trial [2] adequately corrects for differences of female vs. male patients using physiologically derived lung size estimations and lung volumetry from CT scans in critically ill patients undergoing MV.
Methods: Adult patients undergoing controlled MV in an ICU setting were eligible for inclusion. For the primary cohort, routine data from Beth Israel Deaconess Medical Center, Boston, USA, the eICU dataset, and prospectively collected data of the EPvent-2 RCT [3] were harmonized. Within this study population, subcohorts of patients with 1) esophageal manometry (Pes) data and 2) available chest CT scans were derived. Additionally, applicable analyses were repeated in patients with acute respiratory distress syndrome (ARDS) from 9 RCTs.
In the primary analysis, lung sizes of female vs. male patients of the same PBW were compared using the proxies of static respiratory system (Crs) and lung (Clung) compliance, as well as anatomical and aerated lung volumes measured from chest CT scans. Additionally, the risk of receiving high (≥15cmH2O) driving pressures (DP) at similar Vt/kgPBW was compared between males and females, and its potential impact on mortality was assessed using mediation analysis.
All analyses were adjusted for a comprehensive confounder model and/or males and females were matched by PBW or Vt/kgPBW, as applicable.
Results: 26,467 (38.7% female, Fig. 1A) patients were included in the primary cohort. Out of these, 694 patients had available Pes measurements, while 3,410 had available CT scans. The pooled ARDS RCT cohort comprised a total of 5,092 patients.
In the primary cohort, at the same PBW, female patients had a lower Crs (-3.1 ml/cmH2O, 95%CI -3.7 to -2.5, p < 0.001) and a lower Clung (-8.9 ml/cmH2O, 95%CI -15.2 to -2.5, p = 0.007) than male patients. CT-based lung volumetry (Fig. 1) demonstrated a 403.5 ml (95%CI 297.1 to 510.0, p < 0.001) lower anatomical and a 231.9 ml (95%CI 136.5 to 327.2, p < 0.001) lower aerated lung size among females compared to males of the same PBW. At comparable standardized Vt/kgPBW, females were at an absolute 5.1% (95%CI 3.7 to 6.4, p < 0.001) increased risk of high DP (Fig. 2). Mediation analysis revealed that this increased risk of high DP partially explained excess mortality among females (9.7% proportion mediated).
Findings on DP and Crs were confirmed in the ARDS RCT cohort (Fig. 3).
Conclusions: The ARDSnet PBW equation overestimates lung sizes of female compared to male patients, resulting in an excess risk of high driving pressures and increased mortality even at guideline-adherent tidal volumes.

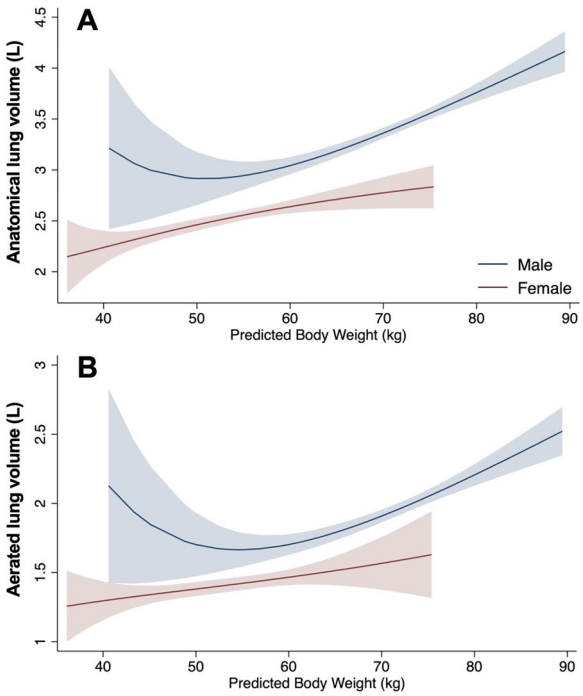

Fig. 1 (abstract 000053) AI-based CT ling volumetry among male and female patients
The PBW overestimated CT-derived anatomical (Panel A) and aerated (Panel B) lung volumes in female compared to male patients. Using the COVID-AI module within 3D slicer, lung volumes were measured for 3,410 patients in the primary cohort with available chest CT scans. On these data, fractional polynomial regression models were fit.

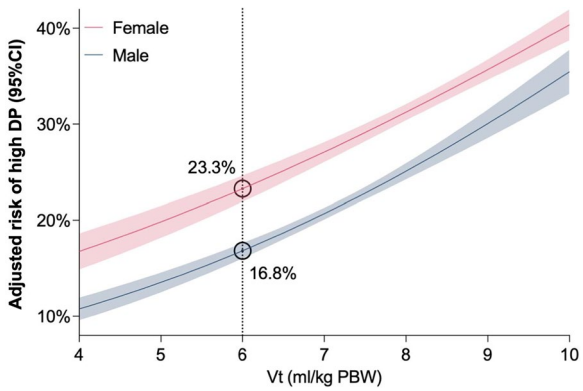

Fig. 2 (abstract 000053) Risk of high driving pressures by standardized tidal volume and sex
The adjusted absolute risk of high driving pressure (≥ 15cmH2O) ventilation was modelled for a clinically meaningful range of tidal volumes among male and female patients of the primary cohort (n = 26,467). Estimates were adjusted for age, body mass index, indicators of disease severity (non-respiratory SOFA score, PF-ratio, paCO2, arterial pH), year, and study center. Abbreviations DP, driving pressure, Vt, tidal volume, PBW, predicted body weight

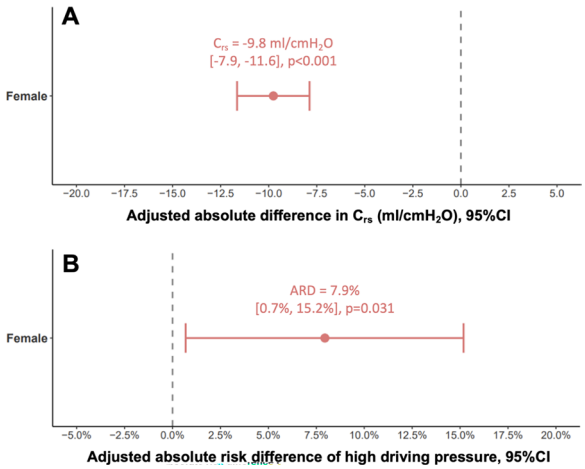

Fig. 3 (abstract 000053) Result from a pooled cohort of 9 ARDS RCTs Panel A shows differences in functional lung sizes (as approximated by Crs) among male and female ARDS patients of the same predicted body weight. Panel B shows the adjusted absolute risk difference for ventilation with driving pressures ≥ 15cmH2O in females compared to males, given the same standardized tidal volume.
The pooled RCT cohort included a total of 5,092 patients with ARDS from the ARMA, ALVEOLI, FACTT, EDEN, SAILS, ROSE, ICAR, EPVent-1, and EPVent-2 trial. The confounder model included age, body mass index, PF-ratio, paCO2, arterial pH, and non-respiratory components of the SOFA score. *Abbreviations: Crs, Respiratory system compliance; ARD, adjusted absolute risk difference.*

Intensive care Medicine Experimental 2025* 13(1):*000059

Introduction: Incorrect placement of nasoenteric tubes (NETs) in critically ill patients is associated with complications such as aspiration pneumonia and pneumothorax. Radiographic confirmation remains the gold standard, but is time-consuming and not always readily available. Gastric ultrasound (GUS) has emerged as a potential bedside tool for confirming NET positioning, offering a rapid and non-invasive alternative.

Objectives: To systematically evaluate the accuracy, feasibility, and clinical outcomes of gastric ultrasound for confirming nasoenteric tube position in critically ill patients.
Methods: A systematic search was conducted in PubMed, Embase, Scopus, and Cochrane Library from inception to January 2025. Studies evaluating gastric ultrasound for NET placement confirmation in adult critically ill patients were included. Accuracy metrics (sensitivity, specificity, positive predictive value [PPV], negative predictive value [NPV]), feasibility, and comparison with standard methods (radiography, pH testing, auscultation) were extracted. The QUADAS-2 tool was used for quality assessment.
Results: A total of 14 studies, comprising 1,987 critically ill patients, met the inclusion criteria. The pooled sensitivity of gastric ultrasound for confirming correct NET placement was 92% (95% CI: 88–96%), and specificity was 89% (95% CI: 85–93%). Positive and negative predictive values were 95% and 87%, respectively. GUS showed near-equivalent accuracy to radiography (diagnostic concordance: 94%) and outperformed pH testing (sensitivity: 70–85%) and auscultation (misplacement rate: 30%). The median time for ultrasound confirmation was 4.5 min (IQR: 3.2–6.0), compared to 45 min (IQR: 30–65) for radiographic confirmation. Operator experience influenced accuracy, with a learning curve of 25–30 scans.
Conclusions: Gastric ultrasound is a feasible, rapid, and accurate method for confirming nasoenteric tube positioning in critically ill patients. Its high sensitivity and specificity make it a promising bedside tool, potentially reducing reliance on radiographic confirmation and facilitating earlier enteral nutrition. Standardization of ultrasound protocols and further large-scale studies are needed for widespread implementation.

Diaphragmatic Dysfunction Assessed by Ultrasound: A Key Predictor of Prolonged Ventilation in Emergency Department

G. Sansone[1]; F. Barbato[1]; G. Porta[1]; E. Allegorico[1]; C. Serra[1]; V. Minerva[1]; V. Caterino[1]; P. Arbo[1]; V. Latini[1]; R. Allocca[1]; A. Giaquinto[1]; A. Pagano[1]; G. Bosso[1]; FG. Numis[1]

Intensive care Medicine Experimental 2025* 13(1):*000060

Introduction: Respiratory failure is a common and critical condition in the emergency department (ED), often requiring non-invasive ventilation (NIV) or continuous positive airway pressure (CPAP). In severe cases, invasive mechanical ventilation may be necessary. The diaphragm, responsible for much of the inspiratory volume, plays a critical role in respiratory mechanics, and its dysfunction can impact ventilatory outcomes. Diaphragmatic ultrasound, a non-invasive diagnostic tool that assesses diaphragmatic excursion and thickening, is becoming increasingly important in evaluating critically ill patients. However, its use in the ED is limited due to the fast-paced nature of care. This study aimed to evaluate the feasibility and utility of diaphragmatic ultrasound in guiding management and improving outcomes in ED patients with respiratory failure.
Objectives: The primary objective was to assess the feasibility of performing diaphragmatic ultrasound in ED patients with respiratory failure requiring NIV or CPAP. The secondary objective was to determine if diaphragmatic ultrasound could provide meaningful information to guide clinical decisions and improve patient outcomes, particularly by predicting ventilation time and need for invasive interventions.
Methods: An observational study was conducted in the ED of Santa Maria Delle Grazie hospital in Pozzuoli (NA) from November 2023 to April 2024. Patients with type 1 or type 2 respiratory failure requiring NIV or CPAP were included. Diaphragmatic ultrasound was performed at baseline to measure diaphragmatic excursion and thickening fraction (DTF). The primary outcomes were in-ED and in-hospital ventilation times, and length of stay in the ED. Secondary outcomes included mortality, need for endotracheal intubation (ETI), and need for rescue NIV. Statistical analyses included comparisons of continuous and discrete variables, and regression analysis to assess the relationship between diaphragmatic function and ventilation time.
Results: A total of 44 patients were included in the study. The average age was 74 years, with respiratory failure caused by acute heart failure, pneumonia, chronic obstructive pulmonary disease (COPD), and acute respiratory distress syndrome (ARDS). Patients with diaphragmatic dysfunction (defined as excursion < 10 mm and/or DTF < 30%) required significantly longer ventilation times both in the ED and during hospitalization. Regression analysis revealed a significant correlation between diaphragmatic excursion and both in-ED ($p = 0.011$) and in-hospital ventilation times ($p = 0.004$). Diaphragmatic dysfunction was associated with prolonged ventilation, though no significant differences were observed in mortality or need for intubation between the groups.
Conclusions: Diaphragmatic ultrasound is a feasible tool for assessing diaphragmatic function in ED patients with respiratory failure. The presence of diaphragmatic dysfunction, as indicated by reduced diaphragmatic excursion and DTF, is associated with prolonged ventilation times, both in the ED and during hospitalization. Early identification of diaphragmatic dysfunction may help clinicians better predict ventilation needs and optimize management strategies, potentially improving patient outcomes by reducing the risk of complications associated with prolonged ventilation.

Intensive care Medicine Experimental 2025* 13(1):*000062

Introduction: Weaning from mechanical ventilation is one of the most challenging aspects of managing critically ill patients and involve a gradual and complex process that begins as soon as the decision to initiate mechanical support is made. Both premature and delayed weaning can significantly impact patient outcomes, increasing morbidity and mortality, as well as the overall cost of medical care. Therefore, it is crucial for the practitioner to be well-informed about of all available diagnostic tests with the aim of identifying the opportune moment for the discontinuation of this support.
Objectives: To assess the diagnostic test accuracy of end-expiratory diaphragm thickness (EeDT) for assessing readiness for mechanical ventilation withdrawal in adult population.
Methods: Searches were conducted in MEDLINE, Embase, CENTRAL, and CINAHL, with additional publications identified through conference proceedings and contact with experts. Diagnostic test accuracy studies were independently assessed for inclusion, data extraction, and risk of bias (QUADAS-2), without language or date restrictions. Included studies focused on adults diagnosed with ventilatory failure requiring invasive support for more than 24 h.
Results: Eleven studies with 617 participants were included. The median prevalence of weaning failure was 34% (range 9% to 73%), and the included studies reported postoperative cardiovascular (9-30%), COPD (7-70%), brain trauma/stroke (4-25%), ARDS (0-6%), trauma (11-15%), and sepsis (3-18%) as the most prevalent indications for mechanical ventilation. The reported cut-off for EeDT 1.7 a

15.5 mm, being performed during, or after a spontaneous breathing test with pressure support (< 10 cmH2O), or T-piece.
The pooled sensitivity and specificity for retrieved studies were 0.69 (95% CI 0.50 to 0.83) and 0.59 (95% CI 0.32 to 0.82), for a mean LR + 1.7 (95% CI 1.00 to 2.90), LR- 0.53 (95% CI 0.34 to 0.81), DOR 3.0 (95% CI 1.0 to 7.0), and AUC of 0.69 (95% CI 0.65 to 0.73). The ROC plot indicated a high degree of heterogeneity between studies for estimates of sensitivity and specificity.
Conclusions: End-expiratory diaphragm thickness for assessing readiness for mechanical ventilation withdrawal in adult population demonstrate weak diagnostic accuracy. On average, this test yield a 31% chance of incorrectly indicating successful weaning, and a 41% chance of mistakenly suggesting failure. Given the potential negative consequences of improper ventilator withdrawal, physicians should integrate the results of physiological, ultrasound, and paraclinical measures to minimize uncertainty in deciding which patients should progress toward ventilator withdrawal.

End-expiratory diaphragm thickness (EeDT) SROC curve

Effect of oxygen targets on pulmonary hemodynamics after out-of-hospital cardiac arrest—a sub-study of the box cardiac arrest trial

S. Mölström[1]
[1]Department of anesthesiology and intensive care, Odense University Hospital, J. B. Winsløws Vej, Odense Municipality, Denmark, Odense, Denmark
Correspondence: S. Mölström
Intensive care Medicine Experimental 2025* 13(1):*000064

Introduction: Hypoxia may induce harmful effects in critically ill patients, potentially resulting in pulmonary vasoconstriction. We aimed to assess the impact of two different oxygen targets on pulmonary hemodynamics in comatose patients resuscitated from out-of-hospital cardiac arrest (OHCA). Furthermore, we assessed the prevalence of pulmonary hypertension in patients with OHCA and its association with outcome.
Methods: Predefined, two-centre, prospective, double-blinded sub-study of the "Blood pressure and oxygenations targets after out-of-hospital cardiac arrest (BOX)"-trial. Patients were randomized to a restrictive oxygen target of a partial pressure of arterial oxygen (PaO2) of 9 to 10 kPa or a liberal oxygen target of a PaO2 of 13 to 14 kPa. Invasive hemodynamic assessment was recorded from pulmonary artery catheterization and serial blood-gas analyses for an initial 48 h. The primary endpoint was the difference in pulmonary vascular resistance (PVR) within 48 h between oxygen groups from a repeated measurements-mixed model.
Results: Among 789 randomized patients, 730 (93%), who all had right heart catheterization, were included in this sub-study. At admission, the median PVR, mean pulmonary artery pressure (mPAP), and pulmonary artery pulsatility index (PAPi) were 2.4 wood unit (WU) (95% CI, 1.7-3.4), 25 mmHg (95% CI, 21-30) and 1.3 (95% CI, 0.8-1.8), respectively. The average PVR in the liberal oxygen group was comparable to that of the restrictive group (mean difference 0.05 WU, 95% confidence interval (CI) -0.09 to 0.18 WU, p = 0.48). mPAP, PAPi, and right atrial pressure did not differ between groups (p > 0.05). The adjusted odds ratio for one-year mortality increased progressively and linearly over a wide mPAP range. Compared with mPAP < 20 mmHg, pulmonary hypertension (mPAP > 30 mmHg) was associated with an increased risk of mortality (OR = 4.2; 95% CI, 2.0–9.2, p < 0.001).
Conclusions: Pulmonary hypertension is an independent risk factor for mortality in comatose resuscitated patients after OHCA. However, a restrictive oxygen strategy aiming at a PaO2 of 9 to 10 kPa during post-resuscitation critical care did not result in a higher PVR or deterioration of right ventricular function compared to a liberal oxygen strategy.

The adjusted odds ratio (95% confidence interval) for 1-year all-cause mortality is plotted for mean pulmonary artery pressure relative to a reference value of 20 mmHg. The adjusted odds for one-year mortality increases progressively and linearly over a wide mPAP range, beginning at 10 mmHg and extending through values > 30 mmHg. The histogram represents the density of patients across mPAP values.

Intensive care Medicine Experimental 2025* 13(1):*000065

Introduction: Critical care service delivery in low- to middle-income countries (LMICs) is a huge challenge. The significant scarcity of resources coupled with high critical care service demand mandates efficiency. There are no validated prognostic scores to assist prioritization in these settings. The purpose of this study is to design a *simple, practical and context-appropriate* prognostic score for predicting ICU mortality in low middle income countries.
Objectives: The aim of this study is to develop a novel prognostic score and investigate its precision, discrimination, and calibration properties in predicting ICU mortality in LMICs.
Methods Model development: A comprehensive review of all the relevant published studies from LMICs was conducted. The most highly cited factors associated with mortality were identified to formulate a ***novel*** context appropriate prognostic score.
Model performance and comparison: This was assessed on a data collected from Medical surgical ICU of Black lion Hospital from Sept 2019 to 2020. Predicted mortality and actual mortality were determined and compared. The score was assessed for its accuracy, discrimination, and calibration using Brier's score, the area under the receiver operating characteristic curve (AUROC), and a reliability diagram for predicting ICU mortality. It was also compared with existing mortality predictor scores i.e., mortality prediction model II (MPM II) and ICU priority level. P value less than or equal to 0.05 was considered statistically significant.
Results Score development: Altered Mental status, **M**echanical ventilation, **M**ore than two organ systems involvement, **P**ressure(systolic) less than 90, **P**otentially irreversible disease condition (ICU admission priority 3/4), **S**uspected infection and **S**evere hypoalbuminemia (serum albumin $\leq$ 2 g/dl)) were the most frequently cited predictors of mortality in low middle income countries. A prognostic tool, (A(MPS)2), was created using these variables. Each of the variables were scored out of one and the maximum possible score was 7.
Score test: The score evaluated on 265 patients admitted to the medical surgical unit of Black Lion hospital. All the selected predictor variables for the model (**A**(**MPS**)2: **A**ltered Mental status, **M**echanical ventilation, **M**ore than two organ systems involved, **P**ressure (systolic) less than 90, **P**otentially irreversible disease condition, **S**uspected infection and **S**evere hypoalbuminemia (serum albumin $\leq$ 2 g/dl)) demonstrated to have a statistically significant difference between survivors and non-survivors.
Score performance and comparison: A (MPS) two was able to correctly predict mortality in 86.4% of the cases with a sensitivity of 87.6% and specificity of 84.6%. The area under the operator curve for AMPS and other commonly used scores were AMPS (Area 0. 92; CI 0.88-0.93), MPM II score (Area 0.86; CI 0.82-0.91) and ICU priority level (Area 0.76; CI 0.68-0.83).
Conclusions: The African Mortality Predictor Score (A(MPS)2) is a promising prognostic score with a great ability to predict ICU mortality in low resource settings. A larger, multicenter study is recommended to further evaluate and validate the findings.

Indirect calorimetry versus urea: creatinine ratio to evaluate catabolism in critically ill patients

J. Azevedo[1]; LC. Silva[1]; AC. Silva[1]; AS. Cruz[1]; FJ. Lobato[1]
[1]Intensive care unit, Hospital São Domingos, São Luís, Brazil

Intensive care Medicine Experimental 2025* 13(1):*000067

Introduction: The ESPEN guideline on nutritional support in critically ill patients identifies three phases in the evolution of critical illness: the early acute phase, the late period of the acute phase, and the rehabilitation phase. Despite this division into phases, there is no clear evidence of metabolic behavior, especially in the transition from the second to the third phase, when the catabolic state gives way to anabolism.
Although indirect calorimetry can be a reliable measure for determining the beginning of the anabolic phase, it is not widely available in ICUs, unlike urea and creatinine measurements, which are part of routine daily exams in ICUs. Urea:creatine has been demonstrated to be a reliable marker of catabolism.
Objectives: To correlate the behavior of the urea:creatinine ratio with energy expenditure determined by indirect calorimetry in patients with severe COVID-19 to identify the onset of the anabolic phase translated by a reduction in the urea:creatinine ratio and increased energy expenditure in indirect calorimetry.
Methods: This retrospective cohort included 20 patients with severe COVID-19 confirmed by RT-PCR admitted to an ICU for patients with COVID-19 from June 2021 to February 2022 and who underwent invasive mechanical ventilation for at least 3 days and underwent determination of energy expenditure by indirect calorimetry on the 1st, 4th, 7th, 9th, 11th, 14th, 17th and 20th day of hospitalization. The calorimetric results were correlated with the urea:creatinine ratio. Data were obtained from the hospital's electronic medical record. All collected values were categorized into three time periods based on the days after the start of mechanical ventilation: MV days 1 to 4, MV days 7 to 11, and MV days 14 to 20.
Results: Twenty patients were analyzed. The median age was 49 years, the duration of mechanical ventilation was 14 days, ICU stay was 20.5 days, and hospital mortality was 25%. Indirect calorimetry values remained high in the 3 periods (32.5, 31.8, and 29.9 kcal/kg/day, $p = 0.94$), as well as the urea:creatinine ratio (82.7, 91.7, and 85.9, $p = 0.92$). There was no statistically significant differences between the three periods. Hemoglobin and CRP values also did not show a statistically significant difference.
Conclusions: In this study, we observed that energy expenditure measured by indirect calorimetry and the urea:creatinine ratio maintained high values over the 20 days of evolution of patients with COVID-19. The prolonged hypermetabolism observed in this (as in other studies) did not allow us to identify the beginning of the anabolic phase, which would allow us to recommend the urea:creatinine ratio instead of calorimetry to identify the beginning of the anabolic phase.
This study undoubtedly encourages the implementation of this protocol model in other nosologies. Septic patients may constitute a good analysis model.

Intensive care Medicine Experimental 2025 **13(1):*000068***

Introduction: Recent advancements in ultrasound technology have demonstrated significant potential in enabling clinicians to obtain critical measurements more efficiently, particularly in time-sensitive situations. While much attention has been directed towards the assessment of systolic dysfunction, diastolic dysfunction remains challenging to evaluate and is often overlooked in acute clinical scenarios. Its clinical significance, however, cannot be understated. Diastolic dysfunction is frequently implicated in acute heart failure, and is observed in up to 76% of patients with septic shock (1, 2). Additionally, inappropriate or rapid fluid administration can exacerbate diastolic dysfunction by elevating ventricular filling pressures (3). Impaired ventricular relaxation reduces filling time, stroke volume, and coronary perfusion, underscoring its importance. This study aimed to evaluate whether automated ultrasound measurements of key diastolic parameters (E velocity, E/A ratio, septal e', lateral e', and E/e') are comparable to manual measurements performed by trained clinicians.
Methods: This single-centre, cross-sectional observational pilot study compared automated and manual ultrasound measurements of diastolic parameters in a tertiary intensive care unit. Fourteen patients were included, with repeat measurements performed by trained clinicians when significant hemodynamic changes occurred, yielding a total of 21 datasets. Manual measurements of E velocity, E/A ratio, septal e', lateral e' and E/e' were obtained followed by automated measurements. Correlation and agreement were assessed using appropriate statistical methods, including Spearman's or Pearson's correlation for linear relationships and Bland–Altman analysis for agreement evaluation.
Results:

Table 1 (abstract 000068) Automated versus manual measurement of diastology parameters

Parameter	Correlation	Mean bias	Standard deviation	95% limits of agreement
E velocity	$r = 0.867$	-2.744	8.937	(-20.261, 14.773)
E/A	$\rho = 0.916$	0.022	0.118	(-0.209, 0.253)
Septal e'	$\rho = 0.753$	0.263	0.760	(-1.227, 1.753)
Lateral e'	$r = 0.934$	-0.184	0.823	(-1.797, 1.429)
E/e'	$r = 0.931$	-0.364	0.997	(-2.318, 1.59)

All parameters (Table 1) demonstrated strong correlation with manual measurements ($r > 0.75$, $P < 0.001$). The automated measurement of E velocity exhibited a higher mean bias (8.937) and broader limits of agreement (-20.261, 14.773) compared to other parameters. In contrast, E/A ratio exhibited the best agreement, with minimal mean bias and narrow limits of agreement. These findings suggest robust concordance between automated and manual measurements, particularly for certain diastolic parameters.

Conclusions: This pilot study indicates that automated ultrasound measurement of diastolic function parameters can achieve good agreement with manual measurements when performed by trained clinicians. Further research is required to validate the precision and reliability of this automated approach across varying degrees of diastolic dysfunction severity.

Fluid responsiveness tests applicability in a tertiary intensive care unit: a cross-sectional observational study

MHT. Kho[1]; A. Wong[1]
[1]Critical Care, King's College Hospital, London, United Kingdom
Correspondence: M.H.T. Kho
Intensive care Medicine Experimental 2025 13(1):000069

Introduction: A myriad of different fluid responsiveness tests (FRTs) exists in the armamentarium of fluid management, the applicability of which depends mainly on the mode of ventilation, cardiac rhythm, and the availability of continuous cardiac monitoring devices (1-3). Both under-resuscitation and overzealous fluid administration leads to organ dysfunction(4), the former from inadequate organ perfusion and the latter from fluid accumulation syndrome. Higher cumulative fluid balance has been associated with increased hazard of death(5), longer intensive care unit (ICU) stays and more days on ventilator(6). Fluid stewardship, therefore, is highly dependent on FRTs that guide the clinician on when to or not to administer fluid. This study aims to evaluate real-world applicability of FRTs in a tertiary ICU setting.
Methods: This cross-sectional observational study was conducted in a tertiary intensive care unit, including neurosurgical and trauma patients in its case mix. All the patients across the unit over 2 days were included, and the appropriate FRTs were determined for each patient based on their individual disease profile, ventilation parameters, cardiac rhythm, and presence of invasive hemodynamic monitoring devices. Descriptive statistics were used for data analysis.
Results:

Table 1 (abstract 000069) Patient characteristics

Characteristics	n (%)	Characteristics	n (%)
Sepsis	32 (43.8)	Mandatory ventilation	4 (5.5)
Trauma	13 (17.8)	Assisted ventilation	34 (46.6)
Myocardial infarction	4 (5.5)	Spontaneous breathing	35 (47.9)
Post cardiac arrest	6 (8.2)	Right heart dysfunction	6 (8.2)
Neurosurgical cases	30 (41.1)	Intraabdominal hypertension	5 (6.9)
Spine injury	8 (11)	Arterial line	48 (66)
Post surgery	23 (31.5)	PiCCO monitoring	4 (5.5)
Arrhythmia	2 (2.7)	Central venous catheter	37 (50.7)

PiCCO Pulse index continuous cardiac output

73 patients were included for analysis (Table 1). Mini fluid challenge (MFC) was the most widely applicable in our unit due to its minimal prerequisites (Fig. 1). The high number of neurosurgical and trauma cases in our unit precludes the use of positional changes required for passive leg raising. FRTs that utilises the ventilator can be applied in just about half of our patients, which is a reflection of the proportion of ventilated patient in the unit at the time. The low number of patients on continuous cardiac output monitoring necessitates the use of echocardiography, pulse pressure variation, pulse pressure, perfusion index, and end tidal carbon dioxide as a means of monitoring response to FRT.
Conclusions: The applicability of FRTs is highly dependent on ICU casemix. This study provides critical insights into FRT selection, resource allocation, and training needs. MFC was the most versatile FRT, highlighting its utility in diverse ICU populations.

A pilot study comparing systemic vascular resistance derived via ultrasound versus transpulmonary thermodilution

MHT. Kho[1]; R. Cashmore[1]; A. Wong[1]
[1]Critical Care, King's College Hospital, London, United Kingdom
Correspondence: M.H.T. Kho
Intensive care Medicine Experimental 2025* 13(1):*000070

Introduction: Advanced hemodynamic monitoring plays a vital role in the management of critically ill patients in shock by providing essential insights into cardiac output (CO) and its determinants: preload, contractility, and afterload (1). These parameters allow for targeted fluid resuscitation and titration of vasoactive medications, which are crucial for optimizing patient outcomes. However, traditional hemodynamic monitoring methods, such as transpulmonary thermodilution (TPTD), while accurate, are invasive, and time-consuming to set up(2). Additionally, these devices may not be readily available during the early stages of shock or in low-resource environments. Recent advances in ultrasound technology has made it possible to automatically derive systemic vascular resistance (SVR) from automated measurement of stroke volume and heart rate, with manual input of mean arterial pressure (MAP) and central venous pressure (CVP). The objective of this pilot study is to compare the accuracy of ultrasound-derived SVR when operated by trained clinicians to TPTD.
Methods: This is a single-center, cross-sectional observational pilot study conducted in a tertiary intensive care unit. 21 measurements were performed in 14 adult patients with varying types and degrees of shock who were already on pulse indicator continuous cardiac output (PiCCO) monitoring. SVR measurements were obtained directly from TPTD. As for ultrasound-derived SVR, left ventricular outflow tract (LVOT) diameter and automated LVOT velocity time integral (LVOT VTI) were measured by trained clinician, while CVP and MAP from invasive arterial blood pressure monitoring were manually inputted the system to generate the SVR. The resulting data were analysed using appropriate descriptive statistics, Pearson's correlation coefficient to assess the strength of the relationship, and Bland–Altman analysis to evaluate the level of agreement between ultrasound-derived and TPTD SVR readings.
Results: A strong positive correlation was observed between ultrasound-derived and TPTD SVR readings ($r = 0.778$, $P = 0.000$). The mean difference was 70.8 dyn·sec·cm^{-5}, with 95% limits of agreement (LOA) ranging from -481.42 to 623.0 dyn·sec·cm^{-5} (Fig. 1). This strong correlation indicates that ultrasound can be a reliable alternative to TPTD, with an acceptable range of variation for clinical use. Furthermore, when classifying patients into low, normal or high systemic vascular resistance index (SVRI) categories, ultrasound accurately predicted the SVRI category in 81% of cases (17 out of 21). Discrepancies between the two methods were observed in four cases: two patients with normal SVRI according to TPTD were classified as having low SVRI by ultrasound, one patient with low SVRI according to TPTD was categorized as normal, and one patient with low SVRI was classified as high by ultrasound.
Conclusions: This pilot study demonstrates a strong correlation between ultrasound-derived and TPTD SVR readings with

acceptable limits of agreement. In resource-limited settings when advanced hemodynamic monitoring equipment is not available, ultrasound-based SVR measurement by trained clinicians can provide invaluable guidance on clinical management. However, further research is necessary to validate the reliability of this method across different clinical scenarios and to investigate factors that may impact its accuracy.

Impact of fluid creep on volume and chloride load in critically ill adults: a prospective study on its prognostic significance and association with MAKE30

D. Zhou[1]; F. Cao[2]; L. Zhang[2]; Z. Peng[1]; Y. Li[1]
[1]Intensive care unit, Zhongnan Hospital of Wuhan University, Wuhan, China; [2]Department of Emergency and Intensive Care, Xiangyang Central Hospital, Affiliated Hospital of Hubei University of Arts and Science, Xiangyang, China

Intensive care Medicine Experimental 2025* 13(1):*000073

Introduction: This prospective ICU study (n = 1633) reveals fluid creep as the primary fluid source (48.4%), linking high doses (> 802 ml/d) to increased major adverse kidney events (MAKE30), emphasizing cautious fluid management in critical care.
Objectives: Quantify the fluids used for different purposes in the intensive care unit (ICU). To explore sources of fluids besides resuscitation fluids that have a significant impact on the volume and chloride load of critically ill adult patients, and analyze its impact on prognosis.
Methods: We performed a prospective observational study in a 52-bed tertiary academic ICU. Precisely recorded information on the volume intake and output in the first 5 days of ICU stay and the purpose of each fluid prescription, for all patients admitted to the ICU from May to December 2022. All fluids were divided according to the purpose of use into five major categories: resuscitation fluids, fluid creep, maintenance/replacement fluids, nutrition fluids, and blood products. Quantify the trend of the amount of each fluid used in adult critically ill patients and its effect on volume load. Patients were divided into the high fluid creep group (> 802 ml/d) and the low fluid creep group (≤ 802 ml/d) according to the median fluid creep dosage. Logistic regression was used to analyse the correlation between this and the incidence of MAKE30.
Results: A total of 1633 adult critically ill patients were included, with a median age of 67 (55, 76) years, and a median APACHE II score of 22 (16, 29). Fluid creep accounted for 48.4% of the total daily fluid, with a median of 802 (450, 1238) mL, far exceeding resuscitation fluid (8.6%) or maintenance/replacement fluids (6.7%), and was the largest daily fluid use in adult critically ill patients. After adjustment for all confounders, high fluid creep was associated with an increased incidence of MAKE30 (OR = 1.35, 95% CI 1.02—1.79, p = 0.038) and each of its components: in-hospital mortality (OR = 1.49, 95% CI 1.03–2.16), the rate of new renal replacement therapy (RRT) (OR = 1.83, 95% CI 1.27–2.64), and the incidence rate of persistent renal damage (PRD) (OR = 1.75, 95% CI 1.06–2.89).
Conclusions: Fluid creep is the major source of volume and chlorine loading in critically ill adult patients, and high doses are associated with an increased incidence of MAKE30. Special care should be taken when prescribing intravenous fluid therapy.

Intensive care Medicine Experimental 2025* 13(1):*000074

Introduction: Persistent tissue hypoxia from cardiogenic shock (CS) leads to vasoplegia owing to endothelial dysfunction. A low diastolic arterial pressure (DAP) in the first 24 h of admission was independently and significantly associated with mortality in patients with CS. Diastolic shock index (DSI) is a non-invasive hemodynamic parameter which is the ratio of heart rate to DAP, first utilized to evaluate vascular tone in patients with septic shock. There have been no studies utilizing DSI in assessing severity of circulatory dysfunction and classifying patients with CS in order to detect who are more likely to benefit from an early vasopressor treatment and possible escalation of therapy.
Objectives: The primary objective of this study is to determine whether a significant DSI values during the first six hours of assessment is associated with mortality in CS.
Methods: We conducted a single-center retrospective observational study in a tertiary hospital. Adult patients diagnosed to have CS by SCAI classification who have hemodynamic instability not receiving any vasoactive and/or mechanical circulatory therapy on assessment. Patients with moderate to severe aortic regurgitation, atrial fibrillation, hyperthyroidism, on pacemaker, SA and AV node dysfunction, severe anemia and liver cirrhosis were excluded. 266 patients were reviewed but only 54 patients were eligible. DSI was calculated on baseline, 2nd, 4th and 6th hour of initial resuscitation.
Results: Average SAPS score was higher in patients with elevated DSI ($\geq$ 2.2). In-hospital mortality rate remains to be elevated by more than half (52%) similar to the study of Rigamonti et al. and was high (16.7%) in patients with elevated DSI **(Table 1)**. Non-survivors were noted to have higher DSI value as compared to the survivors during the first six hours (**Fig. 3**). For every unit increase in DSI on baseline, odds of mortality increases by less than a half (39%). However, the subsequent increases in DSI from 2nd, 4th, and 6th hour of resuscitation did not show any significant pattern and had no statistically significant relationship with mortality **(Fig. 2)**.
Conclusions: Similar to septic shock, an elevated baseline DSI seems to correlate with inpatient mortality in patients with CS. We failed to demonstrate that changes in DSI during the first six hours of resuscitation impact mortality and therefore we do not recommend DSI as a target for resuscitation in Cardiogenic shock. A larger prospective study is suggested to identify a specific DSI cut-off and evaluate its prognostic value in cardiogenic shock.

Table 1 (abstract 000074) shows the demographic and clinical profile of patients with cardiogenic shock

Lactylation of S100A9 protein: a new insight into sepsis-associated lung injury

X. Zheng[1]; H. Liu[1]; R. Li[2]; E. Chen[1]; C. Ying[1]

Introduction: Sepsis is a life-threatening systemic inflammatory condition often complicated by acute lung injury (ALI), with limited therapeutic options. The pathophysiology of sepsis-induced organ dysfunction remains poorly understood, highlighting the need for novel insights into disease mechanisms.
Objectives: This study investigates the role of (S100A9 in sepsis-associated ALI, focusing on its post-translational modifications and their implications in inflammation and tissue damage.
Methods: Through lactylation proteomics and immunoprecipitation, we identified that S100A9 undergoes lactylation at K4 and K94. Using BMDM cells and confocal microscopy, we demonstrated S100A9 nuclear translocation and its regulation by lactylation. Subsequent mass spectrometry, CUT&Tag, and RNA sequencing revealed that S100A9 interacts with CEBPB to regulate IL-1β transcriptional activation.
Results: We identified that S100A9 undergoes lactylation at lysine residues K4 and K94. LPS stimulation enhances S100A9's colocalization with the nucleus and its presence in nuclear fractions. Furthermore, lactylation of S100A9 enhances its nuclear translocation, and through interaction with Cebpb, it regulates the transcriptional activation of IL-1β, thereby mediating inflammatory responses that contribute to sepsis-induced lung injury.
Conclusions: In this study, we revealed the specific mechanism of sepsis-induced lung injury through S100A9 lactylation modification

and its interaction with transcription factor Cebpb to regulate pro-inflammatory IL-1β gene transcription. Further research is needed to validate these findings and explore their therapeutic implications, particularly in the context of clinical nutrition and metabolic interventions to improve patient outcomes in sepsis-associated ALI.

Early mobilization of critically ill patients: a systematic review of perceived barriers

E. Papadimitriou[1]; S. Petras[1]; S. Fokidi[1]; S. Andreadou[2]; I. Vasileiadis; E. Grammatopoulou[1]; I. Patsaki[1]

Intensive care Medicine Experimental 2025* 13(1):*000079

Introduction: Early mobilization of critically ill patients is a feasible and safe intervention that prevents ICU-acquired weakness and other complications 1. However, its limited implementation suggests a gap between the research evidence and clinical practice 2. It is widely accepted that early mobilization faces a variety of barriers 3. Over the last 15 years, significant efforts have been made internationally to identify and manage these barriers 4, 5.
Objectives: The objective of this systematic review is to identify the questionnaires used for recognizing barriers, as well as to study these barriers faced by physiotherapists at an international level.
Methods: The research was conducted in the following databases: PubMed, Science Direct, Scopus and Cochrane. The keywords which used during the search were: "early mobilization", "early mobility", "early rehabilitation", "intensive unit care patients", "critically ill patients", and "barriers". We included studies from January 2013 to September 2023 and excluded those that were not published in English. The inclusion criteria were as follows: a) qualitative studies in which the questionnaire or interview was used to collect data, b) studies where early mobilization was carried out in the ICU, c) early mobilization was applied to adult patients and d) the participants of the studies included at least the physiotherapy profession.
Results: We included 19 studies and analyzed their data based on the literature search. The participants were doctors, nurses, physical therapists, and respiratory therapists who work in the ICU and are involved in the process of early mobilization. Of the 19 studies, only 3 included exclusively physical therapists. Additionally, 10 studies reported that the sample had an average of more than 5 years of experience in the ICU. In 9 studies, the barriers were categorized into: patients, health care providers, equipment and institutional-related barriers. The most common perceived patient barriers were sedation and medical instability. The most frequently perceived provider barriers were limited staffing and education. Also, insufficient equipment had been reported as a barrier by 16 studies. The most important institutional-related barrier was the lack of communication during early mobilization.
Conclusions: These barriers varied across ICUs and within providers, depending on the ICU patient population, setting, attitude, and ICU culture. Systematic efforts to change ICU culture to prioritize early mobilization using an interprofessional approach and strategies are important steps for successfully implementing early mobility in clinical practice.

Intensive care Medicine Experimental 2025* 13(1):*000080

Introduction: Advances in medical technology have led to an increase of the number of patients who survive critical illness. However, a large percentage of them experience reduced functionality and inability to return to activities of daily living. The international community uses a variety of tools to measure the functional ability of critically ill patients to identify deficits and to design an appropriate rehabilitation program.
Objectives: This systematic review aimed to identify the tools measuring functional ability of surviving critically ill patients and to document the studies testing their reliability and validity.
Methods: The following databases were searched; Scopus and PubMed systematically, by two independent researchers for studies on psychometric evaluation of functional measurement tools implemented post-ICU discharge published in English. Search strategy included keywords like: psychometric properties, validity, reliability, functional, outcome, ability, ICU, survivors critical illness. The assessment of the methodological quality of the studies was performed using the "COSMIN Risk of Bias checklist for Systematic reviews of Patient—Reported Outcome Measures".
Results: 257 studies were identified, of which only 20 were included in the systematic review. The methodological quality of these was low. Barthel Index, Functional Independence Measure (FIM), Chelsea Critical Care Physical Assessment Tool (CPAx), Functional Status Score for the ICU (FSS-ICU), Physical Function in ICU Test (PFIT), ICU Mobility Score (IMS), De Morton Mobility Index (DEMMI), 6 Minute Walk Test (MWT), 2MWT, 30MWT and 5 Sit To Stand have been used after discharge from the ICU to assess functional ability. Yet from these only 9 have been examined for their psychometric properties. FSS-ICU, CPAx and PFIT have the most thorough and extended psychometric evaluation. All had presented moderate to high validity and reliability. Yet, taking into consideration the COSMIN tool there are a lot of domains that have been examined.
Conclusions: Functional assessment tools for survivors of critical illness can provide valid and reliable measures. However, there is a need to test the remaining tools. The need to adopt a tool that assesses all the deficits that this group of patients may present, regardless of their diagnostic category and severity, is highlighted.

Intensive care Medicine Experimental 2025* 13(1)*:000081

Introduction: Burnout syndrome is a multidimensional mental illness that develops due to sustained exposure to professional stressors without a chance for recovery. Anesthesiologists and intensivists are highly vulnerable to suffer from such disorder due to continuous exposure to high level of stress.
Objectives: *The aim of this study* was to identify the prevalence of burnout syndrome among intensivists and anesthesiologists and to the associated risk factors in four Emirates Health Services (EHS) hospitals: Al Qassimi Hospital (AQH) and Sharjah Kuwait hospital (SKH), Ibrahim Bin Hamad Obeiedullah hospital (IBHOH) and Alkuwait hospital Dubai (MBH)
Methods: This cross-sectional study was conducted on all physicians (111 physicians) (consultants, specialists, general practitioners, and residents) from anesthesia and critical care departments from the four hospitals in (EHS) included in the study. A questionnaire including 54 questions covering the demographic, occupational, social data and Maslach Burnout Inventory Human Services Survey (MBI-HSS) for physicians which included 22 items: emotional exhaustion (nine items [score from 0–54]), depersonalization (five items [score from 0–30]) and feeling of personal accomplishment (eight items [score from 0–48]) was used. Each item in (MBI-HSS) was scored using a 7-level scale ranging from 0 to 6 (0 = never, 1 = a few times a year, 2 = once a month or less, 3 = a few times a month, 4 = once a week, 5 = a few times a week, 6 = every day), allowing for subscale assessment in all three dimensions. The physician was diagnosed to be burnt-out if he achieved total scores of Emotional exhaustion (EE) > 27 and either Depersonalization (DE) > 10 or personal accomplishment (PA) < 40. The questionnaire responses were electronically collected for statistical analysis through the EHS research hub. The physician was diagnosed to be burnt-out if he achieved total scores of EE > 27 and either DE > 10 or PA < 40. The questionnaire responses were electronically collected for statistical analysis through the EHS research hub. An approval from Ministry of Health and Prevention Research Ethical Committee was obtained before starting the research. The questionnaire was sent to all concerned physicians included in the study by email. The consent form was attached to the survey and electronic consent approval was obtained through the survey from all participants. *Exclusion criteria: any* physicians who refused to participate, had any history of psychiatric illness or recruited within 6 months prior to survey
Results: The responders were 96 out of 111. They were classified, based on working department and their position. Out of the 96 participants, 42.7% had been diagnosed with burnout. However, most of the participants, 68.8%, exhibited a high grade of the isolated dimension. In relation to burnout diagnosis and Department, participants working in Anesthesia department exhibited the highest rate of burnout (52.1%), compared to those working in ICU department (33.3%). However, the results were not statistically significant. In terms of burnout diagnosis and position, consultants had the highest rate of burnout at 55.6%, followed by residents by 50%. Conversely, General Practitioners had the highest rate of negative diagnoses at 92.3%. With a p-value of 0.041, based on burnout diagnosis across hospitals, participants from AQH had the highest rate of burnout (58.3%), followed by SKH (47.8%). Conversely, HBH had the highest rate of negative diagnosis (91.7%). With a p-value of 0.001, we may conclude that there is a statistically significant association between burnout diagnosis and hospital affiliation. All other factors like work load, job satisfaction, working hours, age, social status, financial satisfaction did not showed significant correlation with burnout.
Conclusions: Based on this study, anaesthesiologists are more vulnerable to burnout compared to intensivists, the work place affiliation is a significant factor as well as the position as consultants are more vulnerable than other positions, followed by residents and the least were general practitioners and physicians working in Alqassimi hospital developed more burnout.

Intensive care Medicine Experimental 2025* 13(1)*:000083

Introduction: Red blood cell (RBC) transfusion is the most frequently administered therapy in intensive care units (ICU). Red blood cell transfusion carries inherent risks including hospital-acquired infections (HAIs). Identification of modifiable risk factors is essential for optimizing patient outcomes.
Objectives: To estimate the association between red blood cell transfusion volume and HAIs in critically ill patients.
Methods: MEDLINE, CENTRAL, Embase, and Transfusion Evidence Library were searched for studies published from database inception until November 2024. Citation searches and reference checks of relevant guidelines were combined. Studies to evaluate the transfusion and anemia pharmacotherapy for critically ill patients were included. The interested outcome was the incidence of HAIs. We conducted a dose–response meta-analysis (DRMA) using a one-stage random-effects model.
Results: We identified 39,453 records from database searches. After combining results from citation searches and reference checks of guidelines, 45 studies were eligible. For DRMA, we eliminated 14 studies without results and 15 studies with critical risk of bias. We included 9,452 patients from 16 studies. Our DRMA showed a U-shaped risk curve, with odds ratios for HAIs decreasing and reaching a trough at three units of RBC transfusion. Three units of RBC transfusion may not increase the risk of HAIs in critically ill patients. The clinical implications of higher RBC transfusion volumes remain uncertain.

Conclusions: Healthcare professionals can adopt a restrictive RBC transfusion strategy in critically ill patients with minimal concern for increasing HAIs.

Early lactate clearance and outcome in severe sepsis: relationship with $ScvO_2$ and implications for resuscitation

E. jung[1]
[1]emergency medicine, Chonnam national University, Gwangju, Republic of Korea
Correspondence: E. jung
Intensive care Medicine Experimental 2025 **13(1)**:0000087

Introduction: Early lactate clearance may be an important indicator of improved survival among patients with severe sepsis. However, the degree to which achieving central venous oxygen saturation ($ScvO_2$) ≥ 70% aligns with lactate clearance during early resuscitation remains unclear.
Objectives: We sought to determine (1) whether early lactate clearance is associated with improved in-hospital survival in emergency department patients with severe sepsis, and (2) the concordance between $ScvO_2$ optimization and lactate clearance during initial sepsis management.
Methods: Within a multicenter shock research network implementing quantitative resuscitation for severe sepsis, we analyzed prospectively collected data from three urban hospitals. Inclusion criteria were:

- Age > 17 years.
- ≥ 2 systemic inflammatory response syndrome criteria.
- Systolic blood pressure ≤ 90 mmHg after fluid challenge **or** initial lactate ≥ 4.0 mmol/L.
- Initial and repeat lactate measurements obtained within 6 h of resuscitation initiation.

Patients were categorized a priori based on previously reported thresholds:

- **Lactate clearance group**: repeat lactate decreased by ≥ 10% from the initial level **or** both initial and repeat lactate ≤ 2.0 mmol/L.
- **Lactate non-clearance group**: repeat lactate decreased by < 10%.

The primary outcome was in-hospital mortality. Multivariate analysis was conducted to assess independent predictors of death.
Results: A total of 166 patients met the inclusion criteria, of whom 15 (9%) showed lactate non-clearance. Overall in-hospital mortality was 19% in the lactate clearance group and 60% in the non-clearance group (P < .001). On multivariate analysis, lactate non-clearance emerged as an independent predictor of mortality (odds ratio, 4.9; 95% CI, 1.5–15.9). Moreover, discordance was observed between lactate clearance and $ScvO_2$ optimization: 79% of those without lactate clearance simultaneously had an $ScvO_2$ ≥ 70%.
Conclusions: In this multicenter cohort of severely septic patients, a failure to clear lactate early in resuscitation was associated with a markedly higher risk of death. Furthermore, achieving $ScvO_2$ ≥ 70% did not reliably ensure lactate clearance. These results support the need for a clinical trial evaluating lactate clearance as a distinct end point in early sepsis resuscitation.

Correspondence: M. Vogt
Intensive care Medicine Experimental 2025 **13(1)**:***000090***

Introduction: Liver transplantation is the only current effective treatment option for patients with end-stage liver disease. Donation after cardiac death (DCD) provides additional potential liver grafts for the growing number of patients on the liver transplant waiting list. However, DCD livers are more prone to the negative effects from an often-prolonged ischemia time compared to traditional donation after brain death (DBD) donors. Recently, the use of ex situ normothermic machine perfusion (NMP) has shown early promising results for increasing acceptable grafts for transplantation and decreasing the incidence of early graft dysfunction.
Objectives: Our study aimed to identify if the use of NMP impacts stability at reperfusion and early clinical outcomes for liver transplant recipients who receive a liver from a DCD donor.
Methods: We performed a retrospective cohort study comparing adult liver transplant recipients who received DCD liver transplants with and without the use of NMP support after harvest and prior to transplant at Mayo Clinic in Rochester, MN from June 2018 through February 2025. Our institution transitioned to use of NMP in November 2023 and 35 patients ultimately received DCD liver grafts with the use of NMP. We then took a random historical sample of 35 different patients prior to November 2023 for our comparison group. We also collected patient age and sex at the time of transplant. Outcomes of interest included total epinephrine and vasopressin dose during the reperfusion phase (1 min prior through 4 min after), incidence of cardiac arrest at reperfusion, development of post-reperfusion syndrome, and 30-day mortality.
Results: The mean age of patients was 55.4 years and 34.3% were female in the non-NMP DCD liver transplant group compared to 54.3 years and 42.9% who were female in the NMP group. During reperfusion, median epinephrine dose was not significantly different between each group (non-NMP: 20 mcg (IQR 30 mcg); NMP: 20 mcg (IQR 10 mcg) p: 0.55) and median vasopressin dosing was also similar (both non-NMP and NMP: 0.0 units (IQR: 0.5 units) p: 0.85). However, there was a significantly higher incidence of post-reperfusion syndrome in the non-NMP group (51.4%) compared to the NMP group (11.4%) (p: 0.0008). One patient developed cardiac arrest during reperfusion in the non-NMP group compared to no patients in the NMP group and all patients in both groups survived for at least 30 days in our study (Table 1).
Conclusions: In conclusion, our single-center retrospective cohort study showed that while epinephrine and vasopressin use were similar between the non-NMP DCD liver transplant recipients compared to NMP-supported DCD grafts at the time of reperfusion, the incidence of post-reperfusion syndrome was significantly lower in patients who received NMP-supported DCD liver transplants. All patients survived for at least 30 days in our study. Future research should be performed to continue to assess the impact of NMP support for DCD liver transplants on relevant clinical outcomes in this patient population.

Table (abstract 000090) Incidence of post-reperfusion syndrome, cardiac arrest during reperfusion, and 30-day mortality for non-NMP DCD liver transplant patients compared to those who received a graft with the use of NMP support in DCD donors

	Development of Post-Reperfusion Syndrome	Cardiac Arrest During Reperfusion	30-day Mortality
Non-NMP DCD liver transplant patients	51.4%	2.9%	0%
NMP-supported DCD liver transplant patients	11.4%	0%	0%

Intensive care Medicine Experimental 2025* 13(1):*000091

Introduction: The discontinuation of mechanical ventilation is a critical phase in intensive care, requiring adequate tissue oxygenation for successful weaning and extubation. Previous studies have linked parameters like venous oxygen saturation (VO_2)and hemoglobin (Hb) to weaning outcomes. This study aimed to assess whether changes in mixed venous oxygen saturation (ΔSVO_2) and hemoglobin (ΔHb) during a spontaneous breathing trial (SBT) can predict successful weaning and extubation.
Methods: A prospective cohort study was conducted at a tertiary cardiac center involving mechanically ventilated adult patients with pulmonary artery catheters deemed ready for weaning. Arterial and venous blood gases and complete blood counts were collected before and after the SBT. Patients were categorized based on SBT success or failure, and clinical outcomes—including ICU and hospital days, post-extubation airway support, and mortality—were recorded.
Results: Of the 85 enrolled patients, 73% successfully completed the SBT. Age and sex distributions were similar across groups. The failure group had longer ICU and hospital stays and more likely required non-invasive ventilation. Notably, pre-SBT SVO_2 was significantly lower in the failure group (68.56 ± 9.77) than in the success group (73.11 ± 8.12, p = 0.033), though post-SBT values and ΔSVO_2 were not significantly different. Overall, SVO_2 dropped significantly after SBT (p = 0.030).
ΔHb showed poor predictive value: AUROC 0.4719(95% CI: 0.3395–0.6044), Sn 61.29%,Sp 34.78%, LR + 0.9892, LR − 1.0202. Similarly, ΔSVO_2 had an AUROC of 0.4860(95% CI: 0.3398–0.6320), Sn 64.52%, Sp 34.78%, LR + 0.9892, LR − 1.020. These results suggest limited predictive utility for both markers. This may reflect the patient population—predominantly post-cardiac surgery cases with minimal expected weaning difficulty—and the institutional approach of performing SBTs only in hemodynamically optimized patients, limiting physiologic variability.
Subgroup analysis revealed that post-SBT lactate levels were significantly higher in the failure group (2.7[1.7–7.9],p = 0.002), with a significant increase from baseline (p = 0.018). In contrast, lactate decreased significantly in the success group (p < 0.001), supporting its potential as a predictive marker. Additionally, the pre-SBT CO_2 gap was higher in the failure group (6.5[4.8–8.1]) versus the success group (5.5[3.9–6.9],p = 0.024), with ΔCO_2 gap yielding an AUROC of 0.6052,suggesting modest predictive value.
Conclusions: We observed that neither ΔHb nor ΔSVO_2 proved reliable for predicting weaning success. The limited utility of these markers may reflect the specific characteristics of the studied population with low weaning complexity. Findings from existing literature may be more relevant to patients with anticipated weaning challenges. Alternative predictors like lactate and CO_2 gap, pose greater promise as potential tools for guiding weaning and extubation decisions.

The application of artificial intelligence technology for assessment of study of the new nurses critical care skill

Z. Yin[1]
[1]Nursing Department of Ruijin Hospital, School of Medicine, Shanghai Jiaotong University, Ruijin Hospital, Shanghai, China
Correspondence: Q. Zhang
Intensive care Medicine Experimental 2025* 13(1)*:000090

Introduction: CPR is an essential competency for training emergency and critical care nurses. Artificial intelligence (AI) technology is emerging as a vital tool.
Objectives: This study employed a mixed-methods approach—integrating quantitative assessments and qualitative interviews—to evaluate the effectiveness of AI-driven CPR study evaluations for newly trained nurses. The findings aim to provide empirical support for optimizing competency-based training systems, particularly for nurses managing critically ill patients in high-stakes clinical environments
Methods Material and method: The study adopted a mixed-methods design, comprising two components:

1. **Quantitative study**: 190 new nurses from Ruijin Hospital, affiliated with Shanghai Jiao Tong University School of Medicine, were randomly assigned to an experimental group (AI-based assessment) and a control group (manual assessment). Operational performance, mastery of theoretical knowledge, and satisfaction levels were compared between the two groups.
2. **Qualitative Study**: Focus group interviews were conducted with 95 participants in the experimental group to explore their experiences and perceived needs regarding AI-driven assessments.
3. All participants underwent standardized training covering CPR techniques (compression depth, frequency, and ventilation ratio) and AED operation protocols. The experimental group utilized an AI assessment system, which automatically scored performance via video capture, posture analysis, and deep learning algorithms.

Results:

1. Operational performance comparison The experimental group's AI-assessed scores (n = 91) averaged 82.35 ± 9.05, significantly lower than the manual scores (90.09 ± 6.85; $P < 0.05$). In contrast, the control group's manual scores (n = 95) averaged 88.08 ± 6.38, showing no significant difference compared to the experimental group's manual scores ($P > 0.05$). These results indicate that AI scoring demonstrated stricter criteria, particularly in technical metrics such as compression depth and interruption duration, whereas manual evaluations prioritized overall procedural fluency.
2. Satisfaction and theoretical knowledge

- Theoretical knowledge: both groups exhibited comparable scores (experimental group: 6.07 ± 0.73 vs. control group: 6.01 ± 0.73; $P > 0.05$). Satisfaction: the manual group reported higher satisfaction (4.73 ± 0.50 vs. 4.21 ± 0.70 in the experimental group; $P < 0.05$). Participants highlighted that AI assessments lacked interpersonal interaction, and technical issues (e.g., system latency) exacerbated anxiety during evaluations.

1. Qualitative insights analysis of interview data identified four key themes:

- Mixed perceptions: participants acknowledged AI's objective feedback, but noted that the silent testing environment heightened nervousness.
- Human–machine interaction dynamics: while the AI interface was user-friendly, real-time performance data were absent. Conversely, traditional assessments risked examiner-induced operational distractions.
- Technical limitations: four participants experienced exam suspensions due to system failures, with some questioning AI's scoring fairness.

Conclusions: AI scoring with human oversight could balance technical precision with holistic evaluation, enhancing both assessment efficiency and standardization.

Intensive care Medicine Experimental 2025* 13(1)*:000094

Introduction: The optimal mechanical ventilation strategy to minimise ventilator-induced lung injury (VILI) remains uncertain [1]. Mechanical power (MP), the energy applied to the respiratory system per unit time, has emerged as a potential unifying VILI determinant [2]. However, the question of whether and how MP should be normalised to individual patients' characteristics remains unresolved. MP normalisations for predicted body weight [3], compliance [4], and lung gas volumes measured by CT scan [5] have been studied although results have been inconsistent. MP ratio, the ratio of MP to an ideal value of MP based on individual patient characteristics, has shown promise in animal models [6] and small human acute respiratory distress syndrome cohorts [7].
Objectives: In this study, we aimed to assess the impact of normalising mechanical power to a range of physiologically relevant variables on mortality.
Methods: In this retrospective observational study, we analysed granular electronic healthcare record data from mechanically ventilated adults in a single centre over a seven-year period. Primary exposures were MP and five normalisations: for dead space (for corrected minute ventilation, ventilatory ratio, end-tidal to arterial CO2 ratio); lung size (compliance) and for idealised MP (MP ratio). We used logistic regression to assess their association with ICU mortality and calculated the area under the receiver operating characteristic curve (AUROC) to compare their predictive performance. Additionally, we evaluated the linearity or presence of a threshold for the relationships between MP and MP ratio and mortality.
Results: A total of 3,578 patients were included in the analysis. The discrimination of MP normalised to compliance (AUROC 0.71 (0.69-0.73), p = 0.007 for DeLong's test) and MP ratio (AUROC 0.71 (95% CI 0.68–0.73), p = 0.0007 for DeLong's test) were statistically better than of standard MP (AUROC 0.69 (95% CI 0.66–0.71) for predicting ICU mortality. Other mechanical power variants did not show statistically significantly different predictive power for ICU mortality compared to conventional mechanical power. The relationships between MP and MP ratio showed a significant but small departure from linearity (see Fig. 1).
Conclusions: Mechanical power normalised to compliance and to idealised mechanical power (MP ratio) had significantly greater predictive power than mechanical power per se on ICU mortality, although the absolute difference was modest.

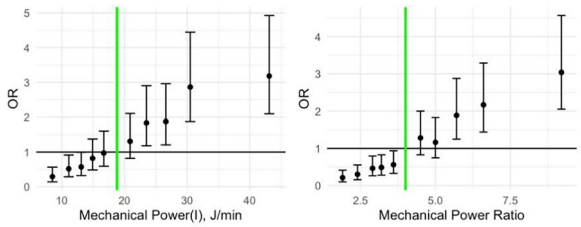

Fig. 1 (abstract 000094) Odds ratios for ICU mortality for 11 quantiles of mechanical power and mechanical power ratio referenced to the median quantile (green line)

Hypotensive exposure duration index: a novel tool for quantifying blood pressure burden and predicting mortality in critically ill patients

H. Chen[1]; XY. Ding[1]
[1]Critical Care Medicine, Provincial Hospital Affiliated to Fuzhou University, Fuzhou, China
Correspondence: H. Chen
Intensive care Medicine Experimental 2025* 13(1)*:000095

Introduction: Blood pressure management is crucial in critical care, but the relationship between blood pressure exposure patterns and outcomes remains incompletely understood. Current assessment methods often fail to capture the combined impact of both magnitude and duration of blood pressure deviations. This study aimed to develop and validate a novel index that quantifies the cumulative burden of blood pressure exposure by analyzing high-resolution blood pressure measurements in critically ill patients.
Methods: In this retrospective study using the Salzburg Intensive Care Database (SICdb), 15,530 ICU admissions with minute-by-minute continuous invasive arterial pressure monitoring were analyzed. We developed the hypotensive exposure duration index (HEDI) based on high-resolution blood pressure data, examining relationships between various blood pressure thresholds (50-120 mmHg) and exposure durations (5 min to 6 h). The association between HEDI and 28-day mortality was evaluated using Cox regression and Kaplan–Meier analysis. Additionally, we employed nine different machine learning algorithms to assess HEDI's predictive value for 28-day mortality, with the dataset randomly split into training (70%) and testing (30%) sets. Subgroup analyses were conducted for patients with sepsis and those who underwent cardiac surgery.
Results: The developed HEDI values were significantly higher in non-survivors compared to survivors (0.27 versus -0.14, p < 0.001). Our high-resolution analysis revealed that mortality risk increased non-linearly with both the intensity and duration of blood pressure deviations. After adjusting for confounders including Simplified Acute Physiology Score III, peak lactate, age, and comorbidities, HEDI independently predicted 28-day mortality (adjusted hazard ratio 1.352, 95% CI 1.297-1.410; p < 0.001). Kaplan–Meier analysis demonstrated significant differences in 28-day survival between HEDI tertile groups (log-rank test: p < 0.001), with patients in the highest HEDI tertile showing significantly lower survival probability. The machine learning model demonstrated excellent discrimination with an area under the curve of 0.908 (95% CI, 0.889-0.927) and a remarkable specificity of 99.8%. Feature importance analysis identified HEDI as one of the most crucial clinical predictors (importance score = 0.09), ranking fourth among all features examined. Similar patterns were observed in both sepsis and cardiac surgery subgroups, though cardiac surgery patients exhibited a notably steeper risk gradient.
Conclusions: The high-resolution analysis of blood pressure exposure patterns provides new insights into the relationship between hypotension and mortality in critical illness. The HEDI effectively quantifies the cumulative burden of hypotensive episodes, capturing both the intensity and duration of exposures and demonstrating a strong independent association with mortality across diverse ICU populations.

This comprehensive assessment of hypotensive burden shows promise as a tool for early risk stratification in critically ill patients, though prospective validation studies are needed to confirm its clinical utility in guiding therapeutic interventions.

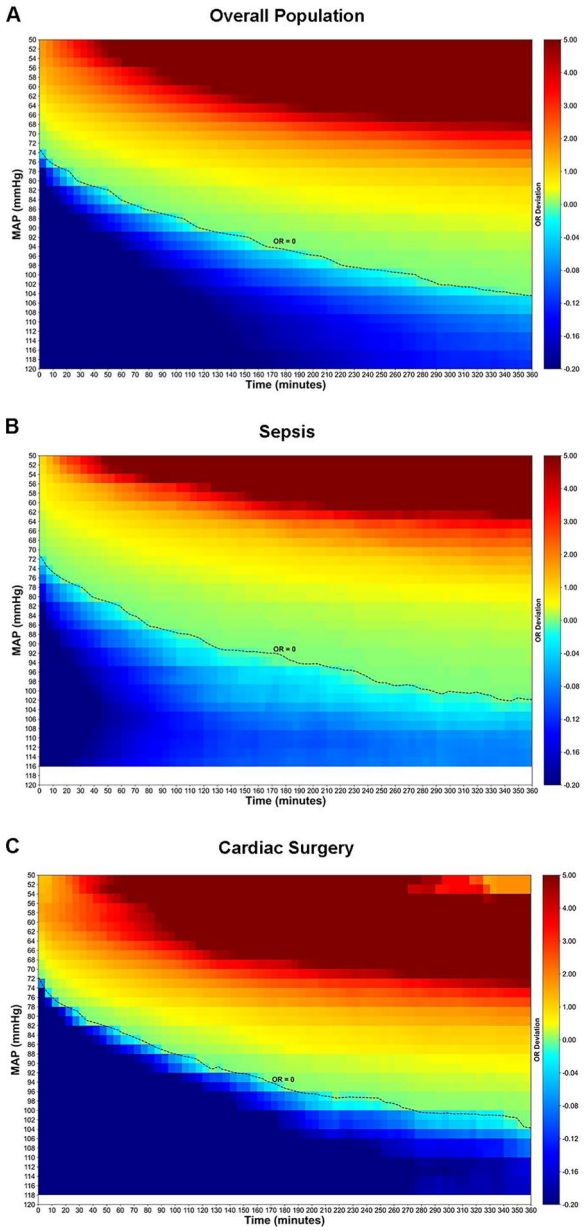

Fig. 1 (abstract 000095) Blood pressure exposure patterns and associated mortality risk across different ICU populations

Heat maps illustrating the relationship between mean arterial pressure (MAP) thresholds (50-120 mmHg, y-axis) and cumulative exposure durations (0-360 min, x-axis) for (A) overall ICU population, (B) sepsis patients, and (C) cardiac surgery patients. The color scale represents odds ratio (OR) deviation from neutral effect (OR = 1), with red indicating increased 28-day mortality risk (positive OR deviation) and blue indicating decreased risk (negative OR deviation). The black dashed line (OR = 0) demarcates the boundary between risk (above) and benefit (below) zones.

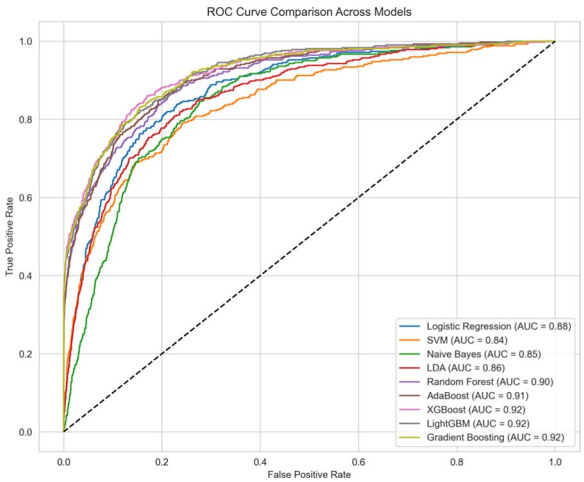

Fig. 2 (abstract 000095) Receiver operating characteristic (ROC) curves for different machine learning models in predicting 28-day mortality

ROC curves comparing nine machine learning models for predicting 28-day mortality in ICU patients. Ensemble methods demonstrated superior performance, with XGBoost, LightGBM, and Gradient Boosting achieving the highest discrimination (all AUC = 0.92), followed by AdaBoost (AUC = 0.91) and Random Forest (AUC = 0.90). Traditional statistical and machine learning approaches showed moderate performance: logistic regression (AUC = 0.88), linear discriminant analysis (AUC = 0.86), naive Bayes (AUC = 0.85), and support vector machine (AUC = 0.84). The dashed diagonal line represents random classification (AUC = 0.5).

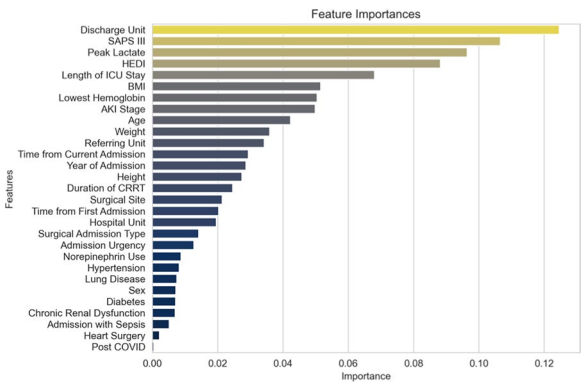

Fig. 3 (abstract 000095) Relative importance of clinical features in mortality prediction

Feature importance analysis identified HEDI as one of the most crucial clinical predictors (importance score = 0.085), ranking fourth among all features. Other significant predictors included discharge unit (0.125), SAPS III score (0.110), and peak lactate levels (0.095), while demographic and comorbidity factors demonstrated relatively lower importance. These findings highlight HEDI's substantial predictive value and potential utility in clinical decision-making.

Role of VExUS score in predicting risk of acute kidney injury in critically ill non-cardiac patients: a prospective observational study

V. Saini[1]
[1]Anaeasthesia and Intensive Care, Postgraduate Institute of Medical Education and Research, Chandigarh, India
Correspondence: V. Saini
Intensive care Medicine Experimental 2025* 13(1)*:000098

Introduction: Although there are numerous signs of venous congestion, each one has its drawbacks. This prompted the creation of the venous Doppler-based VExUS grading system. Previous studies have shown a role for VExUS in predicting AKI, but these patients had recently had heart surgery. Our study's primary goal was to investigate the possibility that serial VExUS scoring could accurately predict AKI in ICU patients without cardiopathy. One of the secondary goals was to determine if there were any relationships between VExUS and fluid balance, 30-day mortality, PaO2/FiO2 ratio, duration of mechanical ventilation, length of ICU stay, and Glasgow Outcome Score.
Objectives: To assess the association between serial VExUS score and occurrence of acute kidney injury [defined using acute kidney injury network (AKIN) criteria] in critically ill non-cardiac patients.
Methods: It was a single-centre observational study done in Main ICU (mostly medical) of PGIMER, Chandigarh. Utilising clinical history, physical examination, lab parameters and transthoracic echocardiography to examine visual ejection fraction, cardiac sickness was ruled out. 30 patients made up the final sample size that could be evaluated, which included all patients with an IVC of 2 cm or greater and a normal VEF. Serial VExUS scoring was done on admission and subsequently for next 6 days or until they developed AKI (whichever was earlier).
Results: 1) Of the 30 participants in the study, 22 (73.3%) had an AKI diagnosis. 2) On days 2, 3, and 5, patients in the AKI group showed a higher mean VExUS score than those in the non-AKI group, which was significant. 3) Logistic regression was unable to forecast the development of AKI. 4) On day 2, the VExUS score threshold was greater than 1, with a sensitivity and specificity of 86.4% and 100%, respectively, and an AUC of 0.932. Similar conclusions were found at day 3, where the AUC was 0.846 and the sensitivity and specificity were 69.2% and 100%, respectively. 5) When a patient's VExUS score increased from the mean score on day 2 to + 1 unit, their risk of developing AKI increased by 4.735 times. 6) On day 3, there was a significantly positive link between VExUS and fluid balance as opposed to a marginally favourable correlation on day 2. 7) On day two, VExUS demonstrated a slight negative correlation with the length of mechanical breathing and the ICU stay. 8) However, multivariate analysis revealed no link between any of the previously mentioned factors and the VExUS score at day two. 9) The VExUS score and 30-day mortality had no correlation.
Conclusions: In critically unwell non-cardiac patients, the VExUS score cannot predict the onset of AKI. Higher daily fluid balance may have a low to moderate correlation with VExUS score. Poorer Glasgow outcome scores, longer durations of mechanical breathing, longer stays in the intensive care unit, and higher 30-day mortality do not result from higher scores.

Efficacy and safety of a repositioning schedule intervention on the incidence of pressure injury in the intensive care unit

D. Daigné[1]; PY. Blanchard[1]; M. Fartoukh[1]; P. Sandra[2]; LB. Romane[2]; R. Alexandra[2]; NO. Arnaud[3]
[1]Médecine intensive réanimation, Assistance Publique Hôpitaux de Paris—Sorbonne Université, Hôpital Tenon, Paris, France; [2]URCEST-CRC-CRB, Assistance Publique Hôpitaux de Paris, Paris, France; [3]URC-ECO, Assistance Publique Hôpitaux de Paris, Paris, France
Correspondence: D. Daigné
Intensive care Medicine Experimental 2025* 13(1)*:000099

Introduction: The incidence of pressure injuries in the ICU ranges from 10 to 26% (1). These injuries are associated with increased morbidity and mortality (2). Many measures are used to prevent pressure injuries, among which repositioning is recommended. Guidelines recommend adapting the frequency of repositioning based on the patient's clinical condition (3).
However, available data do not establish the optimal repositioning frequency. Moreover, a Spanish study reported that repositioning was associated with increased adverse events (clinical instability or unplanned device removal). In 2018, we conducted a pilot study (4) whose results highlighted the feasibility and applicability of an individualized repositioning schedule to prevent pressure injuries. To further explore this approach, we conducted a multicenter study.
Objectives: The aim was to evaluate the efficacy of a schedule in which repositioning frequency was adapted daily according to the patient's pressure injury risk (Braden score) and clinical condition (Table 1), compared with usual care. Efficacy was assessed by the rate of pressure injuries. Secondary objectives included the evaluation of safety and overall cost.

Table 1 (abstract 000099) Repositioning schedule

Braden score (points)	6 to 8	9 to 13	14 to 17	18 to 23
Frequency of skin moisturizing and repositioning	Every 2 h	Every 4 h	Every 6 h without repositioning	Every 12 h without repositioning

Methods: Sixteen French ICUs participated in this study. All patients without pressure injuries, hospitalized in the ICU for less than 72 h, and mechanically ventilated for less than 48 h were consecutively included. This study was a randomized controlled cluster trial with two parallel groups: an intervention group (repositioning schedule individualized according to the patients' risk of pressure injury, assessed by the Braden score) and a control group (usual care). Patients were followed until ICU discharge or death, within a 28-day limit. ICU and hospital length of stay were recorded from each hospital's medical information systems program. This study was approved by the ethics committee and the protocol was registered on ClinicalTrials.gov NCT04550182.
Results: From April 2021 to June 2024, 1232 participants were included, 436 in the intervention group and 796 in the control group. Currently, the database is locked and analyses are about to begin. Results will include the rate of pressure injuries, the rate of adverse events related to the procedure, the time spent treating pressure injuries, nurses' clinical barriers to patient repositioning, risk factors for pressure injuries and the overall cost of the procedure.
Conclusions: The results of this study are expected to provide additional insights into pressure injury prevention in the ICU, clarifying the practice of patient repositioning in terms of frequency, efficacy, safety,

clinical barriers, and cost-effectiveness. In addition, barriers to repositioning in the ICU will be described, considering patients' characteristics, invasive therapies, and workload associated with pressure injuries care.

Intensive care Medicine Experimental 2025* 13(1)*:000102

Introduction: Systematic and structured methods must be used to ensure that healthcare risks are effectively managed. Spanish standard UNE 179003:2013 provides healthcare organizations with a framework and a systematic protocol for managing patient safety from a clinical and organizational perspective.
Objectives: Retrospectively analyze, over the last 6 months, the main adverse events reported in the ICU of HCUV in order to identify risk factors for the creation of plan risk management prior to the implementation of the UNE 179003 risk management standard.
Methods: Retrospective analysis and classification of the main adverse events reported in the multipurpose ICU of HCUV, which unit is certified by the ISO 9001 standard and currently working to be accredited by the UNE 179003 risk management standard.
Results: From June to November 2023, the main adverse events reported in the ICU were collected and analyzed: 24 adverse events and one sentinel event that was analyzed through RCA reported to the center's management. Of the 24 adverse events reported in the last 6 months, 70.66% were related to accidental device removal: nasogastric tube (SNG): 8.3% loss of central lines: 16.66% self-extubations: 29.16% chest tube: 12.5% intracranial pressure drainage: 4.16%. The other 29.08% were related to medication errors: 4.16% non-administration of chemotherapy 8.3% dosing error (related to verbal orders) 8.3%. Failure to suspend enteral nutrition for invasive procedures (tracheostomies, colonoscopies, etc.) 4.16% non-administration of prescribed treatment in acute heart failure 4.16% maintaining closed PIC drainage with increased pressure. We also studied the shift, experience, and occupancy of the unit at the time of the adverse event: 20.83% of AEs occur in the morning shift, 41.66% of AEs occur in the afternoon shift 37.5% of AEs occur in the night shift. In 75% of cases, unit occupancy exceeds 80%, and in the remaining 25%, although it is close. Personnel experience: 70.83% occur with new staff and 29.17% with experienced staff.
Conclusions: We must improve the safety culture to report any AE and improve and increase patient safety.
• Intensive care services are critical areas where most AEs occur and, as studies show, mostly related to medication, as in our unit.
• AEs increase with maximum occupancy and inexperienced staff.
• These notifications have allowed us to identify the main risks of the unit, detecting areas for improvement, and develop contingency plans, barrier measures… to prevent them from happening again.

Therapeutic impact of performing transesophageal echocardiography in critically ill patients: prospective study

J. Cárdenas Giraldo[1]; FÁ. Jaime[1]
[1]Intensive Medicine Service, University General Hospital Dr. Balmis, Alicante, Spain
Correspondence: J. Cárdenas Giraldo
Intensive care Medicine Experimental 2025* 13(1)*:000103

Introduction: Echocardiography has become a fundamental tool in the evaluation and management of critically ill patients. Its use, both as a diagnostic tool and for hemodynamic monitoring, has increased significantly in the last 10 years (1).
However, critically ill patients often present characteristics that limit the obtaining of quality images with transthoracic echocardiography (TTE) and this is where transesophageal echocardiography (TEE) plays a very important role. The conditions in which TEE is superior to TTE are well known, such as: a) hemodynamically unstable patients with suboptimal images in TTE; b) hemodynamically unstable patients on mechanical ventilation; c) postoperative or polytraumatized patients; d) suspected aortic dissection or aortic trauma; e) suspected endocarditis; f) assessment of mechanical prostheses, and e) assessment of embolic source. TEE has other advantages such as its ease of use at the patient's bedside and its low rate of complications (2.6%) (2), as well as representing a safe procedure when performed by intensive care physicians (3).
Although multiple studies have been carried out that demonstrate a diagnostic impact of the use of TEE in critical patients, located between 43-99% (4,5) and therapeutic between 10 and 78% (6,7), the latter resulting in changes in medical treatment and/or surgical interventions in patients, very few of these studies are prospective in design (8,9,10).
The objective of this study is to corroborate and revalidate the effect on therapy of the use of TEE in critical patients through a prospective study carried out in a multipurpose adult ICU in a third level hospital.
Objectives: To evaluate the therapeutic impact of performing transesophageal echocardiography (TEE) in critically ill patients.
Methods: Twenty critically ill patients who underwent TEE were prospectively recruited. The following data were recorded: the indication for TEE, the main findings, the therapeutic impact after the procedure, the latter defined as changes in the patient's acute management that occurred as a result of the procedure, and whether or not there were complications related to the technique. The primary objective was to determine the therapeutic impact after the TEE.
Results: 20 TEE studies were performed. The most frequent indications were to rule out infective endocarditis (35%), followed by poor transthoracic window and hemodynamic assessment (30%), and thirdly to rule out intracavitary thrombi (20%) (Table 1).
Performing TEE had a therapeutic impact in 80% of patients, with the most frequent therapeutic effect being that of shortening the duration

of antibiotic treatment by ruling out endocarditis (25%), followed by adjustment of fluids and inotropes (20%) and electrical cardioversion (15%) (Table 2).
No complications were recorded.
Conclusions: TEE has a high therapeutic impact on critically ill patients and represents a safe procedure when performed by intensive care physicians.

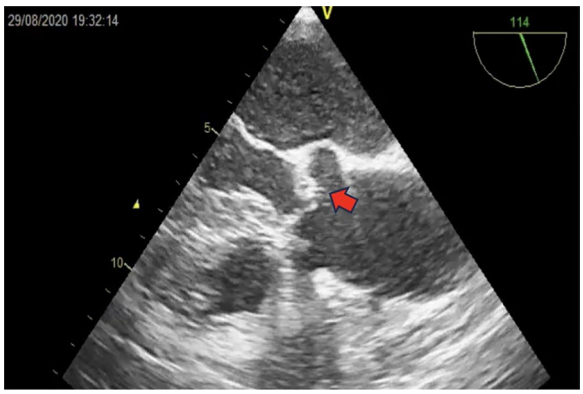

Image 1 (abstract 000103) TEE mid-esophageal plane of the aortic root at 114º. Thickening of the non-coronary leaflet (arrow) suggestive of aortic endocarditis in a patient with pneumonia and meningitis due to *Streptococcus pneumoniae*, a condition compatible with Austrian syndrome

Table 1 (abstract 000103) Indication for TEE

INDICATION FOR TEE	n	%
Rule out infective endocarditis	7	35,0
Poor transthoracic window and hemodynamic assessment	6	30,0
Rule out intracavitary thrombus	4	20,0
Rule out valvular disease	1	5,0
Prosthetic valve assessment	1	5,0
Postoperative follow-up for cardiac surgery and VA ECMO	1	5,0
Total	20	100,0

Table 2 (abstract 000103) Type of therapeutic impact

TYPE OF THERAPEUTIC IMPACT	n	%
Shortening the duration or changing antibiotic treatment	5	25,0
Modification of fluid therapy and/or inotropic agents	4	20,0
None	4	20,0
Electrical cardioversion and reduction of anticoagulation time	3	15,0
Adjustments and decisions related to VA ECMO therapy	2	10,0
Initiation of anticoagulation	1	5,0
Choice of surgical technique	1	5,0
Total	20	100,0

Intensive care Medicine Experimental 2025* 13(1)*:000105

Introduction: Sepsis is a life-threatening condition resulting from a dysregulated host response to infection, leading to severe organ dysfunction and complications. Early implementation of the sepsis bundle has been significantly associated with improved survival rates. The Surviving Sepsis Campaign (SSC) Guidelines recommend that the sepsis bundle be completed within 1 h of detecting sepsis. To enhance compliance with sepsis bundles, Sepsis Performance Improvement Programs have been developed and implemented worldwide. In patients with hospital-onset sepsis, the mortality rate is notably high; however, clinical awareness remains low, and data on compliance with sepsis care bundles are limited. Therefore, systematic interventions are needed to enhance the recognition of hospital-onset sepsis and to improve compliance with the 1-h sepsis bundle.
Objectives: The objective of this study is to evaluate compliance with the 1-h sepsis bundle before and after the implementation of a National Early Warning Score (NEWS)-based management protocol for suspected sepsis in adult patients in general wards.

Methods: In July 2022, our institution developed and implemented a sepsis protocol based on the NEWS within the electronic medical record (EMR) system for adult patients in general wards. The protocol is designed to trigger an automated alert in the system when a patient's NEWS first reaches 7 or higher during hospitalization, allowing nurses to recognize the potential for sepsis and report it to the attending physician. If an infection is suspected, the protocol proceeds with the physician prescribing the individual components of the 1-h sepsis bundle. This is a retrospective observational study designed to compare the outcomes before and after the implementation of a NEWS-based management protocol for suspected sepsis. The pre-intervention period was defined as January to June 2022, and the post-intervention period as January to June 2023, excluding the protocol implementation and awareness period, as the sepsis protocol was introduced in July 2022. To ensure comparability between the pre- and post-intervention groups, data were extracted for patients who had a blood culture order placed within 24 h before or 1 h after the time point at which the first NEWS of 7 or higher was recorded during hospitalization. All data were retrospectively collected based on electronic medical records, and the study was conducted after receiving approval from the Institutional Review Board (IRB).
Results: A total of 197 patients were included in the pre-intervention group and 200 in the post-intervention group. The median age was 68 years (interquartile range [IQR] 60–75), and 270 patients (68%) were male. Solid tumors were the most prevalent comorbidity, present in 212 patients (53.4%). The baseline Sequential Organ Failure Assessment (SOFA) score was 2 (IQR 0–3), and the SOFA score at the time of protocol activation was 6 (IQR 4–8). Among the patients, 87 (21.9%) had septic shock. In terms of infection sources, intra-abdominal infections were the most common, accounting for 206 cases (51.9%). There were no significant differences in general or clinical characteristics between the pre- and post-intervention groups. Following the implementation of the sepsis protocol, compliance with the 1-h sepsis bundle significantly increased (20.8% in the pre-intervention group vs. 47.0% in the post-intervention group, $p < 0.001$). Although the 28-day mortality rate decreased after protocol implementation (22.8% vs. 16.5%), the difference was not significant ($p = 0.112$). A total of 91 patients (22.9%) were admitted to the intensive care unit, and 306 patients (77.1%) were discharged alive.
Conclusions: Following the implementation of a NEWS-based management protocol for suspected sepsis in adult patients in general wards, compliance with the 1-h sepsis bundle significantly increased. Although the 28-day mortality rate decreased after protocol implementation, the difference was not significant, highlighting the need for future studies with an extended follow-up period

Intensive care Medicine Experimental 2025* 13(1):*000107

Introduction: Gram-negative sepsis caused by metallo-beta-lactamase (MBL)-producing organisms is a serious global health concern and optimal treatment remains uncertain. This study compares the effectiveness of meropenem–polymyxin combination therapy with ceftazidime–avibactam plus aztreonam therapy in treating MBL sepsis in an intensive care unit and the use of biomarkers such as procalcitonin, pro-adrenomedullin, neutrophil-to-lymphocyte ratio, lactate, and C-reactive protein for prognostication.

Methods: The study was conducted at the AICU of AIIMS Jodhpur to evaluate the treatment outcomes in patients with Gram-negative sepsis caused by metallo-beta-lactamase (MBL) producers. It was a prospective, open-label, randomized comparative trial lasting 12 months. Patients over 18 years old with culture-proven MBL Gram-negative sepsis were enrolled after obtaining informed consent. A total of 128 patients with Gram-negative sepsis caused by MBL-producing bacteria were screened for eligibility. Among them 48 patients were excluded and 80 patients were recruited for the study. They were randomized into two groups: Group A received ceftazidime–avibactam plus aztreonam, while Group B received meropenem polymyxin combination therapy. Prognostic biomarkers, including proadrenomedullin (ProADM), procalcitonin (PCT) and C-reactive protein (CRP) were evaluated. The clinical data, such as demographics, comorbidities, and sepsis severity scores (SOFA, APACHE II) were collected. Primary outcomes included cure rates based on negative cultures and patient survival. The secondary outcomes included, 28-day all-cause mortality and the incidence of organ failure in terms of acute kidney injury were noted.

Results: The statistical evaluation showed both the groups were comparable in terms of age, SOFA scoring and the APACHE II score at the time of enrolment ($p > 0.05$). The treatment of sepsis caused by MBL producing Gram negative organisms with ceftazidime–avibactam plus aztreonam (Group A) was more effective than meropenem–polymyxin (Group B), with a higher cure rate (73.81% vs. 47.37%) and lower 28-day mortality (11 out of 42 patients as compared to 17 out of 38 in Meropenem Polymyxin group, Fig. 1). The incidence of AKI was also less in the ceftazidime avibactam group. While biomarkers such as ProADM, PCT and CRP showed no statistical difference between the treatment groups, they were significantly ($p < 0.05$) higher among non-survivors as compared to survivors, highlighting the prognostic value of these biomarkers (Table 1, Fig. 2). ProADM demonstrated strong predictive power for patient outcomes (specificity 100%, Figs. 3 and 4). The diagnostic performance analysis revealed that ProADM had the highest AUC (1) in both the groups.

Conclusions: The study found that ceftazidime–avibactam plus aztreonam was more effective than meropenem–polymyxin for treating MBL-producing Gram-negative sepsis. Additionally, ProADM demonstrated strong prognostic value in terms of mortality, though further large-scale trials are required to establish the new cutoff values of ProADM specific to the Indian population.

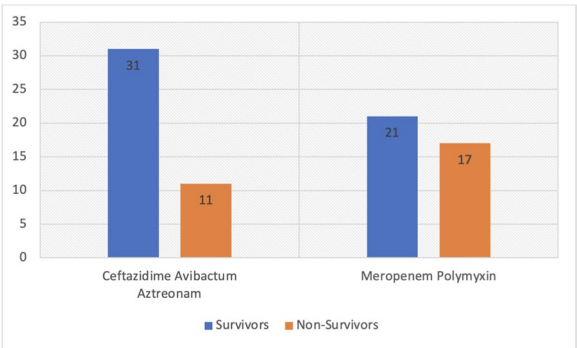

Fig. 1 (Abstract 000107) Bar chart showing increased cure rates and survival in Ceftazidime Avibactam group as compared to Meropenem Polymyxin group

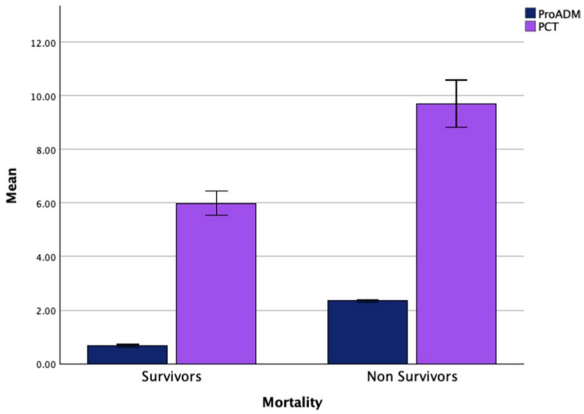

Fig. 2 (Abstract 000107) The bar chart showing higher levels of ProADM and PCT in non-survivors as compared to survivors

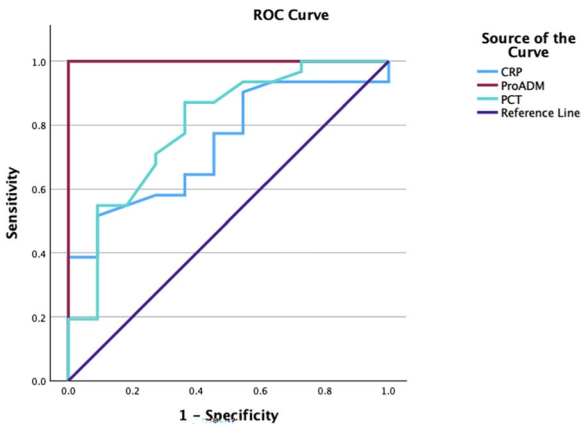

Fig. 3 (Abstract 000107) ROC curve for Ceftazidime Avibactam group. The AUC for ProADM is 1 in both the groups. Thus, it is a better predictor of mortality in terms of sensitivity and specificity as compared to PCT and CRP

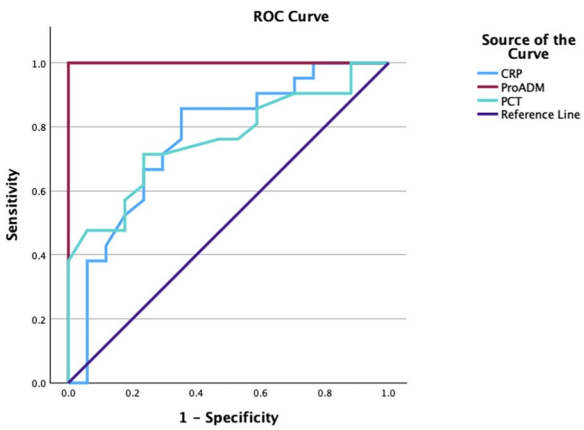

Fig. 4 (Abstract 000107) ROC curve for Meropenem Polymyxin group. The AUC for ProADM is 1 in both the groups. Thus, it is a better predictor of mortality in terms of sensitivity and specificity as compared to PCT and CRP

Table 1 (Abstract 000107) The mean value of ProADM in nMol/L and the mean value of PCT in ng/ml and CRP values in mg/L. The mean values of all the biomarkers were higher among non-survivors as compared to survivors (p < 0.05)

Group		Mortality	N	Mean	Std. Deviation	Std. Error Mean	One Sided p

Introduction: In high-consequence environments, e.g., medical and military environments, detection and identification of auditory alerts is critical. Conventional alerts are often difficult to detect and identify in noisy conditions, where individuals must process auditory information while multitasking. Previously, we reported using alert pairs, one having consonant harmony ("friendly"), the other dissonant harmony ("enemy"). Those alerts yielded robust detection and discrimination despite occupying a common spectral locus, suggesting advantages over simpler alerts in intuitiveness and resistance to masking.

Objectives: This study aimed to assess the detectability and discriminability of novel auditory alert pairs in single- and dual-task conditions.

Methods: Subjects (n = 20) performed auditory detection/discrimination in isolation or with a simultaneous visual working memory task (N-back task). The N-back task was also run in isolation. Alerts were embedded in continuous broadband "military truck noise" (70 dB SPL in the absence of alerts). Taking careful account of the spectral profile of the masker, both alerts occupied a narrow region around 500-Hz. Trials were blocked by signal-to-noise ratio (SNR) and the presence or absence of the N-back task with values of SNR visited via descending and ascending series. Stimuli were presented via headphones.

A free-response vigilance paradigm was employed. The underlying temporal "trials" were unknown to participants. This afforded measures of "hit" and "false-alarm rates" and the computation of bias-free sensitivity (d'). This is in contrast to the biased measures of percent correct typically employed.

Results: As expected, d' increased with SNR. Near-equal detectability between the alerts was achieved. N-back performance decreased that task was performed concurrently with the auditory task. In contrast, there was essentially no effect on performance in the auditory task when it was coupled with the N-back task. Computation of ß, indicated that, overall, subjects adopted conservative response criteria. Thus, when performance was expressed as p(c), the values obtained were less than the maximum (p(c)max) achievable for the relevant value of d'. This underscores the necessity of evaluating performance using objective metrics based on signal detection theory (SDT).

Conclusions: The results represent "proof of concept" for our approach to evaluating detection and discrimination of auditory alerts within a vigilance paradigm. The findings reveal advantages of a SDT-based free-response paradigm over traditional Methods: In addition, they highlight the potential advantages of alerts tailored to the spectral profile of the acoustic environment. This directly impacts professionals in high-consequence settings, such as clinicians, who rely on auditory information when visual attention is occupied with patient care.

Quantifying the impact: each additional 100 ml to daily fluid balance increases acute kidney injury risk in critically ill patients

CC. Theocharidou[1]; E. Orfanidis[1]; E. Kamariotou[2]; A. Chatzigeorgiou[1]; M. Papaioannou[1]; A. Tsangaleas[1]; I. Mouskeftara[1]; M. Tzimou[1]; A. Lavrentieva[1]

Intensive care Medicine Experimental 2025* 13(1):*000109

Introduction: Acute kidney injury (AKI) significantly impacts outcomes in critically ill patients. Fluid management plays a crucial role in both prevention and management of AKI, yet optimal strategies remain controversial.

Objectives: To evaluate the relationship between fluid balance and AKI occurrence in critically ill patients and identify predictors of AKI development.

Methods: In this observational study (July–November 2024), we collected data from ICU patients regarding demographics, case type, APACHE score, AKI occurrence, renal replacement therapy (RRT) requirements, septic shock and mortality. Daily fluid balance was calculated as the net difference between inputs and outputs, standardized as mL/day by dividing by ICU length of stay. Statistical analysis included Mann–Whitney U test, Kruskal–Wallis test, Spearman correlation, and binary logistic regression for AKI predictors.
Results: We included 191 patients. Demographic and clinical characteristics are presented in Table 1 and Table 2. There were 59(30.9%) elective surgical cases and 55(28.8%) emergency surgical cases. Standardized daily fluid balance showed positive correlation with age ($r = 0.21$, $p = 0.004$) and APACHE score ($r = 0.33$, $p < 0.0001$). Emergency surgical cases received more fluids than medical or elective surgical cases ($p = 0.003$). Results are shown in Table 3. Logistic regression identified three predictors of AKI: each one-point increase in APACHE score increased AKI odds by 15.7% ($p < 0.001$); patients without septic shock have 90.4% lower odds of developing AKI ($p < 0.001$); and each 100 mL/day increase in standardized daily fluid balance raised AKI odds by 5.1% ($p = 0.004$).

Table 1 Descriptives characteristics of continuous variables

	Median	IQR [Q1-Q3]	N
ICU days	3	[1–9]	191
Age (years)	64	[53–78]	191
APACHE score	14	[9–22]	191
Total fluid administered (ml)	200	[-1400—2250]	191
Fluids per day (ml/day)	150	[-300—866.67]	191

Table 2 Categorical variables: patient demographics and clinical outcomes

	n	%		n	%	N
Female	86	45%	Male	105	55%	191
AKI	52	27.20%	No AKI	139	72.80%	191
RRT needed	22	42.30%	No RRT needed	30	57.70%	52
Septic shock	67	35.10%	Without septic shock	124	64.90%	191
Alive	124	64.90%	Dead in ICU	67	35.10%	191

Table 3 Differences in standardized daily fluid balance (ml/day)

	Median	IQR	n	Median	IQR	n
Sex	Female			Male		
p = 0.03	237.5	[-181—950]	86	12.5	[-422—700]	105
Septic shock	No			Yes		
p = 0.07	150	[-400—676]	124	237.5	[-139—1062]	67
AKI	No			Yes		
p < 0.0001	-30	[-422—500]	139	673	[-64—1657]	52
RRT	No			Yes		
p < 0.0001	125	[-229—923]	30	1194	[605–4350]	22
Death	No			Yes		
p < 0.0001	-50	[-481—500]	124	580	[12–1194]	67

Conclusions: This study demonstrates that fluid balance is significantly associated with AKI risk in critically ill patients, independent of illness severity and septic shock status. Each additional 100 mL of daily fluid increases AKI risk by 5.1%, emphasizing that "every mL counts" in the fluid management of critically ill patients.

Intensive care Medicine Experimental 2025* 13(1):*000111

Introduction: The surgical stress causes various degrees of immunosuppression and inflammation in the perioperative period, increasing the chances of tumour recurrences and metastasis. Angiogenesis and perioperative inflammation also drive tumour initiation, growth, progression, and metastasis.
Hypothesis: Perioperative Intravenous anaesthesia with combination of lignocaine infusion and propofol (TIVA), will cause less immunosuppression and angiogenesis when compared with inhalational agents in post-operative period in ovarian cancer patients.
Objectives: This study aims to assess the impact of different modes of anaesthesia on perioperative immunosuppression and angiogenesis in patients undergoing ovarian cancer surgery. Due to scarcity of evidence concerning these perioperative phenomena and anesthesia modes, this study was planned. Primary outcome was to compare difference in change of post-operative and preoperative VEGF and T cells (Day 2 -preoperative) in both the groups. Secondary outcomes was to compare changes in level of T cells activity (T helper cell CD4 + and cytotoxic T cells CD 8 +) and VEGF in both groups at Day 2. Glasgow prognostic index (GPI) and systemic immune inflammation index (SII), duration of hospital stay and day of return to intended oncological therapy (RIOT) in both the groups were also compared.
Methods: The study was conducted after approval from ethics committee (AIIMS/IEC/2023/5876) and registration at clinical trial registry-India (CTRI/2024/03/063519) between March 2024 and December 2024. Total 38 patients of American Society of Anaesthesiologists (ASA) physical status grade I to III, aged 25 to 65 years, with ovarian cancer, randomized into two groups. Preoperative biomarkers VEGF, CD4 + and CD8 + cell count were recorded. Patients in group A received TIVA with propofol infusion (Bi spectral index value 40-60) and lignocaine infusion (1.5 mg/kg bolus followed by 2 mg/kg/h infusion), and group B received inhalational agents (minimum alveolar concentration of 1.0) for maintenance. Rest all anaesthesia technique was similar as per the standard protocol. Biomarkers were again recorded on postoperative day 2. SII, GPI, day of discharge and day of RIOT were also noted. Quantitative variables are presented as median (IQR) or mean (SD). Chi-square test was applied for qualitative data. Unpaired Student's t test was applied for comparing quantitative data. The results were significant if P value was < 0.05.

Results: CD4 + (0.335 ± 0.128 vs 0.493 ± 0.451), CD8 + (1161.84 ± 2218.63vs 933.104 ± 1635.320) and VEGF (40.61 ± 62.48 vs 63.88 ± 117.50) were comparable on post-operative day 2 in TIVA and inhalational agents group. Day of discharge in TIVA group was 5 (2) and 5 (2) in inhalational agents group. TIVA group had similar RIOT, 24 (12) days in comparison to 27(11) in inhalational agents group. GPI and SII were also comparable.
Conclusions: The study shows that TIVA and inhalational agents produce similar effects on perioperative immune markers (VEGF, CD4, CD8) in ovarian cancer patients. No significant difference was observed in systemic inflammation, day of discharge or RIOT.
Relevance to patient care: This study suggests that anaesthetic technique does not influence immunosuppression or angiogenesis. Anaesthesia technique can be chosen based on patient profile, comorbidities, and surgical requirements, as both groups demonstrated a comparable profile

The role of magnesium replacement in critically ill patients undergoing continuous renal replacement therapy (CRRT) with Regional citrate anticoagulation (RCA)

A. Kunjumon[1]; MU. Farooq[2]; A. Mahmood[1]
[1]Intensive care, William Harvey Hospital, Willesborough, United Kingdom; [2]Intensive care, William Harvey Hospital, Willesborough, United Kingdom
Correspondence: M.U. Farooq
Intensive care Medicine Experimental 2025* 13(1)*:000112

Introduction: Regional citrate anticoagulation (RCA) in continuous renal replacement therapy (CRRT) works through the chelation of calcium, a critical element in thrombin generation, thereby effectively preventing clot formation within the CRRT circuit. However, the citrate complex does not selectively target calcium, and can also chelate other divalent cations, including magnesium. Current CRRT fluids and standard electrolyte replacement protocols following RCA typically focus on calcium, neglecting the potential for significant magnesium loss. This has the potential for profound hypomagnesemia and associated adverse events in critically ill patients, leading to higher morbidity and mortality.
Objectives: The aim of our study was to appraise clinical practice in routine electrolyte replacement after continuous renal replacement therapy with regional citrate anticoagulation to help prevent adverse effects in already high risk patients. The primary objective of our study was to study the frequency, magnitude and adverse effects of hypomagnesemia in patients undergoing continuous renal replacement therapy with regional citrate anticoagulation, and the degree and extent of magnesium replacement. The secondary objectives were to ascertain the correlation of the reduction in magnesium to various parameters pertaining to the patient as well as continuous renal replacement therapy dosing.
Methods: This was a retrospective analysis of adult patients undergoing continuous renal replacement with regional citrate anticoagulation in the Critical Care Department at a District General Hospital from July to December 2023, with the following exclusions—patients on heparin/prostacyclin and patients without a pre and post filter magnesium levels.
Data collected included demographic profile, such as age, sex, comorbid medical conditions such as chronic cardiovascular and chronic kidney disease. The dose and duration of renal replacement therapy was also noted. Magnesium levels were recorded twice—prefilter (before initiation of renal replacement therapy) and post filter (termination of renal replacement therapy or at 72 h of filtration). Normal magnesium levels was defined as a value of 0.8–1.0 mmol/L; and patients were classified as having hypomagnesemia if the serum magnesium was less than 0.8 mmol/ L. The frequency and quantity of magnesium replaced in mmol was collected for the duration of the continuous renal replacement therapy.
Results: Data from 50 patients were analysed which demonstrated a significant drop in the post-filter magnesium levels. The mean pre-filter magnesium level was 1.12 (SD ± 0.26) and post-filter magnesium levels was 0.86 (SD ± 0.19). There was hence a mean reduction of 0.26 mmol which corresponded to a drop of 22% on the percentage scale. This was statistically significant with a P-value of < 0.001 demonstrating significant hypomagnesemia in patients who undergo continuous renal replacement therapy with regional citrate anticoagulation.
The average magnesium replacement was 44 mmol (52 ± 31). Adverse events such as arrhythmia was noted in 12 patients (24%) of patients. There was no statistical correlation with the reduction in magnesium to age, sex, pre-existing kidney disease, continuous renal replacement therapy dose or duration.
Conclusions: In conclusion, hypomagnesemia has a significant correlation with the use of continuous renal replacement therapy with regional citrate anticoagulation. This can predispose to the development of arrhythmias in critically ill patients, and hence judicious magnesium monitoring and replacement must be undertaken in such patients.
Further studies with larger sample size could be undertaken to look for correlation between hypomagnesemia at different effluent doses and duration of continuous renal replacement therapy. Future studies could also focus on measuring the magnesium levels in the effluent.

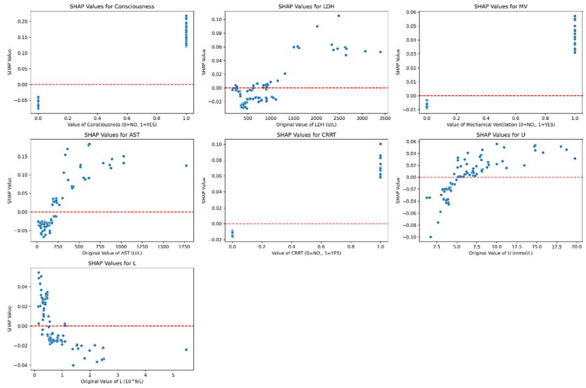
Intensive care Medicine Experimental 2025* 13(1)*:000114



Introduction: Severe fever with thrombocytopenia syndrome (SFTS) is a disease caused by infection with the severe fever with thrombocytopenia syndrome virus (SFTSV), a novel Bunyavirus. Accurate prognostic assessment is crucial for developing individualized prevention and treatment strategies. However, machine learning prognostic models for SFTS are rare and need further improvement and clinical validation.
Objectives: This study aims to develop and validate an interpretable prognostic model based on machine learning (ML) methods to enhance the understanding of SFTS progression.
Methods: This multicenter retrospective study analyzed patient data from two provinces in China. The derivation cohort included 292 patients treated at The Second Hospital of Nanjing from January 2022 to December 2023, with a 7:3 split for model training and internal validation. The external validation cohort consisted of 104 patients from The First Affiliated Hospital of Wannan Medical College during the same period. 24 commonly available clinical features were selected, and the Boruta algorithm identified 12 candidate predictors, ranked by Z-scores, which were progressively incorporated into 10 machine learning models to develop prognostic models. Model performance was assessed using the area under the receiver-operating-characteristic curve (AUC), accuracy, recall, and F1 score. The clinical utility of the best-performing model was evaluated through decision curve analysis (DCA) based on net benefit. Robustness was tested with tenfold cross-validation, and feature importance was explained using SHapley Additive exPlanation (SHAP) both globally and locally.
Results: Among the 10 machine learning models, the XGBoost model demonstrated the best overall discriminatory ability. Considering both AUC index and feature simplicity, a final interpretable XGBoost model with 7 key features was constructed. The model showed high predictive accuracy for patient outcomes in both internal (AUC = 0.911, 95% CI: 0.842-0.967) and external validations (AUC = 0.891, 95% CI: 0.786-0.977). A clinical tool based on this model has been developed and implemented using the Streamlit framework.
Conclusions: The interpretable XGBoost-based prognostic model for SFTS shows high predictive accuracy and has been translated into a clinical tool. The model's 7 key features serve as valuable indicators for early prognosis of SFTS, warranting close attention from healthcare professionals in clinical practice.

Flowchart of the study design.

Intensive care Medicine Experimental 2025* 13(1):*000116

Introduction: Hypernatremia (blood sodium concentration > 145 mmol/L) is a frequent complication in adult ICU patients, associated with increased mortality (1). Most authors recommend limiting the rate of hypernatremia correction to 10-12 mmol/L/day to avoid neurological complications (2). Correction rates > 12 mmol/L/day have been linked to cerebral edema and seizures (3,4). Recently, retrospective studies have challenged this paradigm in adult patients. Feigin et al., in a predominantly non-ICU cohort, found that faster correction was associated with lower all-cause mortality (5). In contrast, Olsen et al., focusing on ICU patients with hospital-acquired hypernatremia, reported higher maximum correction rates correlated with increased mortality (6). Methodical differences between these studies, in addition to residual confounding, may explain discrepancies, warranting further exploration.
Objectives: To investigate the association between hypernatremia correction rate and in-hospital mortality in a large, international dataset of critically ill patients after comprehensive confounder control.
Methods: Adult ICU patients from Charité Universitätsmedizin Berlin (2015-2024) and seven publicly available ICU datasets with a serum sodium measurement > 155 mmol/L were eligible for inclusion. The study was approved by the Charité Ethics Committee (EA2/139/20). A fast correction was defined as mean change > 0.5 mmol/L/h during the first 24 h of severe hypernatremia, with slow correction defined as ≤ 0.5 mmol/L/h. The association of fast vs. slow correction rates and in-hospital mortality was analyzed using a multilevel logistic regression model (random center effects), adjusted for age, sex, Elixhauser index, SOFA score, sodium value at inclusion, RRT, and hypernatremia duration prior to inclusion. Additionally, the relationship between mortality and the maximum correction rate—the highest rate of change between two consecutive measurements during the first 24 h—was assessed.
Results: 9,799 eligible patients (7,992 with complete confounder data) were identified, with 48.4% originating from the Charité dataset. In most cases (60.5%), hypernatremia was acquired in hospital. Fast correction was observed in 12.5% of patients. In unadjusted and adjusted analysis, there was no significant association between a fast correction rate (> 0.5 mmol/L/h) and in-hospital mortality (p = 0.472 and p = 0.924, respectively). In crude analysis, a higher maximum correction rate was associated with an increased risk of in-hospital mortality (OR 1.10 per 1 mmol/L/h, 95%CI 1.03-1.18, p = 0.006), but this association was mitigated after adjustment (aOR 0.98, 95%CI 0.89-1.07, p = 0.63).
Conclusions: This large multinational retrospective study found no significant association between high vs. low hypernatremia correction rates and in-hospital mortality. Our findings emphasize the importance of adequate sample sizes and confounder control. Based on our findings, optimal thresholds of hypernatremia correction rates should be assessed prospectively.

Inspiratory effort during pressure support ventilation: objective vs. subjective assessment

M. Stolinska[1]; S. Eymann[1]; ME. Kajdi[1]; E. Bulleri[2]; A. Pagnamenta[2]; G. Iotti[3]; U. Alig[1]; F. Porta[1]

Intensive care Medicine Experimental 2025* 13(1):*000118

Introduction: The concern about self-induced injuries to lungs or diaphragm during assisted ventilation involves a growing interest in assessing the patient's inspiratory effort. The negative deflection of airway pressure during end-expiratory occlusion (Pocc) has been

proposed as reliable noninvasive method for assessing the pressure generated by the inspiratory muscles (Pmus,occ = Pocc*0.75) with the ongoing ventilation setting [1]. Occlusion pressure at 0.1 s (P0.1) and pressure muscle index (PMI) are alternative, objective indicators of the inspiratory effort [2,3].

Objectives: In a bicentric (Chur-Lugano, CH) prospective observational study on intubated patients during pressure support ventilation (PSV), the primary outcome was the evaluation of the quality of subjective clinical assessment of patient's effort against the objective reference provided by Pmus,occ. The secondary outcome was the evaluation of the information provided by P0.1 and PMI, against Pmus,occ as reference.

Methods: When clinically indicated, clinicians expressed their subjective evaluation of effort (as low—Group 1, acceptable—Group 2, or high—Group 3) based on physical examination and general overview of data from the ventilator. Then, end-inspiratory and end-expiratory occlusion maneuvers were performed for measurement of Pocc, P0.1 and PMI. The objective evaluation considered low effort for Pmus,occ < 5, acceptable for Pmus,occ of 5-10 and high for Pmus,occ > 10 cmH2O. Differences among groups were evaluated by Kruskal–Wallis test and group matching was tested by Spearman correlation. P0.1 and PMI were compared with Pmus,occ as reference, by Pearson correlation. Demographic data, primary diagnosis and SAPS score were recordered. Results are expressed as % or median (interquartile range).

Results: We performed 364 measurements in 104 patients. SAPS score was 47 (18-87). Main reasons for ICU admission were pneumonia (41%) and sepsis (36%). Pmus,occ was 5.8 (3.7-8.5) in Group 1 (n = 89), 8.0 (5.1-12.3) in Group 2 (n = 180) and 9.6 (6.7-13.4) cmH2O in Group 3 (n = 95). The three groups significantly differed from each other ($p < 0.001$), but the agreement between subjective and objective evaluation of effort was poor (rho 0.29 [CI, 0.2-0.38], Fig. 1). Median Pmus,occ was 7.7 (5.1-11.7), PMI was 1 (0-3) and P0.1 was 1.6 (0.8-2.9). The correlation between P0.1 and Pmus,occ (rho 0.78, $p < 0.001$, Fig. 2) showed good capability by P0.1 in identifying the effort level expressed by Pmusc,occ. The correlation between PMI and Pmus,occ was significant but less good (rho 0.48, $p < 0.001$, Fig. 3).

Conclusions: In our population and setting, a disagreement between subjective and objective assessment of effort was frequent. This finding suggests the importance of implementing systematic measurements of inspiratory effort in clinical practice. P0.1, measurable by mini-occlusion maneuvers, is an interesting alternative to Pmus,occ, while PMI is less performant for discriminating the effort level.

Urinary Biomarkers IGFBP7 and TIMP-2: a prospective study on persistent acute kidney injury and renal replacement therapy

D. Angeles Sistac[1]; J. Baldirà-Martinez De Irujo[1]; AJ. Betbesè-Roig[1]; M. Cuartero-Sala[2]
[1]Intensive Medicine, Hospital de la Santa Creu i Sant Pau, Barcelona, Spain; [2]Intensive Medicine, Imperial College NHS, london, United Kingdom

Intensive care Medicine Experimental 2025* 13(1):*000120

Introduction: Acute kidney injury (AKI) contributes to high morbidity and mortality in the ICU. Differentiation between transient and persistent AKI, and establishing early need for renal replacement therapy (RRT) is essential for guiding timely interventions [1-7]. TIMP-2 and IGFBP7 are secreted by renal cells in response to stressors and are measured as the NephroCheck® (NC) score calculated as [TIMP-2] · [IGFBP7] [1,6,8,9]. An elevated NC score (> 2.0) predicts moderate to severe AKI. [1,3,7,10].
Objectives: This study evaluates the NC score to differentiate transient from persistent AKI and need for RRT in a heterogeneous critical care population.
Methods: Prospective, multicenter observational study: 455 ICU patients from five hospitals in Barcelona, Spain. Biomarker analysis on urine samples at admission. AKI was classified according to KDIGO criteria. Patients were grouped by NC scores and AKI subtypes. NC score > 0.3 positive biomarker test result. An NC value ≤ 0.3 low risk for AKI, intermediate from 0.3 to 2, and high > 2. Transient AKI = renal function recovery within 48 h. Persistent AKI = AKI lasting more than 48 h. Data were analyzed using Stata version 18.0. The study received approval from the Ethics Committee of each participating center.
Results: Outcomes by AKI subtype
Persistent AKI patients had higher NC scores, required mechanical ventilation (MV) for a longer duration, had lengthier hospital and ICU stays. Transient AKI patients had a higher median SOFA score at admission. There were no differences in age, gender, chronic kidney disease, basal creatinine, proportion of MV patients, need for RRT or mortality (Table 1).

Table 1 (abstract 000120) Outcomes by AKI subtype

	Total AKI 234 (51.4%)	Transient AKI 67 (28.6%)	Persistent AKI 167 (71.4%)	p-value
SOFA M (IQ 25–75)	6 (4–9)	7 (5–10)	6 (3–9)	0.022
NC score M (SD)	0.63 (1.52)	0.31 (0.95)	0.62 (1.43)	0.01
Hosp. days M (SD)	28.94 (30.53)	20.41 (19.18)	32.36 (33.47)	0.003
ICU days M (SD)	11.25 (12.86)	7.88 (9.51)	12.6 (13.77)	0.005
MV days M (SD)	10.08 (11.49)	6.31 (7.68)	11 (12.43)	0.004

Transient v. persistent AKI patients were compared using T-test or Wilcoxon rank-sum test for quantitative variables, and Chi2 or Fisher test for categorical variables.
Nephrocheck as a risk factor for persistent AKI and RRT
Patients with a high NC required RRT more frequently, had more days of RRT and had a higher risk of persistent AKI than those with lower NC (Table 2). NC values showed a positive correlation with the number of RRT days (Fig. 1).

Table 2 (abstract 000120) NC as a risk factor for persistent AKI and RRT

	NC (≤ 0.3) N = 355 (78%)	NC (0.3 – 2) N = 80 (17.6%)	NC (> 2) N = 20 (4.4%)
RRT N (% comparison)	26 (7.3)[a],*	8 (10)	5 (25)[a],*
RRT days (M comparison)	2.84 (3.19)	4 (2.92)[o],*	14.2 (13.51)[o],*
RRT OR (95% CI)	0.55 (0.26–1.08)	1.21 (0.54 – 2.79)	3.93 (1.34–11.47)*
Persistent AKI OR (95% CI)	0.63 (0.40 – 1.00)	1.11 (0.67 – 1.82)	4.3 (1.61–11.41)*

([a]) Proportion comparisons were conducted using a Chi2 test. ([o]) mean comparisons were assessed with a T-test. Logistic regression was performed for unadjusted models of RRT and persistent AKI. *P < 0.05
Conclusions: In a polyvalent ICU the NC score is significantly predictive for AKI complications. A high NC was a risk factor for persistent AKI, RRT and longer RRT duration. The NC value also correlated with the number of RRT days. Differentiating transient from persistent AKI remains inconsistent. Future studies on NC should focus on: specific guided interventions and clarifying AKI etiologies.

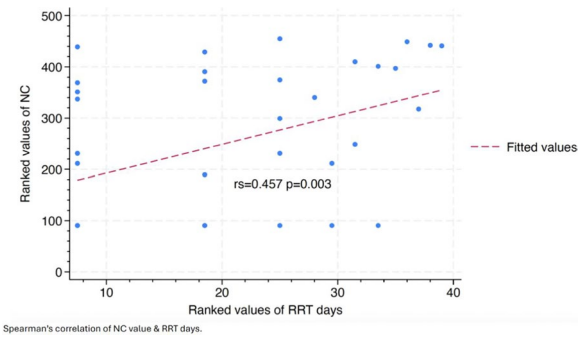

Fig. 1 (abstract 000120) Spearman's correlation of NC value and RRT days

The neglected ICU care in low-income countries: investigating the status and challenges of providing nutritional support in a tertiary referral centre in Addis Ababa, Ethiopia

M. Weldeyohannes[1]; F. Debebe[2]
[1]Anesthesia and clinical nutrition, Addis ababa university, Addis ababa, Ethiopia; [2]Emergency medicine and Critical care, Addis ababa Ethiopia, Addis Ababa, Ethiopia
Correspondence: M. Weldeyohannes
Intensive care Medicine Experimental 2025* 13(1)*:000121

Introduction: Intensive Care Unit (ICU) treatment is costly, and patients often experience malnutrition, leading to poor clinical outcomes. Even previously well-nourished individuals can rapidly develop malnutrition. In certain African countries, malnutrition rates can be as high as 85 percent. The entire cost of ICU treatment, combined with a paucity of resources unfortunately overlooks nutrition and its significant impacts in patient outcomes.
Objectives: To evaluate the difficulties in providing nutritional support in low-resource settings and generate workable alternatives considering all the undesirable ICU complications and outcomes, higher healthcare system costs, and potential prevention.
Methods: Two qualified professionals conducted an evaluation of nutritional practices and interviewed key informants. In light of these findings, recommendations tailored to the specific context were formulated, taking into account feasibility, affordability, accessibility, sustainability, and safety.
Results: The lack of ICU enteral tube feeding provisions has severely impacted Black Lion Hospital critically ill patients, leading to prolonged starvation and its associated consequences. For over two months, gruel has been unavailable, and milk provision has ceased for more than four years due to failed tenders. While eggs are available, they are not regularly supplied as the ICU team did not request them. Furthermore, recommended enteral formulas, total parenteral nutrition, and albumin are either prohibitively expensive or completely unavailable. The absence of a dedicated ICU kitchen and necessary equipment for food preparation exacerbates the situation. There is also a notable lack of formal nutritional assessment and planning due to the insufficient trained workforce. Communication gaps and conflicts of interest hinder collaboration with other ICUs that receive ongoing support.
Conclusions: Long-term action plans and recommendations: structural improvement: (establishing a fully functional and furnished ICU kitchen with the necessary equipment), dietitian support: (exploring the maximum possibilities with the existing potential stakeholders for sustainable professional support to foster better outcomes through patient-centered multi-professional engagement, sustainable service supply and provision: (planning, monitoring and securing uninterrupted nutritional supply of nutrients in collaboration with hospital admins and important stakeholders through continued quality improvement projects and intervention.

Introduction: Outpatient opioid consumption is a major worldwide problem.
Objectives: The objective of OCEANIA-MS is therefore to evaluate whether opioid administration during ICU admission acts as a risk factor for chronic opioid consumption (COC). Secondary objectives: to study other risk factors involved in COC in ICU admitted patients.
Methods: Multicenter (25 Spanish ICUs) prospective 2-month (Oct-Nov 2023) study. Patients > 18 yo admitted to ICU were included. We excluded ICU deceased patients. Opioid doses recorded as IV equivalents of mg of morphine. Telephone follow-up 3 months after hospital discharge. COC was defined as daily intake of opioids 3 months after hospital discharge. Categorial variables: absolute values and %; quantitative variables: median (IQ25-IQ75). Statistical analysis: X2, U Mann–Whitney and logistic regression.
Results: 1,782 patients included. Age: 64 (52-73) yo, 63.5% males. Pre-ICU opioid consumption (OPI-PRE): 8.9% (159). APACHE II 13 (9-18). Mechanical ventilation (MV) 41.5% (740) with median duration: 22 (6-126) h. In-ICU opioids (ICU-OPI): 48.3% (860), with 701 being opioid naïve (OPI-NAÏVE). Median opioid dose expressed as mg of IV morphine: 149.5 (28-652). 155 (9.0%) were discharged to the ward with an opioid prescription (OPI-WARD) and 140 (8.2%) still had an active prescription at hospital discharge (OPI-DISC). Telephone follow-up was completed in 1,491, and 129 (8.6%) were labeled as COC. Amongst COC, 45% presented with the OPI-PRE + ICU-OPI tandem and 4.7% were OPI-NAÏVE. COC was more frequent in: females (14% vs. 8.6%), older age [66 (56-75) vs 63 (50-73) yo]; OPI-PRE users (56.4% vs. 5.7%); tracheostomized

(18.9% vs. 9.5%); in-ICU administration of IV fentanyl (14.5% vs. 9.3%) and IV midazolam (17.1% vs. 9.5%); longer duration of opioid administration [96 (27-288) vs 43 (13-132) h] and MV [89 (14-288) vs. 22 (6-117) h]. ICU-OPI (13.9% vs. 7.6%); OPI-WARD (47.4% vs. 7.4%) and OPI-DISC (62.4% vs. 5.9%) were also associated, together with hospital length of stay [11 (7-27) vs 9 (5-18) days] and Rankin > 2 at hospital discharge (14.4% vs. 9.6%).
After multivariate analysis COC was associated with: age [OR 1.0 (CI95 1.0-1.03)]; IV midazolam [OR 2.1 (CI95 1.0-4.1)]; OPI-PRE [OR 5.4 (CI95 2.9-10.2)]; OPI-WARD [OR 2.5 (CI95 1.2-5.2)] and OPI-DISC [OR 8.5 (CI95 4.4-16.7)]. OPI- NAÏVE did not lead to COC [OR 0.98 (CI95 0.5-1.8)].
Conclusions: Opioid administration during ICU in opioid naïve patients did not act as a risk factor for COC. Limiting opioid prescription at ICU and hospital discharges together with IV midazolam might contribute to lower COC in ICU admitted patients.

Dynamic light intervention may influence the circadian course of serum melatonin: a randomized-controlled trial

S. Schmidt[1]; L. Hancke[1]; N. Engelhardt[1]; N. Kaiser[1]; J. Kaden[1]; C. Spies[1]; A. Luetz[1]
[1]Department of Anesthesiology and Intensive Care Medicine, Charité – Universitätsmedizin Berlin, Berlin, Germany
Correspondence: S. Schmidt
Intensive care Medicine Experimental 2025* 13(1)*:000123

Introduction: Poor lighting in the ICU is increasingly recognized as a significant factor contributing to disturbances in the circadian rhythm of critically ill patients, potentially limiting their recovery [1]. A recent study suggests that incorporating targeted light therapy into a comprehensive redesign of ICU rooms could help reduce the incidence and severity of delirium by modulating 24-hourserum melatonin levels [2].
Objectives: To investigate the impact of a dynamic light intervention on serum melatonin rhythms in critically ill patients.
Methods: This single-center randomized controlled trial enrolled adult mechanically ventilated patients expected to stay in the ICU for at least five days. Patients were randomly assigned to one of three groups using a different light scheduling algorithm (LSA) delivered by a dynamic light ceiling [3]. LSA-1 provided high-intensity white light with blue-enriched episodes. LSA-2 offered the same without the blue-enriched episodes, and LSA-3 served as the control, mimicking standard lighting. Serum melatonin levels were measured every four hours for up to four 24-h assessment periods (AP-A, AP-B, AP-C, and AP-D), with AP-B, AP-C, and AP-D initiated if the patient's Richmond Agitation Sedation Scale was -3 or higher.
Results: Out of 60 enrolled patients, 56 were included in the data analysis, distributed as follows: LSA-1 (n = 20), LSA-2 (n = 17), and LSA-3 (n = 19). The median age of the participants was 70 years (IQR 62-73), and 52% were women. The Acute Physiology and Chronic Health Evaluation on admission was 22.5 (IQR 17-31), while the Simplified Acute Physiology Score on admission was 39 (IQR 33-49). Within the first assessment period in AP-A, median serum melatonin levels exhibit clear day–night patterns across all groups, with levels declining between 6:00 am and 2:00 pm. In the subsequent AP-B and AP-C, the diurnal curve of serum melatonin shows a flattening trend within all intervention groups. In AP-D, a more distinct day–night pattern in serum melatonin levels is observed in patients with LSA-1 and LSA-2, showing a notable peak in nocturnal melatonin for those with LSA-1 (Fig. 1).
Conclusions: This preliminary descriptive data analysis indicates that high-intensity dynamic white light therapy may affect circadian melatonin rhythms in mechanically ventilated ICU patients. Further statistical analysis and large-scale studies are required to validate this hypothesis.

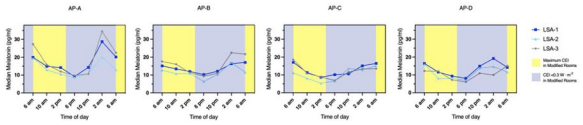

Fig. 1 (abstract 000123) AP = assessment period, AP-A = first day of intervention, AP-B = second day of intervention or later, AP-C = third day of intervention or later, AP-D fourth day of intervention or later. CEI, circadian effective irradiance

Outcomes and challenges in treating acute subdural hematoma in older adults with a GCS score of 3–5: a nationwide retrospective analysis in Korea

KS. Eom[1]
[1]Neurosurgery, Wonkwang University Hospital, Iksan, Republic of Korea
Correspondence: K.S. Eom
Intensive care Medicine Experimental 2025* 13(1)*:000124

Introduction: Ultra-severe traumatic brain injury (TBI) is a subgroup of severe TBIs, defined as patients with an initial Glasgow Coma Scale (GCS) score of 3–5. Although life-sustaining management is taken in the initial treatment, patients in this category are characterized by extremely severe injury, very poor prognosis, and low chances of recovery and survival. Therefore, deciding whether to perform aggressive neurosurgical treatment or discontinue treatment in this condition is one of the most frequently encountered but difficult decisions for physicians. Since age has been generally recognized as the most important factor in poor prognosis and increased mortality in many studies on TBI, the increase in the older adult population is becoming an increasingly important issue for those managing TBI. In particular, clear guidelines are lacking, and various ethical, financial, and cultural issues often arise for this population; hence, careful consideration of multiple factors is required when choosing an appropriate neurosurgical strategy.
Objectives: In this study, the author analyzed the current status, characteristics, treatment, and outcomes of geriatric patients with acute subdural hematoma (ASDH) and a GCS score of 3–5, which is known to a condition that account for a large proportion of TBIs and is associated with a poor prognosis. In addition, the benefits of surgical intervention were evaluated to establish future treatment guidelines for ASDH with a GCS score of 3–5.
Methods: We analyzed the data of 205 older adults (aged 65 years or older) with ASDH and a GCS score of 3–5 registered in the Korean Neurotrauma Data Bank System from January 2018 to June 2021. The patients were divided into death and survival groups, and the demographic, clinical, and radiological characteristics; treatment methods; mortality rates; and treatment outcomes were analyzed, along with the relationship between variables and mortality. We also compared the Glasgow Outcome Scale-Extended (GOSE) scores and investigated

whether surgical treatment affected mortality and good recovery rates according to age.

Results: According to the GOSE, 76.1% of patients died, 12.7% survived in a vegetative state, 3.9% had severe disabilities, and only 4.0% showed good recovery. The Glasgow Coma Scale (GCS) score at admission was significantly associated with pupil reactivity; Rotterdam computed tomography score; time interval from injury to operation and arrival to operation; treatment; and hospital stay between patients who died and those who survived. Surgical treatment was significantly associated with a lower mortality rate but not with good recovery rates.

Conclusions: In older adults with ASDH and a GCS score of 3–5, surgical treatment improves survival rates compared to conservative treatment, but many survivors remain in a vegetative state or with severe disability. Therefore, in the treatment of older adults with ASDH and a GCS score of 3–5, the benefit of surgical intervention is limited to improving survival rates. Thus, when treating ASDH with a GCS score of 3–5, it is crucial to consider the patient's and family's acceptable quality of life rather than merely extending life. These findings provide data to guide discussions with families regarding prognosis and may support future treatment guidelines for ASDH with a GCS score of 3–5.

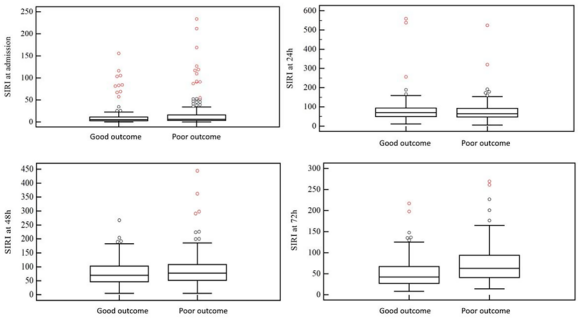
Association between systemic inflammation response index and poor neurologic outcomes in out-of-hospital cardiac arrest patients



T. SHIN[1]
[1]Emergency medicine, Seoul st mary's hospital, Seoul, Republic of Korea
Correspondence: T. SHIN
Intensive care Medicine Experimental 2025* 13(1):*000125

Introduction: Post-cardiac arrest syndrome (PCAS), a systemic inflammatory syndrome following CA, occurs during the reperfusion period after the ROSC. It shares several pathophysiological mechanisms with sepsis, and causes hypoxic brain injury. However, inflammatory markers to the outcome has not yet been fully investigated.An inflammation-related marker, the systemic inflammation response index (SIRI), which was developed in 2016 that can reflect the cancer-related inflammatory response, is calculated as neutrophils × monocytes/lymphocytes.
Methods: In this retrospective, observational single-center study, we tested the hypothesis that SIRI is associated with the neurological outcomes of OHCA patients treated with TTM. Venous blood sample were routinely collected at admission and at 24 h, 48 h and 72 h after the ROSC. The primary outcome was poor neurologic outcome (CPC3-5) at 6 months after CA.
Results: A total of 317 of 516 patients (61.4%) treated with TTM were included in the analysis. 127 of 317 patients (40.0%) had good neurologic outcome, and 190 of 317 patients (60.0%) had poor neurologic outcome. SIRI at 72 h were higher in poor neurologic outcome group, while SIRI at admission, 24 h and 48 h had no significant difference.
Conclusions. SIRI at 72 h after the ROSC were associated with poor neurological outcomes at 6 months after CA in patients treated with TTM.

	AUC	95% CI
SIRI at admission	0.560	0.502-0.617
SIRI at 24h	0.528	0.470-0.586
SIRI at 48h	0.556	0.498-0.613
SIRI at 72h	0.686	0.630-0.738

ROC curve of SIRI

Difference of SIRI score bewteen good and poor outcome

Table 3 (abstract 000123) Odd ratio for poor neurologic outcomes at 6 months after ROSC

	Poor neurologic outcomes at 6 months			
	SIRI at admission	SIRI at 24h	SIRI at 48h	SIRI at 72h
Multivariate	1.006	0.999	1.004	1.010
	(0.994-1.018)	(0.994-1.004)	(0.997-1.010)	(1.001-1.019)

Understanding perceptions and barriers to developing critical thinking among critical care medicine trainees: a qualitative exploration

C. Dsilva[1]; D. Dinakar[1]
[1]Critical Care Medicine, St Johns Medical College Hospital, Bengaluru, India
Correspondence: C. Dsilva
Intensive care Medicine Experimental 2025* 13(1):*000127

Introduction: Critical thinking involves analysing information objectively, evaluating different perspectives and reaching informed Conclusions: Without critical thinking, students rely on heuristics or "shortcuts" that can lead to cognitive biases and clinical errors which can be dangerous in an ICU setting. Critical care trainees are

superspeciality graduates who are adult learners, and inculcating critical thinking in them may be fraught with challenges.
Objectives: To explore the challenges and barriers of faculty in teaching critical thinking (CT) skills in trainees of critical care medicine and their possible solutions
To explore how critical care teachers define and conceptualize critical thinking.
Methods: Study design: qualitative research, phenomenology framework
Inclusion criteria: teaching faculty from critical care medicine departments with more than 1 year teaching experience.
Using purposive sampling, faculty were recruited from 4 tertiary teaching hospitals in South India with a DM/IDCCM critical care training programme. Written informed consent taken.
In-depth interviews were conducted in person or online using MS teams platform. Interviews conducted until thematic data saturation achieved. All interviews were audio recorded and transcribed using an AI software (TurboScribe.AI) interpretative phenomenological analysis (IPA), based on Heideggerian hermeneutics was used to find meaning in the teachers' experiences. Inductive coding of the transcripts was done. Coding was aided by the NVIVO 15 software. Clustering of codes into categories followed by the arrival of larger themes was done to arrive at the first level of thematic analysis.
Results: Demographics of participants have been shared in Table 1. Mean age of participants was 39 years. Thematic analysis identified broad themes of Student related, teacher related and system-related barriers to developing critical thinking. Themes and subthemes derived have been shown in Fig. 1.
Strategies to include critical thinking included (see Table 2)
·Encouraging independent analysis: progressively transitioning from shadowing to autonomous case management.
·Feedback and mentorship: individual mentoring for underperforming students, addressing academic and personal challenges.
·Structured protocols: providing a foundation for systematic decision-making while encouraging deviation when justified.
·Creating a conducive environment
Conclusions: Inculcating critical thinking is essential, however its development is hindered by hierarchical barriers, time constraints, trainee fatigue, and an overemphasis on algorithmic learning.
•Effective strategies such as curriculum reforms, faculty training, creating supportive learning environments and structured mentorship can help in enhancing the critical thinking skills of future intensivists. There is also a need to include assessments for critical thinking in ICU trainees.

Table 1 (abstract 000127) Demographic factors of participants

Demographics	N
Age in yrs :	
40+	3
35-40	7
30-35	4
Males/Females	8/6
MICU/SICU/NICU	9/3/2

Table 1 : Demographic factors

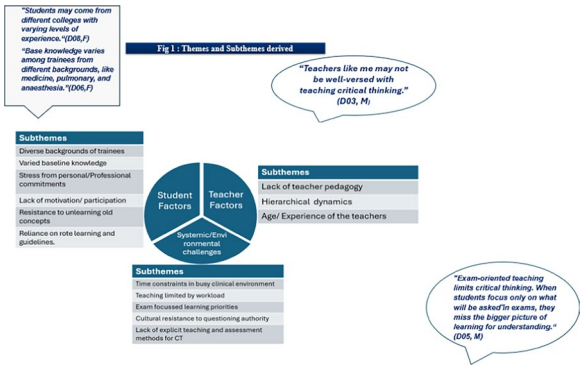

Fig. 1 (abstract 000127) Themes and subthemes derived from thematic analysis

Table 2 (abstract 000127) Strategies to foster critical thinking

Table 2
Strategies to Foster Critical Thinking

- **Encouraging Independent Analysis:** Progressively transitioning from shadowing seniors to autonomous case management.
  Encourage students to ask "why and how"
- **Feedback and Mentorship:** Individual mentoring for students, addressing academic and personal challenges.
- **Balancing Algorithmic and analytical learning approaches:** Providing a foundation for systematic decision-making while encouraging deviation when justified.
- **Creating a Conducive Environment:**
  Allowing room for questions and ensuring students feel safe to express themselves without fear.
  - Foster a welcoming and non-hierarchical teaching culture.
- **Curriculum redesign** to incorporate open-ended evaluations
- Developing **reflective practices** and time for introspection

Intraoperative transfusion rates during double lung transplantation in patients with extracorporeal membrane oxygenation as bridge-to-transplant: a retrospective study

C. Dibiasi[1]; C. Martin[1]; A. Benazzo[2]; PM. Böhm[2]; J. Gratz[1]; E. Schaden[1]; M. Wiegele[1]

Intensive care Medicine Experimental 2025* 13(1):*000128

Introduction: Double lung transplantation (DLT) is a life-saving intervention for patients with end-stage respiratory failure without other treatment options. For a subset of these critically ill patients, extracorporeal membrane oxygenation (ECMO) has demonstrated its value as an essential bridging therapy while waiting for DLT. Patients bridged with ECMO have a significantly increased risk of perioperative bleeding, but there is insufficient data to identify specific risk factors associated with increased transfusion rates.
Objectives: To evaluate intraoperative transfusion rates in DLT patients bridged with ECMO.
Methods: We performed a retrospective study and screened all adult patients undergoing DLT between 2013 to 2024 at the Medical University of Vienna. We included patients who were admitted to the ICU preoperatively. Exclusion criteria were DLT on cardiopulmonary bypass, multiorgan transplantation and single-lung transplantation. Patients were assigned to one of three groups: i) veno-venous (VV), ii) veno-arterial (VA) or iii) no ECMO bridging. We assessed the number of intraoperative red blood cell (RBC) transfusions as primary outcome. The number of intraoperative fresh frozen plasma (FFP) and platelet transfusions were secondary endpoints. We described baseline characteristics and transfusion requirements separately for each group using median, 1st and 3rd quartiles, as well as absolute and relative counts. We performed negative binomial regression modelling to assess the effect of ECMO bridging, ECMO blood flow, platelet count and fibrinogen concentration on intraoperative transfusion requirements. We adjusted the model for age, ECMO duration and sequential organ failure (SOFA) score.
Results: We screened 1033 patients who underwent DLT within the study period and included 148 patients who had been admitted to an ICU prior to DLT. Of those, 37 (25%) patients did not undergo ECMO, 99 (67%) underwent VV-ECMO and 12 (8%) VA-ECMO bridging. Baseline characteristics are given in Table 1.

	No ECMO	VV ECMO	VA ECMO
Age (years)	55 (36–60)	54 (40–60)	42 (32–49)
Weight (kg)	62 (53–76)	75 (65–85)	63 (50–75)
Height (cm)	170 (165–179)	173 (165–180)	169 (164–178)
Preoperative SOFA score (-)	4 (3–6)	8 (6–9)	8 (7–10)
ECMO duration (days)	0 (0–0)	7 (3–17)	3 (1–11)
Preoperative fibrinogen (g/L)	4.51 (3.86–5.46)	3.97 (2.85–5.23)	4.06 (2.96–4.84)
Preoperative platelet count (G/L)	2.33 (1.82–2.85)	1.41 (1.13–1.91)	1.54 (0.91–2.57)

Patients without bridging received 3 (1–6) RBC concentrates, 3 (1–9) units of FFP and 0 (0–1) platelet transfusions intraoperatively. Patients with VV-ECMO bridging received 5 (2–9) RBC concentrates, 4 (1–11) FFP and 1 (0–2) platelet transfusion during surgery. Patients who were bridged with VA-ECMO, were transfused with 9 (4–11) RBC concentrates, 7 (2–10) FFP units and 1 (1–3) platelet concentrates. Regression analysis showed that preoperative VV-ECMO as well as VA-ECMO were associated with higher transfusion rates, although this was not statistically significant (Fig. 1). ECMO blood flow was not statistically significantly associated with a higher transfusion rate. A higher preoperative platelet count was statistically significantly associated with a lower rate of platelet transfusions (Fig. 1). Fibrinogen concentration was not associated with intraoperative transfusion rates.
Conclusions: In critically ill patients, we observed higher intraoperative transfusion requirements for patients who were bridged to DLT using ECMO. However, after adjusting for baseline differences between patients with and without preoperative bridging, the effects of preoperative VV and VA-ECMO on intraoperative transfusion rates had wide confidence intervals and were not statistically significant. Further studies investigating the underlying mechanisms of coagulopathy in patients supported by ECMO are required to pre-hoc identify patients who will experience intraoperative bleeding during DLT.

Incidence rate ratios showing the effect of preoperative ECMO bridging, ECMO blood flow, platelet count and fibrinogen concentration on intraoperative transfusion requirements. The model was adjusted for age, ECMO duration and sequential organ failure score.

A nurse-led initiative: exploring nurses' willingness and barriers to adopt pupillometers in the neuroscience intensive care unit (NICU) for future practice

CZ. Ooi[1]; CSE. Koh[1]; WJ. Chin[1]; HSA. Ang[1]; S. Amalraj[1]; A. Binte Mohd Saniff[1]
[1]Nursing- Neuroscience Intensive Care Unit, Jalan Tan Tock Seng, Tan Tock Seng Hospital, Singapore, Singapore, Singapore

Intensive care Medicine Experimental 2025* 13(1):*000130

Introduction: Traditionally, pen torches have been used to assess the pupil response as a key component of the Glasgow Coma Scale (GCS) to detect neurological deterioration. However, these assessments are subjective, lacking both precision and reproducibility, which potentially affect clinical decision-making.
With technological advancements, pupillometers have emerged both locally and internationally as a more reliable alternative. Given that nurses routinely perform pupil assessments, their acceptance and willingness to adopt this technology into clinical practice are essential.
Objectives: This study aims to uncover nurses' perspectives and potential to expand pupillometer adoption in the NICU.

Methods: To minimize selection bias, a mixed-methods survey was administered to all 83 NICU registered nurses (RNs) at Tan Tock Seng Hospital who routinely perform pupillary assessments. With an 80.7% response rate, all responses remained anonymous to reduce response bias. The survey incorporated both Likert-scale and closed-ended questions, and data collection which spanned four weeks. Finally, statistical analysis was conducted to identify factors that facilitate or hinder nurses' willingness on the adoption of pupillometer.
Results: This study evaluates the perceptions of nurses who routinely perform pupillary assessment on the adoption of pupillometer. Out of 83 RNs who were invited to participate in the survey, 67 (80.7%) of them had responded. While 67.2% of nurses had prior experience with a pupillometer, a strong majority recognized its advantages, with 82.1% acknowledging its more accurate readings and 86.6% affirming its reliability in providing objective Results: 65.7% acknowledged a pupillometer is safe to be used on patients at the bedside. Additionally, time efficiency was a key factor, with 68.6% of nurses perceiving the pupillometer to take less than 30-60 s for pupillary assessment, demonstrating its potential to streamline assessments and reducing the need for subjective verification by colleagues (74.6%). Although only 37.3% initially preferred it over a pen torch, 59.7% expressed willingness to adopt it, with 85.1% supporting additional training to enhance confidence and competence.
The bar chart further highlights key facilitators for the pupillometer adoption, including the elimination of the need for subjective verification by colleagues (74.6%), followed by 67.2% of nurses who valued the objective outcomes provided, and perceived accuracy based on their experience (65.7%). Other factors including improved availability (62.7%) and accessibility (44.8%) near the nursing counter would also encourage adoption.
Given these findings, integrating pupillometers with structured training, improved accessibility and availability can enhance patient safety, optimize nurses' workflow, and support evidence-based neurological assessments in the ward.
Conclusions: Despite being available for decades, pupillometers remain underutilized. Yet, factors such as cost, perceived lack of necessity, logistical challenges and limited awareness contributed to the barriers. Notably, nurses play a pivotal role in integrating this technology into routine practice, making their willingness to adopt it essential. While NICU nurses have shown readiness, targeted training, improved accessibility, and greater availability are needed to strengthen their confidence.
Although this study was confined to the NICU, expanding research to other specialties could provide broader insights and attitudes towards the pupillometer adoption. Additionally, to facilitate the use of pupillometers as evidence-based neurological assessment in clinical practice, further quantitative studies will be significant in evaluating the clinical impact of pupillometers in neurological assessments.

Introduction: Antithrombin III (ATIII) is a key regulator of coagulation, playing a vital role in maintaining hemostatic balance. Reduced ATIII levels have been observed in trauma patients, potentially contributing to an increased risk of mortality, thromboembolic events, and coagulopathy. While ATIII deficiency has been associated with worse clinical outcomes in critically ill patients, less is known about its impact on trauma patient populations.
Objectives: This meta-analysis aims to evaluate the association between low ATIII levels and clinical outcomes, including mortality, thromboembolism, disseminated intravascular coagulation (DIC), and shock in trauma patients.
Methods: PubMed, Embase, and the Cochrane Library databases were searched for randomized controlled trials (RCTs) and observational studies that compared trauma patients with low ATIII levels to those with normal ATIII levels and reported outcomes related to mortality, thromboembolic events, DIC, and shock. Heterogeneity was assessed using the I^2 statistic. A random-effects model was applied to all outcomes to account for potential variations across studies.
Results: We included nine studies with a total of 1,629 trauma patients, all of which contributed data to at least one analyzed outcome. Trauma patients with low ATIII levels had a significantly higher risk of mortality (OR 3.61; 95% CI 2.36-5.50; $p < 0.01$; Fig. 1.1) and thromboembolic events (OR 2.14; 95% CI 1.21-3.80; $p = 0.009$; Fig. 1.2) compared to those with normal ATIII levels. While the risk of DIC was elevated in patients with low ATIII, this association was not statistically significant (OR 3.00; 95% CI 0.78-11.45; $p = 0.08$; Fig. 1.3). Additionally, the incidence of shock was significantly higher in patients with low ATIII levels (OR 3.42; 95% CI 2.51-4.68; $p < 0.01$; Fig. 1.4).
Conclusions: These findings suggest that low ATIII levels are associated with worse clinical outcomes in trauma patient populations. Further research is needed to determine whether targeted ATIII management strategies could improve outcomes in trauma patients.

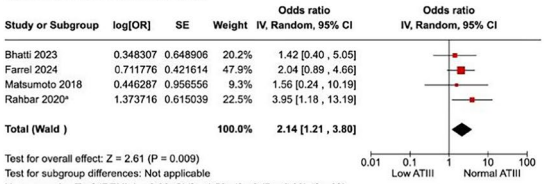

Figure 1.1 Mortality was significantly higher in trauma patients with low ATIII levels compared to those with normal ATIII levels.

Footnotes

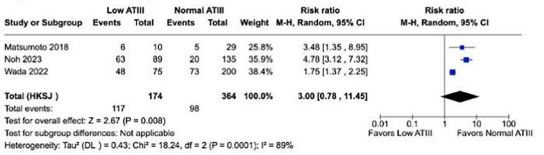
[a]In Nedorn et al., Low ATIII was defined as <81%
[b]In Noh et al., Low ATIII was defined as <70%
[c]In Wilson et al., Low ATIII was defined as <70%

Figure 1.2 Trauma patients with lower ATIII have a higher chance of developing any type of thromboembolic event.

Footnotes

[a]Rahbar used <90% ATIII cutoff, while Bhatti, Matsumoto, and Farrell used <80%.

Figure 1.3 The risk of Disseminated Intravascular Coagulation was higher but not significant in trauma patients with low ATIII.



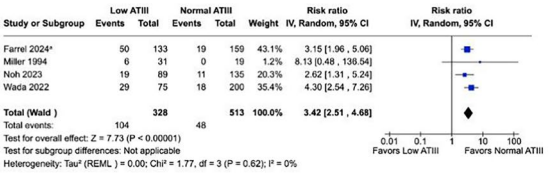


Figure 1.4 The risk of shock was significantly higher in trauma patients with Low ATIII.

Footnotes

[a]Farrell et al. was included in the analysis as their definition of hemorrhage closely aligned with the shock definitions used in other studies.

Forest plots show pooled odds ratios (OR) and risk ratios (RR) with 95% confidence intervals (CI) for clinical outcomes in trauma patients with low ATIII levels. (1.1) Mortality, (1.2) thromboembolic events, (1.3) disseminated intravascular coagulation, and (1.4) shock.

Intensive care Medicine Experimental 2025* 13(1)*:000137

Introduction: Sepsis, characterized by dysregulated immune responses leading to multi-organ dysfunction, remains a major cause of mortality (1, 2). Current therapeutic strategies mainly target inflammation, yet effective immune-modulatory approaches are lacking. CD11b, an integrin highly expressed on myeloid cells, critically regulates immune cell adhesion, migration, and pathogen clearance (3). Our previous studies showed increased CD11b expression in peripheral blood mononuclear cells (PBMCs) from septic patients and mouse sepsis models, suggesting its immunoregulatory role in sepsis.
Objectives: We aimed to determine whether pharmacological activation of CD11b signaling enhances innate immunity, improves pathogen clearance, protects against organ injury, and ultimately reduces mortality in sepsis.
Methods: Sepsis was induced in C57BL/6 mice by cecal ligation and puncture (CLP). Mice were randomized into four groups: Control (saline), CD11b blockade (anti-CD11b antibody, 2.5 mg/kg at 3 h and 6 h post-CLP), leukadherin-1 (LA-1) post-treatment (5 mg/kg LA-1 immediately post-CLP), and LA-1 combined treatment (5 mg/kg LA-1 24 h pre- and immediately post-CLP). Survival rates were analyzed using Kaplan–Meier curves (log-rank test) over 14 days. Organ dysfunction was assessed via serum creatinine (Cr), blood urea nitrogen (BUN), CK-MB, AST, and ALT levels at 24 h post-CLP. Lung injury was evaluated histologically (H&E staining); hippocampal dendritic spine density was assessed by Golgi staining. Blood bacterial load was quantified at 24 h post-CLP; macrophage phagocytic activity was determined using fluorescently labeled *Escherichia coli* at 16 h post-CLP. Flow cytometry assessed pulmonary immune cells, including neutrophils, Ly6C + monocytes, and macrophage polarization (M1/M2 ratio).
Results: CD11b blockade significantly decreased 14-day survival ($p < 0.05$, log-rank test). Conversely, LA-1 improved survival in both post-treatment and combined treatment groups. LA-1 treatment significantly ameliorated organ dysfunction, reflected by lower serum creatinine, BUN, CK-MB, AST, and ALT levels (all $p < 0.05$ vs. Control). Histological analyses demonstrated significantly reduced lung injury and increased hippocampal dendritic spine density following LA-1 treatment ($p < 0.05$). Additionally, LA-1 markedly enhanced pathogen clearance, evidenced by reduced blood bacterial load and increased macrophage phagocytosis. Flow cytometry revealed that LA-1 significantly reduced pulmonary Ly6C + monocyte infiltration, increased neutrophil recruitment, and restored macrophage M1/M2 polarization (all $p < 0.05$ vs. Control).
Conclusions: CD11b activation significantly boosts innate immune responses, improves pathogen clearance, reduces organ dysfunction, and increases survival in sepsis. Unlike traditional anti-inflammatory therapies, activation of CD11b signaling represents a novel immunotherapeutic strategy with potential for clinical translation.

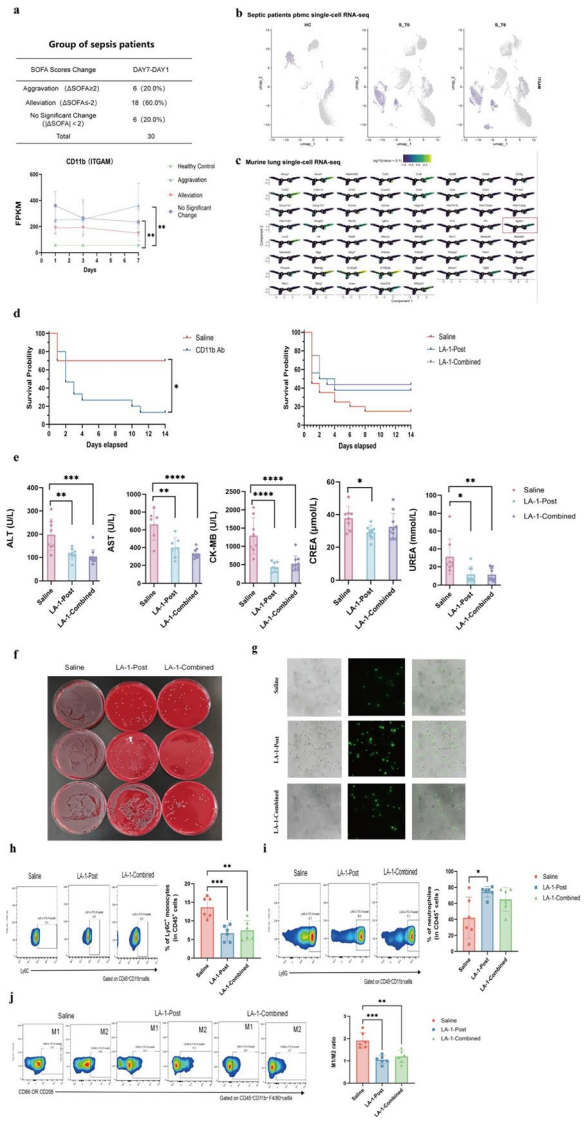

Fig. 1 (abstract 000137) Activation of CD11b signaling enhances innate immune function and improves outcomes in septic mice. (a) Transcriptomic analysis showing significantly elevated CD11b (ITGAM) expression in peripheral blood mononuclear cells (PBMCs) from septic patients on Days 1, 3, and 7 compared to healthy controls. (b) Single-cell RNA-seq (GSE167363) confirmed CD11b upregulation at diagnosis (S_T0) and 6 h post-diagnosis (S_T6) across multiple immune subsets in septic patients. (c) Trajectory analysis of murine lung single-cell RNA-seq (GSE207651) confirmed increased CD11b expression during sepsis progression. (d) Kaplan–Meier survival curves demonstrated significantly decreased 14-day survival following CD11b antibody blockade (*P < 0.05 vs. Control) and significantly improved survival after leukadherin-1 (LA-1) post-treatment or combined treatment (Log-rank test). (e) LA-1 treatment significantly attenuated organ dysfunction post-sepsis, indicated by lower serum creatinine (CREA), blood urea nitrogen (BUN), CK-MB, aspartate aminotransferase (AST), and alanine aminotransferase (ALT) levels (*P < 0.05, **P < 0.01, ***P < 0.001, ****P < 0.0001 vs. Control). (f-g) LA-1 significantly enhanced pathogen clearance, reducing blood bacterial load (f) and improving macrophage phagocytic capacity (g) compared to controls (g). (h-j) Flow cytometry analysis of pulmonary immune cells at 24 h post-CLP revealed decreased Ly6C + monocyte proportions (h), increased neutrophil infiltration (i), and maintained macrophage M1/M2 polarization balance (j) in LA-1-treated mice compared to controls (j) (*P < 0.05, **P < 0.01, ***P < 0.001). Data are mean ± SD, analyzed using ANOVA or log-rank tests as appropriate

Intensive care Medicine Experimental 2025* 13(1):*000140

Introduction: In-hospital cardiac arrest (IHCA) is an event that significantly impacts on patient safety. In previous studies, Deep learning-based early warning scoring (DEWS) has been effective in predicting IHCA and to reduce false alarms.
Objectives: We examined whether DEWS outperforms MEWS in IHCA prediction while reducing false alarms and improving with site-specific learning
Methods: DEWS analyzes age, blood pressure, heart rate, respiratory rate, and body temperature (DeepCARSTM, VUNO Inc, Korea). A retrospective analysis was conducted on adult patients admitted to general wards. The implementation period was from January 2022 to January 2023 and the site-specific learning period was from December 2022 to November 2023. The model was trained using one year of data for each period. The improvement in IHCA prediction was compared between the two periods.
Results: During the implementation period, 27,962 admissions were recorded, while 23,649 admissions were analyzed during the learning period. During implementation and learning period, there were 2.22 and 2.36 cardiac arrests per 1,000 admissions, respectively. During the implementation period, the AUROC of DEWS was 0.832 (p < 0.01), higher than 0.732 in MEWS, with a sensitivity of 38.8% and a specificity of 98%. False-positive alarms decreased by 43% in DEWS. During the learning period, the AUROC of DEWS and MEWS was 0.859 and 0.714, respectively. With a cutoff of 91 in DEWS, sensitivity was 21.7% and specificity 99%, while for a cutoff of 5 in MEWS, sensitivity was 17.1% and specificity 99%. DEWS predicted 6 additional IHCA earlier than MEWS in the 18 h pre-IHCA interval.
Conclusions: Our study showed that DEWS outperformed MEWS in predicting IHCA and that site-specific customization enhanced IHCA prediction performance.

The ROC analysis demonstrates that DCARS (AUC = 0.8589) outperforms NEWS (AUC = 0.7141) and SPTTS (AUC = 0.5723) in predicting cardiac arrest.

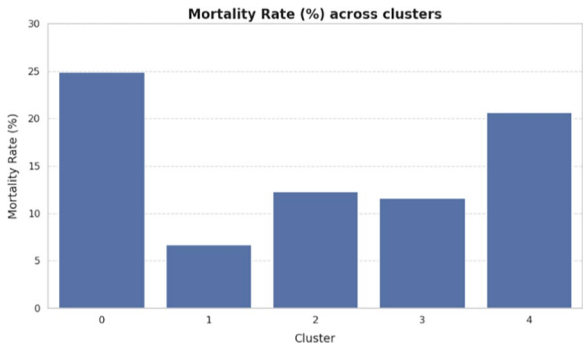
Intensive care Medicine Experimental 2025* 13(1)*:000141



Introduction: The high variability in patient responses to sepsis presents a significant challenge to early diagnosis and increases the risk of mortality. The current international consensus sepsis-3, based on the SOFA score, applies a uniform classification to septic patients, overlooking their inherent heterogeneity.
Objectives: This study aims to address this limitation by identifying sepsis subphenotypes through the clustering of ICU data, enabling a more personalized approach to diagnosis and treatment.
Methods: We analyzed data from the publicly available MIMIC-IV database, identifying a total of 36,581 septic patients. These included individuals diagnosed with sepsis at admission (14,753) and those who developed the condition during hospitalization (21,828). Laboratory test results, vital signs, and demographic data were collected, with the most abnormal values recorded within the first 24 h of ICU stay. Missing data were imputed using the MissForest technique, and dimensionality was reduced through Uniform Manifold Approximation and Projection (UMAP). Clustering was performed using the Gaussian Mixture Model (GMM) to identify sepsis subphenotypes. To evaluate the quality of the clustering, we applied the silhouette score, a metric that measures cluster cohesion and separability.
Results: Our clustering analysis identified five distinct sepsis subphenotypes, achieving a silhouette score of 0.29.
Conclusions: The identification of five distinct sepsis subphenotypes in this study supports the hypothesis of the condition's inherent heterogeneity. These findings underscore the need for further research to develop new metrics that effectively capture this variability, enabling more tailored diagnostic and therapeutic approaches.

Cluster 4 performed with the longest ICU stay among all (48.14—221.98), followed by Cluster 0 (39.37—168.29), Cluster 3 (33.65—159.87), Cluster 2 (21.66—114.84), and Cluster 1 (18.25—115.97).

Cluster 0 performed with the highest SOFA scores (6.00—11.00), followed by Cluster 4 (5.00—10.00), Cluster 3 (4.00—8.00), Cluster 2 (3.00—6.00), and Cluster 1 (2.00—5.00).

Cluster 0 showed the highest mortality rate (24,89%), followed by Cluster 4 (20,6%), Cluster 2 (12,3%), Cluster 3 (11,6%), and Cluster 1 (6,7%).

Evaluation of the concordance of transcranial Doppler pulsatility index in the middle cerebral artery and internal carotid artery

Y. Fujimoto; K. Numata[1]; S. Aya[1]; Y. Tukasa[1]; F. Shigeki[1]
[1]Emergency and Critical Care Medicine, St. Marianna University School of Medicine, Kawasaki, Japan

Intensive care Medicine Experimental 2025* 13(1):*000143

Introduction: The pulsatility index (PI) derived from transcranial Doppler is a valuable monitoring tool in neurointensive care. However, the approach through the temporal bone is reportedly unsuccessful in 10-20% of cases due to poor ultrasound penetration and presents technical challenges, necessitating trained personnel for accurate measurements. In contrast, the approach through the mandibular angle offers a relatively simpler and more feasible alternative.
Objectives: To evaluate the consistency between PI obtained by measuring the middle cerebral artery (MCA) from the temporal bone and the internal carotid artery (ICA) from the mandibular angle via transcranial ultrasound.
Methods: This is a single-center retrospective observational study. It includes cases from our ICU between May and September 2024 in which transcranial ultrasound was performed during the treatment of neurological disorders. Cases in which measurement through the temporal bone window was not possible were excluded. Measurements of MCA taken through the temporal bone are considered the gold standard, and we calculated the agreement rate with measurements of the ICA taken from the mandibular angle, and the correlation coefficient of the PI between the temporal bone and mandibular angle windows.
Results: Data from 46 cases, totaling 116 measurements, were analyzed. The patient demographics showed 40% male, with a median age of 50 years. The primary diagnoses were subarachnoid hemorrhage in 40% and intracerebral hemorrhage in 30% of cases. A significant correlation ($p < 0.001$) was found between the PI of the MCA through the temporal window and the PI of the ICA through the mandibular window with a correlation coefficient of 0.946. The accuracy for detecting a PI $\geq$ 1.5 at the temporal bone in the ICA was as follows: sensitivity of 93.0%, specificity of 81.3%, positive predictive value of 96.9%, and negative predictive value of 65.0%. We explored factors leading to lower underestimation of measurements in the mandibular angle window than in the temporal bone window. No significant effects could be identified in patient background such as age or gender, but patients with cerebral hemorrhage and subarachnoid hemorrhage tended to have lower measurements in the mandibular angle window (OR: 6.34, 95%CI 1.96-20.5, and OR: 2.72 95%CI 1.08-6.85). Measurements in the mandibular angle window tended to be higher when the Hb concentration at the time of measurement was below 10 g/dL (OR: 0.42, 95%CI 0.19-0.93).
Conclusions: Despite the inclusion of various diseases, the PI of the MCA through the temporal window and the PI of the ICA through the mandibular window were shown to be strongly correlated. To further validate the usefulness of this method, prospective studies and multicenter research are needed.

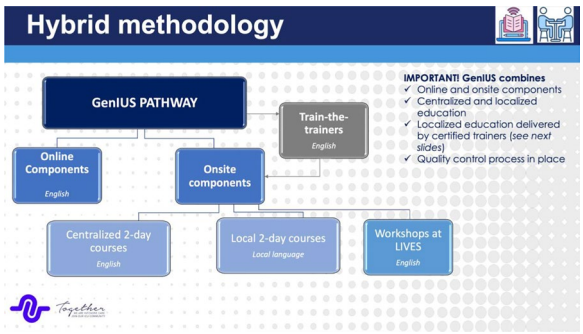
Intensive care Medicine Experimental 2025* 13(1):*000144

Introduction: Point-of-care ultrasound (POCUS) is revolutionizing critical care, yet a globally recognized, standardized training pathway remains elusive. The European Society of Intensive Care Medicine (ESICM) has launched the General Intensive Care Ultrasound (GenIUS) pathway—a comprehensive, sustainable and holistic educational framework designed to transform ultrasound education for intensivists. Unlike existing programs, GenIUS is not merely a course but a structured, competency-based pathway, integrating cutting-edge learning modalities while fostering long-term sustainability through the development of local trainers. Importantly, its development has been informed by existing ESICM educational initiatives, including the European Diploma of Echocardiography (EDEC) and the Intensive Care Fundamentals (ICF) course, ensuring alignment with established critical care training standards.
Objectives: The GenIUS pathway aims to:



1. Establish a holistic training model covering cardiac, thoracic, abdominal, neuro, and vascular ultrasound, ensuring comprehensive critical care assessment.
2. Deliver a groundbreaking hybrid educational approach that seamlessly integrates online modules, virtual reality experiences, live mentoring, and hands-on training.
3. Empower local trainers through a robust train-the-trainer (TtT) model, ensuring the program's scalability and sustainability.
4. Align with and complement existing ESICM learning pathways to create a cohesive ultrasound training ecosystem.

Methods: GenIUS follows a meticulously designed blended learning strategy, combining online self-directed modules (including a dedicated eBook), interactive monothematic sessions, web-based virtual reality experiences, and structured online mentoring. The

onsite component consists of mandatory two-day immersive courses, delivered both centrally at ESICM events and locally through certified trainers. The Faculty Development Day, a core feature of GenIUS, establishes a network of certified regional educators, ensuring standardized, high-quality ultrasound training across diverse healthcare settings. By leveraging insights from EDEC and ICF, the pathway incorporates best practices from previous ESICM educational models.
Results: By merging technology-enhanced learning with practical skill development, the GenIUS pathway is redefining how intensivists acquire and retain ultrasound skills. The localized faculty model ensures long-term sustainability by shifting expertise to regional trainers, reducing dependency on external faculty while maintaining educational rigor through ESICM oversight and quality control mechanisms. The 2025-2026 pilot phase will provide crucial data on learner engagement, competency acquisition, and the success of the decentralized training model.
Conclusions: The GenIUS pathway offers a comprehensive approach to CCUS training, by integrating innovative digital learning, immersive hands-on training, and a scalable faculty development strategy. Its alignment with **EDEC and ICF** reinforces its role within the broader ESICM educational framework, ensuring that ultrasound competency is developed in a structured and progressive manner. More than just a certification, it is a movement toward universal ultrasound competency.

Learning components and resources of pathway

Intensive care Medicine Experimental 2025* 13(1)*:000145

Introduction: Insufficient availability of organs results in long organ-transplant waiting lists and subsequent suffering and death among people in need of organs. Introducing novel donation processes such as uncontrolled donation after circulatory death has the potential to increase the donor pool and thus help reduce the gap between demand and supply of donor organs.
Objectives: Protocols for uncontrolled donation after circulatory death have only been implemented in a few countries in Europe. The present study aimed to explore relatives' experiences following a family member's circulatory death after out-of-hospital cardiac arrest, and to explore relatives' perspectives on being asked to decide about organ donation in this situation.
Methods: Using a qualitative approach, we conducted semi-structured interviews with 13 participants. Data were analysed using thematic analysis with an inductive, descriptive approach.
Results: The analysis generated three themes: 'fluctuating between hope and despair', which describes relatives' experiences of their family member's sudden cardiac arrest; 'exposed to vulnerability', concerning their experiences of death and perspectives on decision-making about donation; and 'Balancing a major life change', which involves experiences of facilitators and barriers to dealing with the loss. Knowing the wishes of the deceased helps family members to make their decision about consent to donate their loved one's organs. Otherwise, this decision could be experienced as unmanageable. Factors that could facilitate family members' experiences of donation after out-of-hospital cardiac arrest and death are being able to confirm the death themselves and having enough time to say farewell. Experiences of loneliness arise when losing a family member in out-of-hospital cardiac arrest, and in this situation trust in healthcare professionals and other people affects how experiences are perceived.
Conclusions: To provide comprehensive, high-quality care for relatives, specific guidelines are needed for structured proactive support and follow-up, taking into consideration the specific context, communication and needs of relatives.

Participant	Sex	Age (yrs)	Relation to the deceased	Present in the emergency department	Deceased persons sex	Deceased persons age (yrs)	Cause of death	Time between death and interview (months)
1	Female	58	Wife	Yes	Male	58	Myocardial infarction	12
2	Female	77	Wife	Yes	Male	72	Cardiomyopathy	19
3	Female	54	Mother	Yes	Female	29	Pulmonary embolism	6

Intensive care Medicine Experimental 2025* 13(1)*:000148

Introduction: Congenital diaphragmatic hernia (CDH) has a high mortality rate, particularly in low- and middle-income countries (LMICs) due to variations in neonatal intensive care quality. Postnatal predictors of mortality have been studied, including prematurity or low birth weight, large defect size, associated cardiac defects, severe pulmonary hypertension, the need for extracorporeal membrane oxygenation (ECMO), birth at non-tertiary centres, and poor gas exchange early postnatally. These factors highlight the need for targeted interventions to reduce mortality. Vietnam, an LMIC, faces significant challenges in managing neonates with CDH due to limited resources and a lack of advanced diagnostic and treatment options. Central hospitals, designated to handle severe cases, often experience delays in treatment initiation, impacting neonates' outcomes. Understanding Vietnam-specific risks and prognoses for CDH is crucial for mitigating adverse outcomes and reducing mortality.

Objectives: This study aimed to investigate the mortality rate and associated factors in neonates with CDH in Vietnam

Methods: This retrospective observational study included neonates with CDH admitted to a central children's hospital in Vietnam between November 2021 and September 2023. We collected data on neonates' characteristics, management, complications, and outcomes, comparing these data between neonates who survived and those who died in the hospital. We also employed logistic regression analysis to identify factors associated with hospital mortality.

Results: Of 74 CDH neonates, 64.9% (48/74) were male, and 50.0% (37/74) died in the hospital. The median gestational age at birth was 38 weeks (interquartile range [IQR]: 38-39), and the median age at admission was 5.2 h (IQR: 3.0-15.8). All neonates were transferred from various prior hospitals to our study site, with an immediate postnatal intubation rate of 83.8% (62/74). Our neonates presented in severe conditions, characterized by significant differences in pre- and post-ductal SpO2 levels (2.5%; IQR: 1.0-10.0), elevated mean pulmonary artery systolic pressure (PASP) at admission (51.7 mmHg; standard deviation: 18.3), high median Oxygenation Index measured 6 h after birth (13.3; IQR: 6.8-28.2), and increased median Vasoactive Inotropic Score at its peak during surgical intensive care unit stay (35.0; IQR: 15.0-80.0). Despite more than half of the neonates receiving high-frequency oscillatory ventilation (HFOV) as the initial ventilation mode (52.7%; 39/74), a small proportion received management with ECMO (6.8%; 5/74). The rate of surgical repairs performed was also relatively low (70.3%; 52/74). Greater pre-ductal and post-ductal SpO2 differences (adjusted odds ratio [AOR]: 1.386; 95% CI: 1.045-1.840), higher admission PASP (AOR: 1.080; 95% CI: 1.015-1.150), and the use of HFOV as the initial ventilation mode (AOR: 9.700; 95% CI: 1.341-70.176) were independently associated with an increased risk of hospital mortality.

Conclusions: This study investigated a selected cohort of neonates with CDH admitted to a central children's hospital in Vietnam, revealing a high mortality rate. The neonates presented with severe conditions and received limited intensive neonatal care, with a low rate of surgical repairs. Greater pre- and post-ductal SpO2 differences upon admission, higher PASP at admission, and utilization of HFOV as the initial ventilation mode were independently associated with an increased risk of hospital mortality. These findings highlight the importance of enhancing neonatal intensive care and ensuring the availability of surgical repairs in Vietnam to reduce mortality rates in neonates with CDH.

Intensive care Medicine Experimental 2025* 13(1)*:000150

Introduction: Clinicians in intensive care units (ICUs) perceive the care they provide as inappropriate when they feel that it clashes with their personal beliefs and/or professional knowledge. Clinicians who provide care perceived as inappropriate may experience moral distress. This situation may jeopardize the quality of care and increase staff turnover.
Objectives: First, to determine the prevalence of perceived inappropriateness of care among Dutch ICU clinicians. Second, to identify personal, professional, departmental, and work-related characteristics associated with clinicians' perceived inappropriateness of care, mental well-being and intention to leave the job. Third, to explore solutions to reduce perceived inappropriate ICU care.
Methods: In November 2024, we conducted a single-day cross-sectional study among physicians and nurses providing bedside care in 47 (68%) adult ICUs in the Netherlands. Perceived inappropriateness of care, relevant characteristics and solutions were assessed with online questionnaires. Validated measures were used to assess job strain [1], the ethical work environment [2], and symptoms of burn-out [3]. Multilevel modeling was used to identify associated factors.
Results: Of 1477 clinicians, 1058 completed the questionnaire (72% overall response). Perceived inappropriateness of care in at least one patient was reported by 276 clinicians (26%); 23% among nurses, 36% among physicians. Of these 276 individuals, 227 reported 259 situations of inappropriate care. The most common reports were perceived disproportionate care (n = 172; 66%; Fig. 1) of which 61% referred to "too much care". Independently associated with perceived inappropriateness of care rates were being an ICU nurse versus physician (odds ratio [OR], 1.78; 95% CI, 1.37-2.33; p < .001), the number of ICU beds (OR, 0.97; 95% CI, 0.94-0.99; p = .004), a culture of avoiding end-of-life care decisions (OR, 1.92; 95% CI, 1.51-2.45; p < .001); and a culture of mutual respect within the interdisciplinary team (OR, 0.84; 95% CI, 0.70-1.00; p = .045; Fig. 2). Perceived inappropriateness of care was independently associated with higher emotional exhaustion (β, .07; 95% CI, 0-.15; p = .049) and higher intent to leave the job (OR, 1.59; 95% CI, 1.13-2.23; p = .008). Commonly mentioned solutions to reduce inappropriate ICU care were: moral deliberation and multidisciplinary meetings to discuss ethical dilemmas, involving ICU nurses more in end-of-life care decisions, patient education about the implications of ICU treatment, mandatory and more frequent family meetings, increase of nursing capacity to improve patient flow to the nursing ward, and more uniform ICU admission criteria.
Conclusions: Among Dutch ICU clinicians, especially nurses, perceptions of inappropriate care were frequently reported and were inversely associated a good ethical work environment and team climate. Providing care they perceive as inappropriate puts ICU clinicians at risk for burn-out and leaving the job.

Intensive care Medicine Experimental 2025* 13(1)*:000151

Introduction: Double-lumen tubes (DLT) are the most commonly used devices for one-lung ventilation (OLV), but they are prone to malpositioning during patient positioning. The EZ blocker (Teleflex Life Sciences Ltd., Athlone, Ireland) has shown promise in providing effective OLV.

Objectives: This study compared the incidence of malposition between the two devices during patient positioning in adult patients undergoing OLV. The primary outcome was an incidence of malposition during patient positioning. Secondary outcomes were time taken for device placement, number of attempts for successful placement, ease of insertion, quality of lung collapse, and adverse effects.

Methods: The trial started after approval of the institutional ethics committee (AIIMS/IEC/2022/5251), CTRI registry (REF/2022/11/047711), and written informed consent from patients. Patients were randomly assigned to two groups: EZB and DLT (n = 42 each). Device position was assessed by fibreoptic scope (3.7 ID) before and after patient positioning. Time, attempts for device placement, quality of lung collapse, and adverse effects were also noted.

Quantitative variables were presented as mean ± SD or median (IQR). Categorical variables were expressed as numbers or percentages. Continuous data were analysed using Student's t-test, and categorical data using the Chi-square test. The Mann–Whitney U test was used for ordinal variables and quantitative variables with a non-normal distribution

Results: There was no significant difference in the incidence of malposition during positioning between the EZB group and DLT group (Table-1). The median time taken for device placement was significantly longer in EZB group (480 s) compared to the DLT group (300 s). There was no significant difference in the quality of lung collapse between the groups (Fig-1)

Table 1 (abstract 000151) Comparison of endpoint variables between study groups

	EZB group (n = 42)	**DLT group (n = 42)**	**Mean difference (95% CI)**	**p-value***
Incidence of malposition	9 (21.4%)*	6 (14.3%)		0.57
Time for device placement (Sec)	480 (300–795) **	300 (180–600)	180 (25.33–366.09)	0.04
No. of intubation attempts (1/2/3)	24/15/3***	23/14/5		0.812

* Values are in absolute number/percentage
** values are in median (IQR)
*** values are in absolute number

Conclusions: Although the time for device placement was longer with the EZ blocker, the incidence of malposition during patient positioning was comparable between the two devices.

Intensive care Medicine Experimental 2025* 13(1)*:000152

Introduction: Immunosuppression is a common phenomenon in critically ill patients, regardless of sepsis presence. The interaction between programmed cell death-1 (PD-1) and programmed cell death-ligand 1 (PD-L1) is believed to play a significant role in immune suppression.
Objectives: The primary aim of this study was to investigate the association between the dynamic changes of two negative co-stimulatory markers, neutrophil PD-L1 mRNA expression and serum soluble PD-L1 (sPD-L1) levels, and clinical outcome in a heterogeneous population of patients admitted to a general intensive care unit (ICU). Additionally, a subgroup analysis was conducted to assess these markers in trauma patients.
Methods: This prospective study included critically ill patients admitted to a multidisciplinary ICU. Baseline levels of interleukin (IL)-6, IL-8, IL-10, and tumor necrosis factor (TNF)-α were measured. Serum sPD-L1 and neutrophil PD-L1 mRNA relative expression were measured within 24-48 h of admission (baseline) and on days 4, 8, and 13, using ELISA. Data were analyzed using mixed-effects linear and logistic regression models.
Results: A total of 42 patients were included in the final analysis, with 25 (60%) being male. The median age (IQR) was 57 (41-71) years, and the median APACHE II and SOFA scores were 16 (12-20) and 8 (7-10), respectively. Trauma was the admission diagnosis for 21 (50%) patients, and the all-cause ICU mortality rate was 35%. Admission serum sPD-L1 was positively correlated with C-reactive protein and IL-6, 8 and 10. Baseline neutrophil PD-L1 mRNA expression was positively correlated with γ-globulins and TNF-α. While serum sPD-L1 levels significantly increased over time in the overall cohort, neutrophil PD-L1 mRNA expression remained unchanged. The longitudinal change in serum sPD-L1 levels was identified as an independent risk factor for ICU mortality (OR: 2.58, 95% CI: 1.17-5.72, P = 0.02). We found no association between sPD-L1 and trauma.
Conclusions: The dynamic change in serum sPD-L1 levels over time was independently associated with ICU outcome, highlighting their potential role as a prognostic marker. It could also guide immunomodulatory treatment in critically ill patients with severe immunosuppression.

Effect of remifentanil vs. fentanyl on delirium incidence in mechanically ventilated critically ill patients: a retrospective observational study

H. Okano; H. Okamoto[1]
[1]Department of Critical Care Medicine, St. Luke's International Hospital, Chuo City, Japan
Correspondence: H. Okano
Intensive care Medicine Experimental 2025* 13(1)*:000155

Introduction: Remifentanil, an ultra-short-acting opioid analgesic characterized by organ-independent metabolism, has been approved in Japan since 2022 for use in critically ill patients requiring mechanical ventilation. Previous studies (1) have primarily investigated remifentanil's potential to reduce mechanical ventilation duration; however, recent evidence (2) suggests it may also decrease the incidence of delirium among critically ill medical patients. Nevertheless, these prior reports have not directly compared remifentanil monotherapy with fentanyl monotherapy. Thus, direct comparisons between remifentanil and fentanyl monotherapy in medically critically ill patients are necessary.
Methods: This was a single-center retrospective observational study conducted among patients admitted to the intensive care unit (ICU) requiring mechanical ventilation between April 2021 and May 2024. The study included patients who underwent mechanical ventilation for more than 24 h. Patients were excluded if they were postoperative, post-cardiac arrest, readmitted to the ICU, did not initiate mechanical ventilation within 24 h of ICU admission, had a mechanical ventilation duration of less than 12 h, had an unknown transfer status or sedation dose, received both remifentanil and fentanyl, had a tracheostomy at ICU admission, or had a history of convulsive seizures.
Multivariate logistic regression analysis was performed to adjust for baseline patient characteristics. The primary outcome was the incidence of delirium during mechanical ventilation, reported as an odds ratio (OR) with a 95% confidence interval (CI).
Results: Among 582 patients admitted to our ICU and placed on mechanical ventilation, 198 met the eligibility criteria, with 41

receiving remifentanil and 157 receiving fentanyl. After adjustment for covariates including age, sex, BMI, neuromuscular blockade, vasopressor use, and APACHE II score, remifentanil use was associated with a reduced incidence of delirium, although this association did not reach statistical significance (OR 0.42; 95% CI, 0.14–1.29; P = 0.13) (Table 1).
Conclusions: In this study, the use of remifentanil was not significantly associated with a reduction in the incidence of delirium among mechanically ventilated critically ill patients. However, due to the limited sample size, the possibility of a clinically meaningful effect cannot be ruled out. Further large-scale, well-designed studies are warranted to clarify the potential impact of remifentanil on delirium.

Table 1 (abstract 000155) Association between remifentanil use and delirium: multivariate logistic regression analysis

VARIABLE	ADJUSTED OR (95% CI)	P-VALUE
Remifentanil (vs. Fentanyl)	0.42 (0.14–1.29)	0.13
Age	1.07 (0.81–1.40)	0.63
Male sex	0.81 (0.39–1.68)	0.57
BMI (kg/m²)	0.88 (0.61–1.26)	0.48
Neuromuscular blockade	0.93 (0.44–1.98)	0.85
Vasopressor use	1.29 (0.62–2.69)	0.50
APACHE II score	1.18 (0.90–1.56)	0.23

APACHE II :Acute Physiology and Chronic Health Evaluation II, BMI : body mass index, CI :confidence interval, OR : odds ratio.

Proactive desmopressin plus 3% saline (PD-3S) therapy for severe hypotonic hyponatremia in ICU—a practical approach

EYK. Cham[1]; PKN. Lam[2]; KM. Ho[3]
[1]Intensive Care Unit, North District Hospital, Hong Kong, Hong Kong; [2]Intensive Care Unit, New Territories East Cluster, Hong Kong, Hong Kong; [3]Department of Anaesthesia and Intensive Care, The Chinese University of Hong Kong, Hong Kong, Hong Kong
Correspondence: E.Y.K. Cham
Intensive care Medicine Experimental 2025* 13(1)*:000156

Introduction: Severe hypotonic hyponatremia (SNa < 120 mmol/L) can cause symptoms from malaise to seizures. Rapid correction risks osmotic demyelination syndrome. Variability in treatment can lead to inconsistent sodium corrections and increased workload from frequent intravenous fluid adjustments and monitoring.
Objectives: To evaluate the safety and efficacy of a standardized approach—**P**roactive **D**esmopressin plus **3**% hypertonic **s**aline (PD-3S) protocol—in treating severe hypotonic hyponatremia patients.
Methods: We conducted a descriptive, observational, single-center study from January 2023 to December 2024 at North District Hospital ICU. The study included adult patients (age ≥ 18) with severe hypotonic hyponatremia (SNa < 120 mmol/L) without renal or liver failure or neurosurgical conditions. PD-3S therapy aims for a controlled increase in serum sodium levels [1,2], with an increase in SNa of less than 10 mmol/L within the first 24 h and a maximum of 18 mmol/L within 48 h [3]. After obtaining baseline renal function tests, paired serum and urine osmolality, and electrolytes, desmopressin is administered immediately (2 mcg IV) and then every four hours (1 mcg IV). The 3% NaCl infusion is initiated based on body weight through a peripheral intravenous cannula (< 50 kg: 10 ml/h, 50-70 kg: 15 ml/h, > 70 kg: 25 ml/h). Serum and urine biochemistry are monitored every six hours. If the rate of SNa increases is inadequate, the infusion rate will be increased by 5 ml/h; if the rises in SNa are considered too rapid, a 250 ml bolus of 5% dextrose will be administered over 30 min and pausing the saline infusion during this period. Daily morning reviews guides adjustments as needed. The PD-3S protocol is discontinued and patients are discharged from the ICU only when SNa is higher than 120 mmol/L.
Results: The study included 19 patients (median age 72, 79% female). The median SNa [interquartile range] was 106 mmol/L [103-112], and the median serum osmolality was 224 mOsm/kg [215-236]. The causes for hyponatremia were due to SIADH (37%, n = 7), polydipsia (26%, n = 5), diuretics (21%, n = 4) and reduced solute intake (16%, n = 3). On presentation, all patients exhibited symptoms attributed to hyponatremia, including 10% (n = 2) with seizures, 20% (n = 4) in a stupor state, and 78% (n = 15) with symptoms such as nausea and malaise. The two patients with seizures had no more seizures after initiation of PD-3S and anticonvulsive therapy. The length of utilizing PD-3S therapy was 56 h [38-84] and total ICU length of stay was 72 h [58-106]. The rate of changes in SNa is illustrated in Fig. 1. No overcorrection, hypertonic saline extravasation, or thrombophlebitis occurred in the study patients and none exhibited osmotic demyelination syndrome at the three-month follow-up.
Conclusions: The standardized PD-3S treatment protocol for severe hypotonic hyponatremia was effective and safe in critically ill patients.

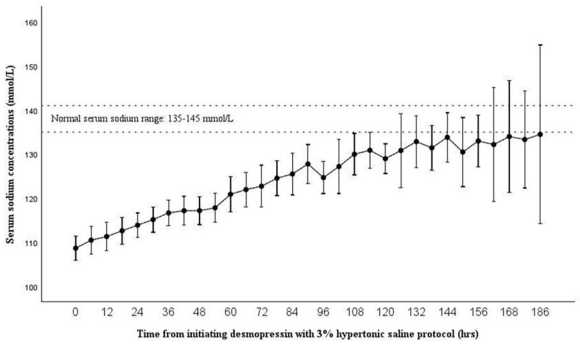

Fig. 1 (abstract 000156) Trend in the changes in serum sodium concentrations (SNa) over time since initiation of the PS-3S protocol

Introduction: The Sequential Organ Failure Assessment (SOFA) score, designed to reflect organ failure, is a well-established prognostic score in the ICU setting. Its kidney component is based on serum creatinine (Scr) and 24-h urine output. The limitations of Scr in acute kidney injury assessment are well recognized. We evaluated the role of 6 h urine collection creatinine clearance (CrCl6hr) as a predictor of 90-days (90d) mortality.
Objectives: Comparing between Scr, CrCl6hr, kidney SOFA component, and categorized CrCl6hr, SOFA score and SOFA score based on categorized CrCl6hr, in 90d mortality prediction.
Methods: A prospective observational study in an 18-bed mixed medical-surgical ICU in a tertiary university-affiliated hospital. Urine collection was performed from midnight to 06:00 in the first two days of admission of all ventilated patients admitted to the ICU. Patients were included if their ICU admission lasted more than 48 h. Urine collection volume was recorded, and creatine level at the collection was evaluated. Serum creatinine was assessed each morning. CrCl6hr was calculated in the first two admission days (based on the formula: CrCl6hr = urine creatinine * urine volume / Scr * 360); patents were grouped to 5 groups based on their CrCl6hr according to KADIGO categories (0—≥ 90 ml/min, 1 -60-89 ml/min, 2—30-59 ml/min, 3—15-29 ml/min, 4—< 15 ml/min). Using logistic regressions, Scr and CrCl6hr were evaluated as 90d mortality predictors; categorized CrCl6hr and kidney SOFA component were evaluated as 90d mortality predictors; SOFA score, and SOFA score using the categorized CrCl6hr instead of the kidney component were evaluated as 90d mortality predictors. ROC were plotted for each comparison. We compared the predictive strength for 90d mortality in each comparison using the c-index (AUC) from logistic regressions.
Results: 164 patients were included. Mean Scr was 1.38 mg/dl (IQR 0.74, 1.68) in the 1st day, and 0.92 mg/dL (0.69, 1.61) in the 2nd day. Mean CrCl6hr was 75.52 ml/min (24.88, 106.83) in the 1st day, and 72.83 ml/min (35.08, 95.24) in the 2nd day.
The comparisons of the different AUCs of all assessed factors are presented in Table 1. The ROCs are presented in Figs. 1 to 3.

Table 1 (abstract 000158) Comparison of area under the curve of receiver operator curves of the different variables examined as 90d mortality predictors

	Scr	CrCl6hr	p value
Continuous variable			
1st admission day	0.65	0.73	0.004
2nd admission day	0.63	0.75	0.0002
Kidney SOFA component based on			
1st admission day	0.65	0.71	0.07
2nd admission day	0.64	0.74	0.0051
Total SOFA score based on			
1st admission day	0.61	0.65	0.022
2nd admission day	0.65	0.71	0.0001

Scr – serum creatinine; CrCl6hr—creatinine clearance based on 6 h urine collection.

Conclusions: Performing 6 h urine collection is feasible. It allows better 90d mortality prediction compared to the currently used SOFA score.

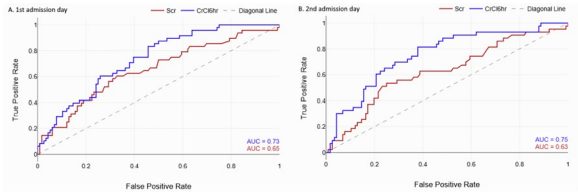

Fig. 1 (abstract 000158) ROC of serum creatinine and CrCl6hr for 90-d mortality in the first and second admission days. Scr—serum creatinine; CrCl6hr—creatinine clearance based on 6 h urine collection; AUC – area under the curve

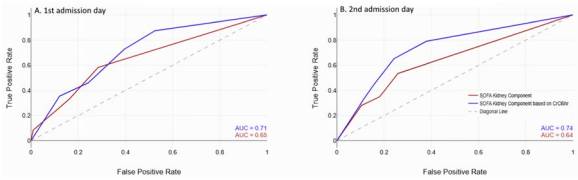

Fig. 2 (abstract 000158) ROC of SOFA kidney component, and SOFA kidney component based on CrCl6hr for 90-d mortality in the first and second admission days. Scr—serum creatinine; CrCl6hr—creatinine clearance based on 6 h urine collection; AUC—area under the curve

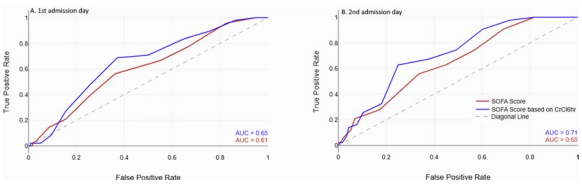

Fig. 3 (abstract 000158) ROC of SOFA score and SOFA score based on CrCl6hr for 90-d mortality in the first and second admission days. Scr—serum creatinine; CrCl6hr—creatinine clearance based on 6 h urine collection; AUC—area under the curve

Intensive care Medicine Experimental 2025* 13(1):*000159

Introduction: Since 2011, the international guidelines recommended against obtained daily CXR for ICU patients. However, despite this recommendation, a restrictive approach has not been uniformly accepted, and at the majority ICUs daily CXR remains the standard

Objectives: To assess the feasibility and the safety of the reduction of unnecessary CXR in ICU and its outcomes and economic impacts.
Methods: This project included two periods. Retrospective period (pre-intervention period, from 01 March 2024 to 31 May 2024) followed by interventions and prospective period (post-intervention, from 01 June 2024 to 31 August 2024). We collect for all admitted patients in ICU, the demographic data, number of CXR performed during ICU stay, the indication of any CXR performed during prospective period, the intubation requirement, the duration of intubation, ICU length of stay (LOS) and ICU mortality. During the post-intervention period all CXR performed must be justified and reported. The CXR was ordered at ICU admission (if clinical indicated), after any intra-thoracic procedures or any acute clinical deterioration. The primary outcome was a reduction of the rate of utilization of CXR in ICU to more than 50% within 3 months. The secondary outcomes were the assessment of the ICU LOS, the duration of mechanical ventilation, the ICU mortality and the cost saving. The interventions were based mainly on Staff education and awareness, optimize communication within the ICU staff, encourage collaboration between intensivists, radiologists, and other specialists involved in the ICU patients care to develop strategies and reach consensus on appropriate indication for CXR use. All statistical analysis was performed by using Microsoft Excel and SPSS 20.0.
Results: During pre-intervention period, 290 patients were included versus 257 patients in the post-intervention period. The age, gender APACHE II were similar between the two groups. Intubation was required in 38.3% of patient in pre-intervention period and 42% of the patient in the post-intervention period ($p = 0.372$). During the pre-intervention period, 1619 CXR was performed versus 502 CXR in the post-intervention period. The average number of CXR per patient was 5.6 in the pre-intervention period versus 1.95 in the post-intervention period ($p < 0.001$). The average number of CXR per patient days was 1.12 in the pre-intervention period versus 0.4 in the post-intervention period ($p < 0.001$) with reduction of CXR performed by 64%. The average number of CXR per ventilation days was 2.72 in the pre-intervention period versus 0.9 in the post-intervention period ($p < 0.001$) with a reduction of CXR performed by 67% for intubated patients. The ICU LOS, duration of intubation and ICU mortality were similar between the two periods. The direct cost saving was 36,890 € in three months with decrease of direct cost by 70%.
Conclusions: The performance improvement project decreased the CXR utilization in ICU patients by more than 60% and direct cost reduction by 70% without concomitant negative impact on the outcomes.

Noninvasive monitoring of intracranial pressure in patients with acute liver failure using transcranial Doppler ultrasonography

EM. Gutzwiller[1]; S. Blake[1]; L. Duka[1]; J. Rafia[2]; C. De Matteo[1]; T. Tavarez[1]; R. Temes[1]; J. Onwochei[3]
[1]Neuroscience ICU, North Shore University Hospital, Manhasset, United States of America; [2]Neurocritical Care Unit, Jamaica Hospital, New York, United States of America; [3]Transplant Hepatology, Gastroenterology, Internal Medicine, North Shore University Hospital, Manhasset, United States of America
Correspondence: E.M. Gutzwiller
Intensive care Medicine Experimental 2025* 13(1)*:000160

Introduction: Acute liver failure (ALF) leads to cerebral edema and intracranial hypertension, necessitating early detection and management. Standard imaging and EEG cannot provide an accurate correlate of increased intracranial pressure (ICP).
Objectives: This early pilot study investigates the use of transcranial Doppler (TCD) ultrasound to assess cerebral hemodynamic patterns, with the future aim of guiding goal-directed hypertonic and/or hyperosmolar therapy.
Methods: Seven ALF patients admitted to the Intensive Care Unit (ICU) at North Shore University Hospital in NYC, USA, with encephalopathy were monitored using TCD on the day of admission, the day prior to orthotopic liver transplant (OLT), and postoperatively to assess cerebral blood flow velocities and infer ICP changes. Waveform features of the right middle cerebral artery (MCA), obtained via temporal windows, including mean flow velocity (MFV), pulsatility index (PI), peak systolic velocity (PSV), and end-diastolic velocity (EDV), were analyzed. Symmetrical TCD data were also collected. The following flow patterns were defined: low-flow pattern when MFV was below normal reference values, independent of PI; high-resistance pattern with normal MFV and elevated PI; and hyperemia pattern when MFV was elevated, independent of PI.
Results: Preliminary results from seven ALF patients with varying etiologies, including postpartum ALF, EBV hepatitis, HBV reactivation, and acetaminophen intoxication, demonstrated distinct cerebral hemodynamic patterns across different hepatic encephalopathy (HE) severities (West Haven Criteria Grade 1–4). TCD findings indicate that low cerebral blood flow with high resistance (elevated pulsatility index [PI]) correlates with worsening encephalopathy (Table 1). Three patients with Grade 4 HE exhibited markedly elevated PI (≥ 2.0) and reduced mean flow velocity (MFV ≤ 53 cm/s), consistent with cerebral edema on CT scan and ICP. Notably, in Case 1 (postpartum ALF, Grade 4 HE), TCD spectral Doppler studies demonstrated a progressive increase in PI (1.47 to 2.28) prior to OLT followed by a dynamic reduction in PI from 2.28 pre-transplant to 1.25 post-transplant, aligning with clinical improvement (Fig. 1). In patient case 7, who was intubated for Grade 4 encephalopathy, serial TCDs showed decreasing PI and normalization of flow velocities over time, paralleling neurological recovery and successful extubation (Fig. 2).
Conclusions: Preliminary findings suggest TCD is a valuable non-invasive tool for assessing ICP in ALF patients. The most common cerebral hemodynamic pattern observed was low flow with high resistance. Ongoing data collection may help refine its role in monitoring neurological complications, guiding hypertonic/hyperosmolar therapy, and providing insights into prognosis and the timing of interventions such as liver transplant. Multi-center studies are needed to evaluate multimodal ICP assessment when invasive monitoring is contraindicated and to validate TCD as a standard of care for ALF patients.

Table 1 (abstract 000160) This table summarizes the clinical characteristics, hepatic encephalopathy severity, and transcranial Doppler (TCD) hemodynamic parameters of seven patients with acute liver failure (ALF). Most patients with severe encephalopathy (Grade 3-4) exhibited a low-flow, high-resistance waveform pattern, indicative of intracranial hypertension (ICH). In contrast, one patient (Case 4) showed hyperemia, suggesting altered cerebral autoregulation. Encephalopathy severity (West Haven Criteria) ranged from Grade 1 to 4. TCD parameters include mean flow velocity (MFV), pulsatility index (PI), peak systolic velocity (PSV), and end-diastolic velocity (EDV)

Cases	Age	Sex	ALF etiology	OLT	Encephalopathy grades	MFV (cm/s)	PI	PSV (cm/s)	EDV (cm/s)	Waveform pattern
1	35	F	Post-partum	Yes	4	53	2.28	143	21	Low flow, High resistance
2	30	F	EBV hepatitis	Yes	1	45	1.02	77	30	Low flow, High resistance
3	59	F	HBV reactivation	Yes	4	32	0.91	51	22	Low flow, High resistance
4	27	F	Acetamino phen intoxication	No	No	79	0.78	116	54	Hyperemia
5	27	M	Acetamino-phen and alcohol intoxication	No	2	53	1.45	108	32	High resistance
6	61	M	HBV reactivation	Yes	3	48	1.6	99	22	Low flow, High resistance
7	29	M	Alcohol intoxication	No	3	63	1.64	141	38	High resistance

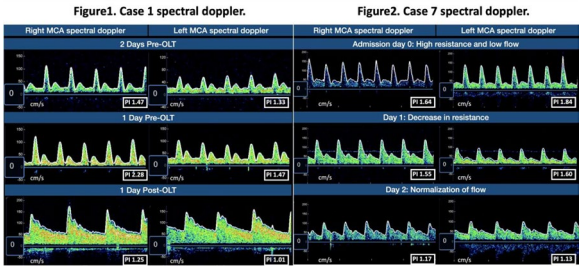

Fig. 1 (abstract 000160) Serial TCD spectral Doppler waveforms in Case 1 (postpartum ALF with Grade 4 encephalopathy)
This figure illustrates the progression of cerebral hemodynamics in a patient with ALF secondary to postpartum etiology, who developed severe hepatic encephalopathy (Grade 4) and underwent orthotopic liver transplantation. TCD spectral Doppler recordings of the right and left middle cerebral arteries (MCA) are shown at three time points. These findings suggest that TCD can track dynamic changes in ICP and cerebral autoregulation in ALF patients, potentially serving as a noninvasive monitoring tool to guide timely interventions.
Figure 2. Serial TCD spectral Doppler waveforms in Case7.
The patient was intubated for Grade 4 encephalopathy, serial TCDs showed decreasing PI and normalization of flow velocities over time, paralleling neurological recovery and successful extubation.

Engaging ICU patients and family members in research: identifying strategies

R. Kleinpell[1]
[1]Center for Research Development and Scholarship, Vanderbilt University School of Nursing, Nashville, United States of America
Correspondence: R. Kleinpell
Intensive care Medicine Experimental 2025* 13(1):*000161

Introduction: The COVID-19 pandemic and resulting limitations in family visitation practices in the intensive care unit (ICU) dramatically changed the way patients and family members are recruited and participate in research. As a result, there is an urgent need to identify strategies for involving patients and family members to foster patient centered outcomes research.
Objectives: The objectives of this session are to review results from a 2-year project which focused on identify barriers and strategies to enlisting ICU patients and family members in research in the ICU.
Methods: Group Concept Mapping, a mixed-methods approach for stakeholder engagement, was used to solicit input on perceived barriers to conducting research in the ICU. Four virtual sessions held with 16 patients/family members and 23 healthcare professionals (clinicians, researchers). Participants then sorted the barriers into conceptually similar domains and rated them on feasibility and impact of addressing.
Results: A total of 98 unique barriers were identified and organized into 7 clusters: Negative Experiences Surrounding ICU Stay, Difficult Research Logistics, Patient & Family Characteristics, ICU Setting Limitations, Post-Critical Illness Issues, Research Fears, and (Mis)perceptions About Research. Strategies were then identified to address the perceived barriers.
Conclusions: A number of strategies can be used by ICU clinicians and researchers to engage patients and family members in research. This session will review the project results, highlighting implications for clinical research.

Code ICH: impact of first-hour ED intervention on hematoma expansion in non-traumatic intracerebral hemorrhage

EM. Gutzwiller[1]; J. Smith[2]; U. Nureen[2]; J. Tirado[2]; D. Ledoux[2]
[1]Neuroscience ICU, North Shore University Hospital, Manhasset, United States of America; [2]Neuroscience ICU, Staten Island University Hospital—North Campus, New York, United States of America
Correspondence: E.M. Gutzwiller
Intensive care Medicine Experimental 2025* 13(1):*000162

Introduction: Hematoma expansion is a major determinant of poor outcomes in patients with intracerebral hemorrhage (ICH). The first hour following emergency department (ED) presentation is a critical window to initiate interventions that may limit expansion risk.

Objectives: This study describes the implementation of a Code ICH protocol at Staten Island University Hospital (SIUH) and evaluates the impact of tranexamic acid or desmopressin (TXA/DDAVP), antithrombotic reversal, blood pressure control, and black hole signs on CT on hematoma expansion.
Methods: A retrospective cohort study included 139 non-traumatic ICH patients admitted between January 2023 and December 2024 at SIUH, New York City. A Microsoft Teams group chat was used to alert the care team upon ED identification of ICH. Key variables included the use of an ICH order set within the first hour and black hole signs on initial CT. The order set included blood pressure control, glucose and temperature management, and TXA/DDAVP administration, with a scheduled repeat head CT at three to six hours. The primary outcome was hematoma expansion, defined as a $\geq$ 5 mL volume increase on follow-up CT. Secondary outcomes included the association between early implementation of the ICH order set and expansion rate and the modified Rankin Scale (mRS) at discharge. Logistic regression was used for predictive analysis.
Results: Of the 139 patients, 11 (7.9%) experienced hematoma expansion. Expansion occurred in four patients (5%) in 2023 and five (8%) in 2024. Among patients with expansion in 2023, three cases were attributed to hypertension and one had an unknown etiology. In 2024, four cases were attributed to hypertension and one the lack of reversal. TXA/DDAVP administration was not significantly associated with hematoma expansion. Use of the ICH order set increased from 53% in 2023 to 68% in 2024, representing a 14.8% increase. Earlier order set use was associated with more consistent reversal and blood pressure management. Higher systolic blood pressure was associated with worse functional outcomes (mRS > 3), though no clear threshold was identified. Black hole signs were correlated with expansion but were present in a small subset.
Conclusions: This is one of the first retrospective cohort studies to evaluate the impact of initiating ICH management within the first hour of ED presentation through a Code ICH protocol. While hematoma expansion was infrequent, earlier implementation of the order set that included blood pressure control and antithrombotic, anticoagulation reversal, was associated with more consistent adherence to guideline-based care. These findings suggest that faster ED-based intervention may help improve outcomes, warranting further prospective validation. While black hole signs on head CT appeared predictive, the impact of TXA and DDAVP on expansion remains inconclusive. Future prospective studies with larger cohorts are needed to better characterize predictors of hematoma expansion and functional outcomes in ICH.

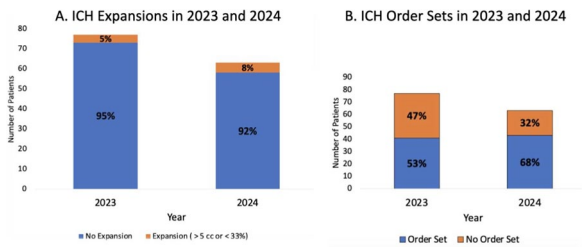

Fig. 1 (abstract 000162) ICH expansion rates and ICH order set use in 2023 and 2024. A. Hematoma expansion rates among ICH patients in 2023 and 2024. In 2023, 95% of patients showed no expansion, while 5% did. In 2024, 92% had no expansion and 8% experienced expansion. Expansion was defined as a > 5 mL increase in hematoma volume between the initial and 6-h CT scan. **B.** ICH order set utilization rates. In 2023, 53% of patients had an order set placed compared to 68% in 2024. Abbreviations: ICH, intracranial hemorrhage

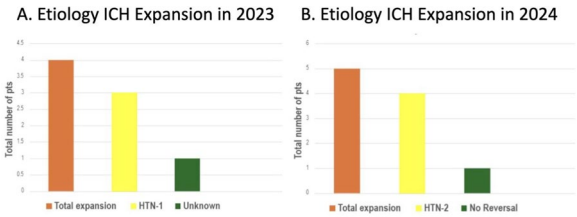

Fig. 2 (abstract 000162) Etiology of ICH expansion in 2023 and 2024. A. Etiology of ICH expansions in 2023. Among 77 ICH cases, four patients experienced expansion. Three were associated with hypertension (HTN-1), and one had an unknown etiology. **B.** Etiology of hematoma expansion in 2024. Among 63 ICH cases, five patients experienced expansion. Four were attributed to hypertension (HTN-2), and one was associated to lack of reversal. Abbreviations: ICH, intracranial hemorrhage; pts, patients; HTN, hypertension

Early enteral nutrition was associated with reduced mortality in septic patients with lower dosage of vasopressors

M. Mo[1]; J. Xie[1]; C. Wu[1]; L. Liu[1]; H. Chen[1]; Y. Yang[1]
[1]Department of Critical Care Medicine, Zhongda Hospital, School of Medicine, Southeast University, Nanjing, China

Intensive care Medicine Experimental ***2025*** **13(1)**:***000164***

Introduction: Enteral nutrition in septic shock patients is a double-edged sword. The impact of early enteral nutrition (EEN) on mortality of septic shock patients remains uncertain, and whether this association is modified by vasopressor dosage remains unclear.
Objectives: The study aimed to investigate the association between EEN and 28-day in-hospital mortality in patients with septic shock, and to explore whether the association varied within different dosage of vasopressors during the first 24 h

Methods: Data were extracted from the Database in Intensive Care. Adult septic patients who received vasopressors within 24 h after Intensive Care Unit admission were eligible for inclusion. The primary exposure was whether the patients received early nutrition within the first 24 h after ICU admission (EEN Group). The primary outcome was 28-day mortality. Multivariate Cox regression models were employed to explore the association between EEN group and 28-day mortality in the overall population and in patients receiving different dosages of vasopressors.
Results: A total of 10,263 patients were screened, and ultimately 1184 patients met the inclusion criteria. The median sequential organ failure assessment (SOFA) score was 9 (interquartile range (IQR): 7–11) and the Acute Physiology and Chronic Health Evaluation (APACHE) II score was 19 (IQR: 14–25). The 28-day in-hospital mortality rate was 19.6%. Compared to patients in the EEN group, patients in the late enteral nutrition (LEN) group had a higher vasopressor (7.5 vs 9.57 ug/min, $p = 0.002$), and higher 28-day mortality (15.5% vs.21.3%, $p = 0.027$). After adjusting for confounders, EEN was associated with a decreased risk of mortality (hazard ratio (HR) 0.722, 95% confidence interval (CI) (0.528-0.985), $p = 0.04$). This result was persisted in patients with vasopressor < 15 ug/min (norepinephrine equivalents) (HR 0.618, 95% CI (0.404-0.946)), other than in patients with vasopressor ≥ 15ug/min (norepinephrine equivalents) (HR 0.818, 95% CI (0.512-1.307); $p = 0.40$).
Conclusions: Early enteral nutrition was associated with improved outcome in septic shock patients, especially in patients with low dosage of vasopressor.

Population pharmacokinetics and optimal sampling design for caspofungin in critically ill children

X. Nuo[1]; Y. Wang[2]; X. Xiang[1]; Y. Shi[1]; X. Zhu[1]
[1]Clinical Pharmacy and Pharmacy Administration, School of pharmacy, Shanghai, China; [2]Pediatric ICU, Children's Hospital of Fudan University, Shanghai, China

Intensive care Medicine Experimental 2025* 13(1):*000168

Introduction: Caspofungin, an echinocandin antifungal, is often used to treat invasive candidiasis in children. Its pharmacokinetics (PK) vary significantly in critically ill pediatric patients, leading to unpredictable behavior in this population. Despite these challenges, comprehensive PK studies on caspofungin in critically ill children are still lacking, highlighting the need for more research. Pediatric clinical studies are further complicated by ethical concerns, recruitment difficulties, and sample collection challenges. [1-2] Optimizing study design, particularly the number and timing of sampling points, can maximize information utilization while minimizing risks and discomfort, ultimately developing more effective sampling plans and enhancing pediatric PK research in larger population.
Methods: The final PPK model was developed using data from critically ill children who received a once-daily, 1-h intravenous infusion of caspofungin for antifungal treatment. Steady-state PK data were collected five days after the initial dose, with samples taken at six potential time points per patient: pre-dose, 1 h, 2 h, 4 h, 8 h (if possible), and 16 h (if possible) post-administration.
The PPK model was developed using the non-linear mixed-effects modeling software NONMEM (version 7.5, ICON Development Matrixs, MD, United States) with the first-order conditional estimation with interaction (FOCE-I) algorithm. Allometric scaling for body size, such as weight (WT), body surface area (BSA), and body mass index (BMI), calculated as WT / (height)2, was employed a priori.
Design software, including $DESIGN in NONMEM [3] and PopED package (version 0.6.0), were utilized to explore design elements such as the number of subjects, sampling size, and sampling windows. The designs were evaluated to ensure the precise estimation of typical PK parameters, defined as a relative standard error (RSE) of less than 50%. The final sampling design was further validated through SSE. In the second phase of the study, approximately 40 participants will be recruited to receive a daily 1-h intravenous infusion of caspofungin.
Results: A total of 80 plasma samples were collected from 14 critically ill pediatric patients. The median (range) age and weight were

4.63 years (0.33-16) and 15.9 kg (4.9-64), respectively. All baseline blood biochemistry results were within normal ranges (**Table 1**).

A two-compartment model with allometric scaling on WT (an exponential of 1 for volume (V) and ¾ for clearance (CL)) was found to accurately describe the time course of caspofungin. After stepwise covariate modeling, baseline aspartate aminotransferase (AST) was identified as a significant covariate for the exchange rate between the central and peripheral compartments (Q). All pharmacokinetic parameters were precisely estimated (RSE < 45%), indicating the model's robustness (**Table 2**). GoF and VPC plots (**Fig. 1**) further confirmed that the final PPK model effectively represents caspofungin's observed time course.

Four sampling points per subject were sufficient for precise parameter estimation (RSE < 50%). The optimized sampling time points were identified as 119 h, 121 h, 126.5 h, and 144 h (**Table 3**). The sampling windows showed that effectiveness reaches 95% within the time intervals of 119-120 h, 120.5-121.5 h, 126-127 h, and 143-144 h. Sensitivity analysis indicated that covariates had minimal impact on the outcomes of the optimized sampling design (**Table 4**). SSE results demonstrated that PK parameters and inter-individual variability could be estimated with greater precision (RSE < 45%) using these sampling windows (**Fig. 2**).

Conclusions: The developed PPK model for caspofungin well described the PK profiles of critically ill pediatric patients. The proposed sampling design allowed fewer blood samples and flexible sampling windows, without the loss of precision in PK parameter estimates.

Table 1 (abstract 000168) Demographic and laboratory information of patients

Characteristics	Median[min,max] (n=14)

Intensive care Medicine Experimental 2025* 13(1)*:000170

Introduction: Thoracic trauma (TT) causes significant morbidity and mortality, with hemothorax, pneumothorax and pneumonia as common complications. [1]
Analgesia is key to preventing respiratory complications. [2] Erector spinae plane block (ESPB) improves pain and respiratory function with < 3% of complications. [3, 4]
Objectives: The objective of this study is to evaluate ESPB in TT patients, its impact on opioid use and outcomes.
Methods: Observational ambispective study of TT patients (Jan 2022–Oct 2024). Qualitative variables compared using χ^2 or Fisher's test. Quantitative variables analyzed with Student's t-test for normal data or the Mann–Whitney test otherwise. A significance level of 5% was considered. Analysis performed with IBM SPSS v26.
Results. 124 patients were analyzed, 24 received ESPB. Mean age was 48 years, 72% were male. Median ICU stay was 3 days, and hospital stay was 12 days. 92% had blunt TT. The most frequently associated injuries were traumatic brain injury (51%) and orthopedic trauma (48%). Three required thoracic surgery. The most common thoracic injuries were pulmonary contusion (54%), pneumothorax (21%) and hemothorax (21%).
25% needed high-flow oxygen therapy (HFOT), and 44.4% invasive mechanical ventilation (IMV). The median duration of IMV was 3 days,

and 11.3% required a tracheostomy. Pneumonia was the most common respiratory complication (12.9%), followed by acute respiratory distress syndrome (ARDS) (3.2%). Acute kidney injury (AKI) occurred in 17.7%. The mortality rate in our series was 9.7%.
Among the 24 patients with ESPB, all had blunt TT, one was anticoagulated. Catheter placement was not associated with complications. ICU stay ranged from 1-7.75 days without ESPB and 3-4.75 days with ESPB, while hospital stay was 13.5 and 9 days, respectively.
IMV was required in 16.7% of patients with ESPB and 51% without ESPB (p0.002), with a duration of 1-4.7 days versus 1-13 days. No patient with ESPB required tracheostomy. There were no differences in the need for HFOT or ARDS. One patient with ESPB developed pneumonia compared to 15 in the non-ESPB group (p0.305).
AKI occurred in 20% of patients without ESPB and in 8.3% with ESPB (p0.241). Mortality was 11% in patients without ESPB compared to 4.2% in those with ESPB (p0.458).
Opioids were required in 73% of TT patients, with fentanyl (55%) and morphine (19%) being the most commonly used. The daily infusion dose was 0.6 mg for non-ESPB patients and 0.45 mg for ESPB patients (p0.1). Total stay opioid rescue doses were 0.75 mg for non-ESPB patients and 0.15 mg for ESPB patients (p0.79). 79% of patients who received ESPB did not require opioids after its insertion.
Conclusions: ESPB reduced opioid use in TT. 79% of patients did not need opioids after insertion. It decreased the need and duration of IMV, hospital stay and complications such as pneumonia, renal failure and mortality (without statistical significance).
In conclusion, the use of the ESP block minimizes the use of opioids and improves clinical results in patients with TT.

Intensive care Medicine Experimental 2025* 13(1)*:000172

Introduction: Acute respiratory distress syndrome (ARDS) presents with heterogeneous lung parenchyma, including collapsed, normal, consolidated, and distended alveolar units, each with unique mechanics. Positive end-expiratory pressure (PEEP) is commonly applied to recruit collapsed units and improve compliance. However, excessive PEEP may overdistend normal lung units, increase dead space, worsen compliance, and elevate driving pressure, leading to complications such as tidal hyperinflation. Optimal PEEP determination is challenging, as driving pressure alone cannot always distinguish under-recruitment, overdistension, or tidal hyperinflation.
Objectives: This multicenter observational study evaluates the utility of time constant exp (TCe) and dynamic compliance ratio (C20/Cdyn) for guiding PEEP titration, aiming to optimize recruitment while minimizing adverse effects on cardiac output.
Methods. Patients who satisfied select criteria for moderately severe ARDS on mechanical ventilation were included in this study. All patients were paralyzed or deeply sedated. Initial ventilatory settings included volume controlled mode, tidal volumes of 6 mL/kg and PEEP of 5–8 cm H2O, at the discretion of bedside intensivists. Ventilatory parameters (PF ratio, PEEP, driving pressure, TCe, C20/Cdyn) were recorded within two hours of intubation, titrated to minimize driving pressure, and re-recorded post-titration. Additional data included ventilatory ratio, PaCO2 gap (surrogates for dead space ventilation and cardiac output), and vasopressor requirements. Standard ARDS management guidelines were followed, including prone positioning.
Results: Of the cohort, 39 out of 89 (43.8%) required vasopressor support, and 73 out of 89 patients (82%) underwent prone positioning. Logistic regression revealed ventilatory ratio (OR = 147.34, p = 0.047, estimate = 4.99) and PaCO2 gap (OR = 3.49, p = 0.004, estimate = 1.25) independently predicted vasopressor requirements. ROC curve analyses established cutoffs for PaCO2 gap (≥ 7), ventilatory ratio (≥ 2), C20/Cdyn (< 0.92), and TCe (≥ 0.48) as predictors of vasopressor need. Linear regression identified predictors of PaCO2 gap (R^2 = 0.57), which included C20/Cdyn before and after PEEP application, PEEP value immediately after intubation, driving pressure immediately after intubation. Predictors for ventilatory ratio (R^2 = 0.83) using linear regression revealed PEEP, PF ratio, C20/Cdyn, Tce before and after titration. A co-relation matrix was drawn using a heat map that identified decrease in C20/cdyn with near sustenance of TCe were predictive of the need for vasopressors. Multiple modeling of Spearman co-relation revealed time constant and compliance ratio (C20/Cdyn) had significant co-relation with ventilatory ratio (r = 0.356 and -0.793, respectively), and CO2 gap (r = 0.487 and -0.626, respectively). Using ROC approach, the cut-off was identified using highest Youden index. The cut-off for CO2 gap was 7 (66.67% sensitivity, 100% specificity) and ventilatory ratio of 2 (100% sensitivity and 62% specificity) for the vasopressor need. Similarly cut-off for C20/Cdyn and TCe for the vasopressor need was identified as < 0.92 (45.95% sensitivity, 100% specificity, AUC of 0.724) and 0.48 (21.62% sensitivity, 87.1 specificity with AUC 0.405). The cut-off of c20/Cdyn, TCe, driving pressure for the need for prone position were 0.83 (100% sensitivity, 19.64% specificity), 0.35 (100% sensitivity, 1.79% specificity) and 16 (16% sensitivity and 85% specificity). These co-relations were further confirmed by agreement analysis using Bland–Altman technique.
Conclusions: Driving pressure alone is insufficient for PEEP titration in ARDS. Parameters such as TCe and C20/Cdyn improve recruitment assessment and overdistension detection. Sustained TCe (> 0.48) with reduced C20/Cdyn (< 0.92) during PEEP titration indicates overdistension, while reduced TCe (< 0.35) with sustained C20/Cdyn (> 0.92) suggests effective recruitment. These findings underscore the importance of comprehensive ventilatory strategies in ARDS management.

Introduction: Necrotizing pneumonia (NP) is a rare complication of community-acquired pneumonia (CAP), with an estimated incidence of approximately 10%. It is characterized by the rapid progression of consolidation areas to cavitation and necrosis, associated with pulmonary vascular obstruction due to thrombus formation. These alterations in the lung tissue favor the growth of the bacterial inoculum and impair the action and penetration of antibiotics, thereby being associated with high morbidity and mortality.
Objectives: The aim of this abstract is to present the clinical features of patients with NP admitted to the Intensive Care Unit (ICU) of a peripheral hospital in Portugal and to compare them with existing literature.
Methods: A literature review was conducted, followed by a retrospective study of data from electronic medical records from patients with CAP who developed NP during their stay at the ICU, between January 2023 and July 2024.
Results: A total of 3 patients were included, 2 of them female, and with a mean age of 48.3 ± 8.7 years. The most relevant comorbidities were hypertension (n = 2), smoking (n = 2) and alcoholism (n = 1). All patients were admitted with severe respiratory failure, requiring mechanical ventilation due to bilateral CAP (mean C-reactive protein 40.5 ± 8.1 mg/dL). The pathogens identified were methicillin-susceptible *Staphylococcus aureus* (n = 1), *Streptococcus pneumoniae* (n = 1), and *Klebsiella pneumoniae* (n = 1) all with bacteremia. Patients exhibited cardiovascular dysfunction, requiring vasopressor support with norepinephrine (mean dose 0.4 ± 0.2mcg/kg/min), hepatic dysfunction with coagulopathy (mean international normalised ratio 1.56 ± 0.29) and renal dysfunction (mean creatinine level 1.58 ± 0.30 mg/dL). The mean APACHE II was 15.3 ± 2.3 points. 1 patient initiated continuous venovenous hemodiafiltration with an HA380 hemoperfusion cartridge (Jafron Biomedical Co., Ltd.) due to rhabdomyolysis and persistent metabolic acidosis. All patients received targeted antibiotic therapy within the first 24 h. Following clinical deterioration, NP diagnosis was confirmed by chest CT, with bilateral pulmonary areas of necrosis and cavitation, on the 6th (n = 2) and on the 11th day (Picture 1). 2 patients were transferred to a tertiary hospital for venovenous extracorporeal membrane oxygenation due to refractory hypoxemic respiratory failure. The patient with the later diagnosis and more comorbidities died on the day of the diagnosis due to refractory shock. The average length of ICU stay was 9.3 ± 2.3 days.
Conclusions: Despite the small sample size, this study's results are consistent with the literature regarding risk factors for NP, clinical progression, and the most common pathogens. Furthermore, they have contributed to promoting active discussion about this condition within the medical team. Since NP remains a condition that requires specific management recommendations, early suspicion in cases of CAP with unfavorable progression, optimized medical therapy, and the timely decision for surgical intervention are essential in order to achieve better outcomes.

Picture 1 (abstract 000173) chest computed tomography of the deceased patient showing bilateral necrotizing pneumonia, with multiple cavitations and extensive areas of consolidation

Intensive care Medicine Experimental 2025* 13(1):*000178

Introduction: The association between the intensity of radiological examinations related to computed tomography (CT) after severe trauma and subsequent risk of cancers in adults is not well characterized [1,2].
Objectives: This study aims to assess whether cumulative radiation exposure during the first (index) trauma admission is related to the subsequent risk of developing malignant neoplastic conditions, and the risk of dying from a neoplastic cause.
Methods: This was a statewide cohort study utilizing data from all public and private hospitalizations, as well as death and cancer registries, for trauma patients who experienced their first trauma admission between 2004 and 2020, with no documented cancers within 5 years prior to trauma admissions [3]. Radiation exposure from CT scans during the entire index trauma admission was calculated using the dose-length product (DLP). A whole-body CT scan protocol may result in a DLP exposure close to 3000 mGy*cm.
Results: Of the 2,669 patients included, 2,024 (75.8%) were males. The median (interquartile range [IQR]) age of the cohort was 41 years. While alcohol use (n = 1,330, 49.8%) and smoking (n = 1,240, 46.5%) were common, coexisting medical illnesses prior to the index trauma admission, including diabetes mellitus (5.3%), chronic pulmonary

disease (1.8%), ischaemic heart disease (1.5%), and congestive heart failure (1.5%), were uncommon. The median injury severity score (ISS) was 17 (IQR 6-22). Of the 374 patients (14.0%) who died during the follow-up period (median 5.9 years, IQR 4.0-7.9), 21 (5.6% of all deaths) died from a malignant neoplastic disease.
The median total number of X-rays and CT scans performed on patients during the entire index trauma admission were 6 (IQR 3-12) and 3 (IQR 1-5), respectively. The median DLP exposure from CT scans of the cohort was 1,940.5 mGy*cm (IQR 636.5-3,388.0), and this was significantly associated with the severity of injury (Pearson correlation coefficient with ISS = 0.444, p = 0.001). In multivariable logistic regression analyses, after adjusting for age, major comorbidities, smoking, and alcohol use, radiation exposure during trauma admission was quantitatively associated with an increased risk of both new-onset cancers after trauma (OR 1.15 per 1,000 mGy*cm increment, 95%CI 1.03-1.29; p = 0.015) and cancer-related mortality (n = 21 [0.8%], OR 1.08 per 1,000 mGy*cm increment, 95%CI 1.01-1.16; p = 0.048, hazard ratio for the DLP > 5,000 mGy*cm = 3.19, 95%CI 1.14-14.88; p = 0.027) (**Fig. 1**). Lung cancers (19%), glioblastoma multiforme (14%), and pancreatic cancers (14%) were the most common causes of cancer-related deaths.
Conclusions: Radiation exposure from CT scans during trauma admission demonstrated a dose-related association with the risk of new-onset cancers and subsequent cancer-related mortality. These findings suggest that the immediate diagnostic benefits of CT scans for major trauma patients should be carefully weighed against their potential long-term risks for cancer outcomes.

Difference in time to death due to cancers between patients exposed to radiation at dose–length product < 5000 mGy*cm and those > 5000 mGy*cm during index trauma admission (N = 2669).

Intensive care Medicine Experimental 2025* 13(1):*000179

Introduction: External ventricular drains (EVDs) are temporary devices inserted into the lateral ventricles to drain excess cerebrospinal fluid (CSF), manage intracranial hypertension, monitor intracranial pressure, and administer medications. These devices are crucial in neurocritical care and are generally considered closed systems, meaning they do not allow direct communication between the CSF and the external environment under standard conditions. However, manipulation or disconnection of the system can compromise this integrity. Complications are frequent and include haemorrhage, infection, and CSF overdrainage. The infection rate associated with EVDs is reported to be below 10%, with a rate of approximately 11.4 infections per 1000 catheter days. Importantly, the risk of infection increases with the duration of catheterization, with a higher incidence observed beyond 5 days of EVD placement.
Objectives: We conducted a retrospective observational cohort study of patients with EVDs admitted to the Polivalent Intensive Care Unit (ICU) of a tertiary hospital, from January 2022 to December 2023. We characterized the population with respect to demographic variables, clinical variables and infectious complications. We assessed the risk factors for EVD-associated infections, including the number of EVD days and the indications for placement.
Methods: Patients admitted to the polyvalent ICU between January 2022 and December 2023 with an EVD implanted prior to or during their ICU stay were included. Exclusion criteria were: patients who had undergone any neurosurgical procedure prior to EVD placement, those with a CSF fistula, and those with an active central nervous system (CNS) infection before catheter insertion. Infection was defined according to CDC criteria, namely a positive CSF culture with suggestive clinical presentation and/or CSF pleocytosis. For negative cultures, infection was defined based on clinical symptoms and CSF cytological changes (pleocytosis, hypoglycorrhachia, elevated lactate).
Results: We identified 73 patients with EVDs of whom 10 were excluded, leaving 63 patients. The majority were male (60%), with a mean age of 61. The most common indication for EVD placement was non-traumatic subarachnoid hemorrhage with or without intraventricular hemorrhage (59%), followed by intracranial tumor (32%), and traumatic brain injury with hemorrhage (6%). The mean EVD duration was 12 days. Infectious complications occurred in 27% of patients, with an infection rate of 22 infections per 1000 EVD days. Infections were diagnosed on average 19 days after EVD placement, with 65% of infections occurring after 12 days. The predominant pathogen was *S. epidermidis* (23%). The overall in-hospital mortality rate was 41%.
Conclusions: Our findings reveal an infection rate higher than what has been reported in the literature, with infections occurring later, on average after 19 days. This suggests that prolonged EVD duration may have contributed to the increased risk of infection. To further explore the high infection rate, a larger-scale study is proposed. This would include additional risk factors such as infections at other sites, prior or ongoing antibiotic therapy, and the number of EVD cultures drawn. Further research is essential to refine management strategies and improve patient outcomes in neurocritical care.

Intensive care Medicine Experimental 2025* 13(1)*:000183

Introduction: Sepsis and septic shock are life-threatening conditions caused by an uncontrolled immune response to infection, leading to severe circulatory and organ dysfunction 1. The cholinergic anti-inflammatory pathway has shown promise in regulating inflammation, mediated by vagus nerve fibers and nicotinic receptors 2. Research supports the use of cholinesterase inhibitors like physostigmine and neostigmine to modulate immune responses in sepsis, potentially improving recovery and reducing organ failure 3. This study aims to evaluate neostigmine's role in enhancing recovery specifically in patients with septic shock, emphasizing its potential therapeutic benefits**.** SOFA and APACHE II score were also compared at Day 1 and 5 along with 28 days mortality.
Methods: This trial enrolled 92 adult ICU patients with septic shock, randomly assigning them to Group N (neostigmine treatment) or Group C (placebo/control). Neostigmine was administered via continuous infusion pump over five days @ 0.2 mg/hour, while Group C received normal saline as placebo. Standard sepsis management included antibiotics based on blood culture Results: Baseline data collection encompassed demographics, vital signs, laboratory tests, and severity scores (APACHE II, SOFA). Parameters monitored included vasopressor adjustments, shock reversal duration, Procalcitonin levels, and ICU stay. Short-term outcomes, including 28-day mortality, were assessed. Daily observations covered a wide range of clinical parameters, and specific endpoints were evaluated on Day 1 and Day 5, focusing on shock recovery duration and mortality rates.
Results: In Group N, a total of 35 out of 40 patients (87.5%) recovered, with a mean recovery duration of 7.94 $\pm$ 2.59 days. In Group C, 26 out of 40 patients (65%) recovered, with a mean recovery duration of 12.58 $\pm$ 3.75 days with a statistically significant difference ($p < 0.001$) (Table 1).
On day 1 of therapy, the SOFA scores for Group N and Group C were 11.55 $\pm$ 2.22 and 10.80 $\pm$ 2.09, respectively, ($p = 0.125$). By day 5, the SOFA score for Group N was 9.65 $\pm$ 1.31, whereas for Group C it was 13.8 $\pm$ 2.32, indicating a statistically significant difference ($p < 0.001$). The SOFA score after 120 h had a decrease of 1.90 points in Group N, while Group C showed an increase of 3.0 points, which was statistically significant (p-value < 0.001) (Table 2).
In Group N, 14 out of 40 patients (35%) died within 28 days, whereas in Group C, 25 out of 40 patients (62.5%) died. This difference was statistically significant ($p = 0.014$) (Table 3).
Conclusions: Neostigmine has shown encouraging outcomes in treating septic shock, such as accelerated patient recovery, lowered Sequential Organ Failure Assessment (SOFA) scores, decreased mortality rates within 28 days, and reduced dependability on vasopressors. These results imply that neostigmine could provide substantial advantages in enhancing outcomes for individuals with septic shock.

Table 1 (abstract 000183) Comparison of mean duration of recovery from start of treatment between the two groups. (n=80)

Duration of recovery in days	Mean (SD)		p-value
	Group N (n = 40)	Group C (n = 40)	
	7.94 (2.59)	12.58 (3.75)	<0.001

Comparison of mean duration of recovery from start of treatment between the two groups

Intensive care Medicine Experimental 2025* 13(1)*:000184

Introduction: Epidural caudal block is commonly used for paediatric infra-umbilical surgeries under general anaesthesia (GA). The landmark technique has many complications; hence, ultrasound-guided

(USG) blocks are in vogue to overcome them. Aims of our study was to compare first-attempt success rates between short and long-axis USG guided caudal blocks as primary objective and to compare the time taken for performing a successful caudal block, the number of skin punctures, and the incidence of complications between the two groups as the secondary Objectives:
Methods: This prospective randomized trial was conducted in a tertiary care centre after approval from IRB with IEC no. AIIMS/IEC/2022/4155 and was registered with Clinical Trial Registry of India (CTRI/2022/12/048325). 136 ASA I/II paediatric patients aged 0-6 years, undergoing infra-umbilical surgeries under GA, were randomly assigned to two groups: Group S (short-axis) and Group L (long-axis). The caudal blocks were given under USG guidance by short or long axis as per the randomisation in both groups. The first attempt success rate, block performing time, number of skin punctures and complications were noted in Group S and L.
Results: The first attempt success rate was comparable for Group S and Group L ($p = 0.836$) (Fig. 1). The number of attempts for block ($p = 0.719$), the mean time for performing the block ($p = 0.286$) (Fig. 2), and associated complications ($p = 0.722$), all had no statistically significant difference.
Conclusions: Our study found that the first attempt success rate of USG-guided caudal block with short-axis (Group S) and long-axis (Group L) view was comparable to the findings of Gupta K et al. [1]. Group L had a slightly higher block performing time than Group S which was similar in a systematic review and meta-analysis done by Jain D et al. [2]. The number of attempts between two groups suggests no difference as was observed in Erbüyün K et al. [3]. Our study compared the complications like swelling in the back, intravascular puncture, inadvertent subarachnoid injection, and bleeding and was found to be comparable in the two groups as complied with the study of Erbüyün K et al. [3].
We concluded that USG guided caudal block with short axis v/s long axis has a comparable first-attempt success rate in children < 6 years. The block performing time, and the associated complications are comparable as well.

Cervical Spinal Cord Injury: A Review of Ventilator and Tracheostomy Weaning in a London Major Trauma Centre

F. Charlton[1]; R. Davies[1]
[1]Physiotherapy department, King's College Hospital NHS Foundation Trust, London, United Kingdom
Correspondence: F. Charlton
Intensive care Medicine Experimental 2025* 13(1)*:000185

Introduction: Spinal cord injury (SCI) is an insult to the spinal cord that can result in an impairment to the motor, sensory and autonomic pathways. High SCI injury can have a significant impact on respiratory function, due to weakness or paralysis of the diaphragm and respiratory muscles (1). Insult to the cervical spinal cord often sees a requirement for invasive ventilation and subsequent tracheostomy insertion. SCI weaning is a specialist practice, with the Respiratory Information in Spinal Cord Injury (RISCI) guidelines (2) recommended by national SCI centres as best practice to guide ventilator weaning (3). However, little data on current practice is available at the hyper-acute stage.
Objectives: The aim of this study was to observe trends in ventilator and tracheostomy weaning in cervical SCI patients admitted to the intensive care unit (ICU).
Methods: This was a retrospective, observational cohort study of ICU patients admitted following a cervical SCI that required invasive mechanical ventilation via a tracheostomy. Data were collected between June 2022 and June 2024. Data extracted included: tracheostomy insertion date, duration of weaning, date of decannulation, documented use of RISCI guidelines to guide weaning, airway clearance modality utilised for secretion management, incidents of ventilator acquired pneumonia (VAP) and use of oral drying agents and mucolytic agents.
Results: 10 patients with a SCI who required invasive ventilation via a tracheostomy were reviewed. The median (range) ICU length of stay was 61 days (25-196). Time from intubation and tracheostomy insertion was 12 days (6-48). Time from intubation to commencement of ventilator free breathing trials was 18 days (8-51). Time from intubation to the first trial of a one-way speaking valve was 15 days (8-51). 50% (n = 5) of the sample were decannulated prior to discharge from the hospital. Decannulation occurred a median of 40 days (29-153) following tracheostomy insertion. RISCI guidelines were used by clinicians to guide weaning for all patients. All patients required use of mucolytic agents. 20% (n = 2) required drying agents for oral secretion management and all patients had at least one incidence of VAP. The most commonly utilised airway clearance modality was cough assist, used by 100% (n = 10) of the sample. 80% (n = 8) had a documented airway complication and 80% (n = 8) of the sample had dysphagia.
Conclusions: Results demonstrate consistent use of the RISCI weaning tool and cough augmentation modalities across the sample of cervical SCI patients. However, there is notable variation in the duration of ventilator and tracheostomy weaning, reflective of the known complexities of the SCI cohort. Further research would be beneficial, exploring the factors that can impact the weaning process, including incidence of secondary complications, psychosocial factors and rehab practices.

Artificial intelligence based early prediction of bacteremia in patients admitted in medical ICU—experience from a tertiary care hospital in Southern India

G. R[1]; A. M Ahammed[1]
[1]Critical Care Medicine, GG Hospital, Thiruvananthapuram, India
Correspondence: G. R
Intensive care Medicine Experimental 2025* 13(1)*:000186

Introduction: Bacteremia is a frequent and challenging condition with mortality ranging between 3 and 21%. A timely diagnosis and prompt treatment with antibiotics is pivotal for survival. Even though blood culture is the gold standard in bacteremia diagnostics, it is having certain flaws like low true positivity rate, false positivity rate related to contamination is up to 8%, and there is a time lag for reports. Whether machine learning algorithms can be exploited for early prediction of bacteremia is the question which is addressed in our study.
Objectives: To develop and externally validate an Artificial Intelligence Bacteremia Prediction Model (AI BPM)
To evaluate its impact on bacteremia prediction by comparing AI BPM prediction with blood culture reports.
Methods. Parameters used to train the AI model

Age, sex	Presence of fever, hypotension, tachycardia, tachypnea,desaturation, altered mental state
Comorbidities	Labs: raised leukocytes, neutrophils, CRP, Lactate, RFT, LFT
H/o recent hospitalisation	Use of immunosuppressive medications
Recent H/o antibiotic use	Signs of localisations
Recent surgical interventions	Contact with healthcare settings
Presence of indwelling devices	APACHE 4 score

This is a prospective, observational study conducted in the Department of Critical Care Medicine, GG Hospital, Trivandrum, We included all patients admitted in the Medical ICU with at least one set of blood cultures taken. An AI expert created AI model, which was customised to our study criteria, using Random Forest Classifier and implemented using Python version 3.7.3. 566 patients are included in the study, of which 80% dataset is used to train the AI model and 20% dataset is used to test the model performance. Parameters used to train the AI model has been included as a table.
Results.

Model performance metrics and explanation

Metric	Value	Explanation
Accuracy	98%	Percentage of correctly predicted cases out of all cases
Precision	100%	Measures how many predicted positive cases are actually correct. High precision reduces false positives
Recall (sensitivity)	90%	Measures how many actual bacteremia cases were correctly detected. High recall reduces false negatives
F1 Score	95%	Harmonic mean of precision and recall. Used to balance false positives and false negatives
AUROC	0.93	Measures model's ability to distinguish between bacteremia vs no bacteremia. Closer to 1 means better discrimination.

Conclusions: The AI tool developed in our study had a good AUROC of 0.93 to predict bacteremia. The comparatively higher AUROC in our study could be probably due to the larger number of parameters which we took to train the AI model. The sensitivity of 90% and specificity of 100% is also high in our study compared to other peer group studies. With more studies showing the validation of AI model in clinical practice, it can definitely be a promising tool to help clinicians when there is uncertainty regarding the use of empirical antibiotics.

Introduction: Upper gastrointestinal bleeding (UGIB) is frequently suspected in mechanically ventilated critically ill patients. The performance and benefit of upper gastrointestinal endoscopy (UGE) in this setting in still debated. We report the diagnostic and therapeutic impact of UGE in a cohort of unselected mechanically ventilated patients.
Methods: Monocentric, retrospective study in a mixed intensive care unit (ICU).
All the patients who underwent an UGE during their ICU stay between January 2019 and December 2023 were identified. Cases of suspected UGIB were selected from medical records. Patients primarily admitted for gastrointestinal bleeding or in whom UGE was performed for other reason that suspected UGIB were excluded.

Results: 43 patients underwent UGE for suspected ICU-related UGIB
Mean age (years) was 62.2 ± 14.6; mean SAPS II was 50 ± 19; sex ratio (M/F) was 30/13.
48 UGE were performed 17.6 ± 12.5 days after ICU admission. They were motivated by anemia in 28 cases, melena in 10 cases, hematochezia in 6 cases, low transfusion efficiency in 3 cases, and hematemesis in 2 cases.
36 UGE are performed after transfusion of at least one red blood cells pack (2.3 ± 1.4) in the previous 48 h.
UGE was normal in 21 cases, otherwise the main findings were users in 14 cases, esophagitis in 10, gastritis in 4, esophageal varices in 4.
A hemostatic procedure was done during 8 UGE.
Conclusions: If a hemostatic procedure was performed in only 16.7% of UGE, 56% of the endoscopic examinations were abnormal potentially leading to a medical treatment.
The limited number of per-endoscopic hemostatic procedures is an argument to stratify timing of UGE () using recently described dedicated scores. (1)

Introduction: Gastric residual volume (GRV) is a key metric in assessing feeding tolerance among critically ill patients receiving enteral nutrition. Ultrasound (US) has emerged as a non-invasive, bedside tool for GRV estimation. However, its inter-operator reproducibility remains insufficiently validated.
Optimal nutrition is a cornerstone of managing critically ill patients in intensive care units (ICUs), with enteral nutrition (EN) being the preferred method due to its benefits in preserving gut integrity, reducing infection risk, and improving outcomes. However, achieving feeding goals in critically ill patients is often hindered by gastrointestinal intolerance, with gastric residual volume (GRV) serving as a key indicator of feeding tolerance.
Traditionally, GRV is assessed through nasogastric aspiration, a method that, despite being widely used, has several limitations. These include procedural discomfort, variability in measurements, risk of tube displacement, and the potential for nutrient loss. Frequent GRV monitoring can also disrupt enteral feeding, leading to caloric deficits that negatively impact recovery. Given these drawbacks, there is a growing interest in using ultrasound (US) as a non-invasive, bedside tool for GRV assessment.
Ultrasound offers several advantages over nasogastric aspiration, including its ability to provide real-time, reproducible measurements without disrupting feeding or causing discomfort. However, its reliability in clinical practice depends on ensuring inter-operator reproducibility and validating its accuracy compared to the current standard.
Objectives: This study aimed to evaluate the reproducibility of GRV measurement using ultrasound among intensivists and to compare these measurements with traditional nasogastric aspiration.
Methods: A prospective observational study was conducted at Alexandria Main University Hospitals on critically ill patients receiving enteral nutrition. GRV was assessed by ultrasound in the right lateral decubitus position using a standardized protocol, with two attending intensivists performing measurements after specific training. The reproducibility was analyzed using Pearson's correlation, Lin's concordance correlation coefficient, and Bland–Altman plots. GRV measured by ultrasound was compared with nasogastric aspirate values to assess agreement and proportional bias.
Results: The study enrolled 60 patients (57% male, median age 52 years). The Pearson correlation coefficient (r) for ultrasound measurements among intensivists was 0.992, with a concordance correlation coefficient (ρc) of 0.992. Bland-Altman analysis revealed minimal bias (-1.5 mL; 95% CI: -3.7 to 0.7) and narrow limits of agreement, indicating excellent reproducibility. Comparison between ultrasound and nasogastric aspirate GRV measurements showed a high correlation (r = 0.973, ρc = 0.948) with a mean positive bias of 21 mL (95% CI: 15 to 27). Ultrasound demonstrated proportional bias at higher GRVs, with values diverging from nasogastric aspirate.
Conclusions: Ultrasound is a highly reproducible tool for GRV estimation among trained intensivists, with results closely aligning with nasogastric aspiration. Despite minor proportional biases at higher GRVs, ultrasound offers a non-invasive and efficient alternative for assessing feeding tolerance in critically ill patients. Further studies may explore its role in guiding clinical decision-making and optimizing enteral nutrition strategies.

Embedding pastoral and spiritual support in ICU

S. Katsande[1]; S. Van Beveren[2]; MSF. Chong[3]
[1]Intensive Care Unit, Kingston & Richmond NHS Trust Hospital, London, United Kingdom; [2]Pastoral & Spiritual Support, Kingston & Richmond NHS Trust Hospital, London, United Kingdom; [3]Critical Care, Kingston & Richmond NHS Trust, London, United Kingdom
Correspondence: S. Katsande
Intensive care Medicine Experimental 2025* 13(1):*000190

Introduction: Good end-of-life (EOL) care focuses on person-centred, compassionate care, prioritising comfort, dignity and the individual's wishes while also providing emotional, practical and spiritual support for families. Providing opportunities for pastoral support and spiritual reflection help patients and their families cope with the EOL journey. At the end of a person's life the ability to talk to someone about spiritual and existential suffering, which is the morbid suffering relating to loss of hope, futility, remorse, and fear of death, can relieve considerable distress and provide great peace and comfort to a dying person.1
Palliative care in the ICU focuses on preventing and relieving suffering through identification and treatment of pain and other physical, psychological, social and spiritual issues. Spiritual care, however, is not systematically integrated into everyday ICU practice. 2
We challenge the existing approach of care provision in ICU EOL care and argue for using the title of "Pastoral and Spiritual Specialists" rather than "Chaplaincy". These specialists show concern and compassion, provide an avenue for patients and families to open up about their distress and worries and argue for holistic care to be embedded in ICU patient care.
Methods: The percentage of ICU patients, families or carers supported by Chaplains or Pastoral & Spiritual Specialists, was audited over 4 points across a 10-year period from 2015-2024 at Kingston Hospital NHS Foundation Trust (KHFT), a district general hospital in London, UK. Two major changes occurred during this period:
1) At the beginning of COVID-19 Pandemic in 2020, hospital chaplains worked alongside healthcare staff on the clinical frontline at Kingston Hospital to keep families, who were restricted from visiting, updated and supported. From that time, chaplains became an integral part of the ICU team being present in the morning handover and MDT meetings.
2) A name change from "Chaplains" to "Pastoral and Spiritual Specialists" was accompanied with an education programme to improve the level of understanding of Chaplains in EOL care and demonstrate the benefits of spiritual and emotion support to patients, families and staff.
After the above changes were implemented confidential surveys3 with both quantitative and qualitative data were collated and analysed from a total of 30 multidisciplinary (MDT) ICU staff members. We compared data from audits performed in 2015 and 2020 to data in 2023 and 2024 to close the audit loop.
Results: There was a significant increase in percentage of EOL patients, families or carers supported from 27 to 63% (36% increase) when the COVID-19 pandemic started in 2020, as "Chaplains" team were used extensively in Kingston Hospital to keep families, who were otherwise restricted from visiting, updated and supported.
After tailored teaching was provided to enhance ICU doctors' and nurses' knowledge and skills in addressing pastoral, spiritual and cultural needs of ICU service users, there was an increase in the percentage of EOL patients, families/carers supported from 42 to 71% (29% increase)—Graph 1.
The survey highlighted that 13% of staff preferred the use of "Chaplain", 73% preferred a new name change of "Pastoral & Spiritual Specialist", and 14% were "undecisive" (Graph 2). The qualitative data from the survey indicated that there were barriers using term "chaplain" during referrals as it had a religious connotation which resulted in those

who were non-religious to deny the services. The 13% who voted against were concerned if the change of name would lead to those with religious needs being neglected.
Conclusions: ICU-embedded chaplains are a key member of the ICU team who can provide spiritual care and emotional support to critically ill patients and families, acting as a bridge between families and medical staff, particularly during difficult times such as EOL decisions. As we respect the religious and cultural diversities in our increasingly secular society, renaming "Chaplains" to "Pastoral & Spiritual Specialist" offers a more inclusive title, which reduces barriers to communication, addresses patients' unrecognised existential suffering at EOL, and prioritises holistic ICU care. Educating staff about the uncertainties and misunderstandings around the role of Chaplains is significant.

Intensive care Medicine Experimental 2025* 13(1):*000191

Introduction: Sepsis is a severe form of systemic inflammatory response syndrome that is caused by infection. Dysglycemia is a common complication in sepsis and associated with poor prognosis. Compared with static glucose parameters, glycemic variability may be more relevant to the prognosis of critically ill patients. However, prior studies primarily emphasized cross-sectional assessments of glycemic variability, neglecting dynamic fluctuations influenced by clinical interventions and disease trajectories. The association between dynamic glycemic variability and mortality in septic patients remains unexplored.
Objectives: To explore the association between the time-varying glycemic coefficient of variation (GCV) and 28-day mortality in septic patients.
Methods: A retrospective observational cohort study. Adults patients (≥ 18 years) with sepsis admitted to the Department of Critical Care Medicine, Zhongda Hospital, Southeast University, China, between August 2016 and December 2024 were included. Patients with intensive care unit (ICU) length of stay less than 24 h, or fewer than two blood glucose measurements within the first 24 h of ICU admission were excluded. Glycemic variability was quantified as the GCV, calculated daily using the ratio of standard deviation and the mean blood glucose levels. The primary outcome was 28-day mortality. Time-varying Cox models and restricted cubic spline regression were employed to estimate the association between time-varying GCV and 28-day mortality in septic patients.
Results: A total of 2,414 patients were included, with a mean age of 69 years, 66.4% patients were male. The overall 28-day mortality rate was 23.9%. After adjustment for age, body mass index, underlying conditions and severity of disease, baseline GCV (HR 1.08 per 10% increase; 95% CI, 0.96-1.20, $P = 0.189$) was not significantly associated with 28-day mortality, while time-varying GCV (HR 1.28 per 10% increase, 95% CI 1.14-1.43, $P < 0.001$) during the first 14 days was significantly associated with an increased risk of 28-day death. Further analyses indicated that compared to patients with GCV ≤ 0.13, patients with GCV≧0.28 were significantly associated with 28-day mortality (HR 1.48 per 10% increase, 95% CI 1.09-2.01, $P = 0.012$). Subgroup analyses demonstrated that the association between dynamic GCV and mortality was stronger in patients with SOFA scores ≥ 8, lactate levels ≥ 2 mmol/L, non-diabetic individuals, and those requiring renal replacement therapy or mechanical ventilation.
Conclusions: Dynamic glycemic variability is independently associated with increased 28-day mortality in septic patients. Larger prospective studies are required to confirm these findings.

Segregation of healthcare waste in the intensive care unit: a single centre pilot study in Singapore

Y. wong[1]; C. M[1]; B. Tan[1]
[1]anaesthesia, Tan Tock Seng Hospital, Singapore, Singapore
Correspondence: Y. wong
Intensive care Medicine Experimental 2025* 13(1):*000192

Introduction: Singapore's healthcare sector contributes 3.4% of total carbon emissions, ranking Singapore as second globally in healthcare per capital emisions. Locally, medical waste has increased over the

past 5 years from 4400 to 5700 tonnes. Many opportunites to recycle are often missed due to perceived barriers.
Objectives: We aim to increase staff awareness and uptake of plastic waste segregation to facilitate recycling in our hospital.
Methods: We conducted a 2-phase pilot study in 1 Intensive care unit in Singapore for the segregation and recycling of plastic waste in collaboration with a recycling company. In phase 1, we conducted a 1-day trial in a 16-bed ICU whereby a recycling bin was set up for segregating plastic waste. Nursing staff were educated on the types of plastics to be recycled according to the plastic resin identification codes and the recycled waste was weighed. The data collected were used to design the second phase. In phase II, we conducted a 6-week trial in the same ICU where staff were instructed to segregate specific plastic items into a recycling bin for which these bins were weighed daily. In both phases, staff were given a questionaire to fill in during the study period.
Results: In phase 1, the amount of pastic waste generated per patient per day was 0.35 kg. 88.2% of the nursing staff expressed interest in recycling and 61.7% were likely to actively segregate ICU waste. Some barriers included perceived infectious risks, decreased work efficiency and lack of recycling infrastructure.
In phase 2, nurses were asked to segregate 3 specific plastic items—apron covers, water irrigation bottles, and bottle caps. An average of 49.6 kg of plastic waste was segregated per week, averaging 0.44 kg of plastic waste per patient per day. More than 68% of respondents were able to accurately detail the appropriate process of recycling these items. They also suggested including a greater variety of recyclable paper and metal wastes.
Conclusions: Our pilot study highlights the active interest in and feasibility of recycling healthcare waste. Ongoing efforts with our infectious disease department have highlighted greater possibilities for recycling more healthcare waste. Recycling efforts can further be extended hospital wide.

Diagnostic accuracy of transcranial Doppler for delayed cerebral ischemia in aneurysmal subarachnoid hemorrhage: a systematic review and meta-analysis

Y. Fujimoto[1]; K. Yamada[2]; T. Yoshida.[3]
[1]Emergency and Critical Care Medicine, St. Marianna University School of Medicine, Kawasaki, Japan; [2]Department of Traumatology and Critical Care Medicine, National Defense Medical College Hospital, Tokorozawa, Japan; [3]Department of Emergency Medicine, Jikei University School of Medicine, Minato City, Japan.
Correspondence: Y. Fujimoto.
Intensive care Medicine Experimental 2025* 13(1)*:000193.

Introduction: Point-of-care ultrasound use has increased. A systematic review is needed to reevaluate transcranial Doppler (TCD) for assessing cerebral vasospasm in aneurysmal subarachnoid hemorrhage.
Objectives: To assess diagnostic accuracy of TCD for detecting vasospasm and delayed cerebral ischemia (DCI) in adults with aneurysmal subarachnoid hemorrhage.
Methods: We conducted a systematic literature search of MEDLINE, Cochrane Central Register of Controlled Trials, Embase until June 17, 2024, and manually searched the reference lists of the relevant articles. Only English-language publications were included. The publication period was not restricted. Selection and exclusion of studies and data extraction were blinded and checked by two independent researchers. A third reviewer acted as an arbiter. The following data were extracted by pre-defined data extraction form: study characteristics, patient characteristics, index test, reference standard, and diagnostic accuracy parameters. The index test of interest was TCD for assessing DCI. Reference standard in our study was defined as a blinded clinical diagnosis synthesizing test results such as neurological examination, cerebral angiography, computed tomography, or magnetic resonance imaging, due to the absence of a definitive test for DCI in previous studies. We followed the Preferred Reporting Items for Systematic Reviews and Meta-Analyses guidelines and assessed study quality using the Quality Assessment of Diagnostic Accuracy Studies 2 tool. Meta-analysis was conducted to pool the diagnostic accuracy of TCD for detecting vasospasm and DCI. The study protocol was prospectively registered in PROSPERO (CRD42024542692).
Results: Of the 3100 studies identified, 80 studies were full-text reviewed, and 32 studies with 3594 patients were included in the meta-analysis. Pooled sensitivity and specificity were 76% [95% confidence interval: 70—81%] and 77% [68—84%] for spasm and DCI. The area under the receiver operating characteristic curve was 0.82 (Figure). The positive likelihood ratios was 3.4. The negative likelihood ratio was 0.3. Subgroup analysis showed sensitivity and specificity of 75% [69–81%] and 74% [63–83%] using a blood flow velocity $\geq$ 120 cm/s in the middle cerebral artery (19 studies, n = 2302), 80% [49–94%] and 88% [69–94%] using a Lindegaard ratio $\geq$ 3 (5 studies, n = 663), and 79% [72–85%] and 82% [66–91%] in studies with low risk of bias (9 studies, n = 1223).
Conclusions: TCD shows promising diagnostic accuracy for detecting cerebral vasospasm and DCI. Limited studies assessed the Lindegaard ratio accuracy, warranting further research.

*The plots show sensitivity and 1-specificity of individual studies on the diagnostic accuracy of TCD.
*TCD thresholds followed the settings in each study.

Intensive care Medicine Experimental 2025* 13(1)*:000195.

Introduction: Stroke is the leading cause of mortality and long-term disability world-wide. The accurate way to predict the likely long-term outcome (prognosis) for individual patients would help clinicians manage their patients and help relatives and patients come to terms with their changed circumstances. The present study aimed to find out the potential factors that can predict outcome of the critically ill stroke patients using the easily available data like demographics,

comorbidities, clinical presentation and blood investigations (routine plus inflammatory marker) along with the other scores.
Methods: We enrolled a total of 124 patients of either sex, aged above 18 years, diagnosed with ischemic or hemorrhagic stroke and admitted to ICU. The data recorded for each patient included demographic data, comorbidities, drug history, vitals, scores like GCS, NIHSS, APACHE II, routine investigations (CBC, KFT, LFT, TFT, PT, Lipid profile, HbA1C, Serum electrolytes), inflammatory markers, anticoagulation profile (protein C, protein S, antithrombin III), complications and therapies. The primary objective was to find an association between these data and in-hospital mortality. Secondary objectives included association between these data and mortality at 3 months and to find out the functional impairment at 3 months.
Results: Total 124 patients were included in final analysis; out of them 47 patients were diagnosed with hemorrhagic stroke and the remaining 77 with acute ischemic stroke. In the univariate analysis previous history of TIA/stroke; use of anti-hypertensive; hemorrhagic type of stroke; higher NIHSS and APACHE II (both at admission and at 24 h); higher WBC count, NLR, PLR, blood urea, serum creatinine, serum lactate, and serum ferritin; lower GCS, serum T4, protein S, and antithrombin III; and requirement of vasoactive drug infusion, mechanical ventilation and renal replacement therapy were significantly different between survivors and non-survivors (p-value < 0.05). Among these, APACHE II at 24 h [OR (95% CI) 1.34 (1.07 to 1.7); p value = 0.01], need for vasoactive drug infusion [OR (95% CI) 1.63 (0.71 to 3.75); p-value = 0.024] and requirement of mechanical ventilation [OR (95% CI) 14.63 (1.78 to 115.5); p-value = 0.012] were found to be independent predictor of in-hospital mortality. These were also independent predictor [odds ratio (95% CI) 1.79 (1.22 to 2.64), p = 0.003; 2.47 (1.04 to 5.87), p = 0.01 and 11.1 (1.67 to 74.2), p = 0.039, respectively] of 90-day mortality. Around one-third (19 out of 58) of the patients had good functional outcome (mRS 0–2) at 90 days after hospital discharge.
Conclusions: In critically ill stroke patients APACHE II score at 24 h, vasoactive drug infusion and requirement of mechanical ventilation during ICU stay are independent predictors of in-hospital and 90-day mortality.

Intensive care Medicine Experimental 2025* 13(1):*000197.

Introduction: Antimicrobial de-escalation represents a key stewardship strategy in critical care. However, it is underutilized in practice, possibly due to clinical uncertainty and concerns about patient deterioration. Infectious disease (ID) specialists may assist critical care specialists to overcome these barriers through expert consultation and guidance.
Objectives: To evaluate the influence of ID consultation on antimicrobial de-escalation decisions and clinical outcomes in patients with Gram-negative bacteremia.
Methods: A prospective observational study of patients with Gram-negative bacteremia was performed in a general ICU for 6 months. We recorded demographics, ICU length of stay, ICU day of positive blood culture (ICU-POS), antibiotic treatment, blood culture results, time to results, treatment decisions after the results (escalation, de-escalation, or no change), ID consultation, appropriateness of treatment and clinical outcomes.
Results: Out of 68 patients included, 54 (79%) were men. Only six were not treated with antibiotics on ICU-POS. Patient characteristics are summarized in Table 1. Pathogens are summarized in Table 2. Escalation of treatment was performed in 32(47%) patients. Treatment decision was deemed appropriate in 44(65%) patients. Among patients receiving ID consultation (n = 26), recommendations were implemented in 24 cases(92%). Time from blood culture draw to results showed no significant association with treatment appropriateness (p = 0.16) or patient outcomes (p = 0.92). Treatment appropriateness did not significantly affect patient outcomes (p = 0.201). As ID consultation significantly influenced treatment decisions (p < 0.001), antimicrobial de-escalation occurred exclusively in the consultation group (4 patients) and necessary escalation was performed in 20(76.9%) patients. Patients receiving ID consultation demonstrated significantly better clinical outcomes (p = 0.015), with 4.44 times higher odds of improvement and 42% lower odds of mortality compared to the rest.

Table 1 (abstract 000197) Characteristics of patients with Gram-negative bacteremia

	Mean ± SD	Median	IQR [Q25-Q75]	n
Age (years)	69.5 ± 14.0	72	11 [66–77]	68
ICU length of stay (days)	84.1 ± 59.9	84	51 [53–104]	68
ICU-POS day*	46.2 ± 35.0	36.5	59 [15–74]	68
Time from blood draw to results (days)	5.1 ± 1.8	5	8 [3–6]	68

*ICU-POS day = ICU day when positive blood culture was drawn

Table 2 (abstract 000197) Gram-negative pathogens isolated from blood cultures in ICU patients

	n	%
Providencia stuartii	16	23.5
Proteus mirabilis	16	23.5
Acinetobacter baumannii	12	17.6
Klebsiella pneumoniae	12	17.6
Pseudomonas aeruginosa	10	14.7
Stenotrophomonas maltophilia	2	2.9
Total	68	100

Conclusions: Infectious diseases specialists play a crucial role in treatment decisions for Gram-negative infections, significantly improving patient outcomes. Although the appropriateness of treatment decision alone does not appear to significantly influence patient outcomes in this sample, a larger sample size would be needed to detect a true effect.

Video monitoring in the ICU: a "Blessing" or a "Curse"?

K. Bilman[1]; V. Nudelman.[2]
[1]Intensive care unit, Sheba, Ramat Gan, Israel; [2]Icu. sheba medical center, Emek Haela 9, Ramat Gan, Israel
Correspondence: K. Bilman
Intensive care Medicine Experimental 2025* 13(1)*:000198.

Introduction: The General Intensive Care Unit (GICU) at the Sheba Medical Center, a tertiary medical center in central Israel, recently relocated to a new facility, designed to address technological advancements and safety concerns. The new unit, a fortified structure with isolated individual rooms, replaces the previous open-plan ICU. Due to the size and the inability to directly observe patients in multiple rooms, the GICU was equipped with a 98-inch screen in each room and HD PTZ (pan-tilt-zoom) cameras for real-time monitoring. The screens also provide access to electronic health records and multimedia content for patients and families. These innovations enhance safety and care but raise ethical dilemma between patient's privacy and continuous surveillance.
Objectives: To discuss the clinical, operational, and ethical implications of continuous video monitoring in the GICU. To describe the importance of finding balance between safety benefits, workflow efficiency, and ethical challenges affecting patients, families, and staff when using the video monitoring.
Methods: The system employs centralized, high-resolution cameras that enable nurses to monitor patients' physical changes, such as altered breathing, convulsions and signs of delirium or other issues requiring attention. Since the nursing ratio in the GICU is 1:2, when a nurse is caring for one of her patients, the system enables her to view the other patient remotely. This in addition to the option of remote monitoring of the physiological signs on the bedside monitor. We summarized the general feedback that raised from staff, patients, and families to evaluate perceptions of privacy, dignity, and the ethical acceptability of using the security camera monitoring.
Results: Although the continuous video monitoring may have advantages improving detection of clinical deterioration, preventing adverse events or near-miss events, ethical challenges emerged. Conscious or semi-conscious patients expressed discomfort or distress knowing they were constantly observed. Families raised concerns about their loved ones' dignity, especially when monitoring occurred during sensitive moments. Staff reported ongoing struggles to reconcile enhanced safety with preserving patient privacy and dignity in their daily practice. Therefore, the staff may turn-off the cameras and the patients then monitored with the physiological bedside monitor without camera.
Conclusions: Modern multimedia technologies in ICUs improve safety and operational efficiency but pose ethical dilemmas. Continuous video surveillance challenges fundamental principles of privacy and dignity for vulnerable patients. To optimize these systems, we must balance their potential to reduce adverse events against their psychological and ethical impacts. Further research should quantify surveillance efficacy and explore ways such as automating the video analysis and only alerting for potential adverse events without human observation of the video.

Blood pressure threshold and clinical outcome after successful endovascular thrombectomy in acute ischemic stroke

JW. Jung[1]; YD. Kim[1]; J. Heo[1]; H. Lee[1]; HS. Nam.[1]
[1]Neurology, Yonsei University College of Medicine, Seoul, Republic of Korea
Correspondence: J.W. Jung
Intensive care Medicine Experimental 2025* 13(1)*:000200.

Introduction: Despite successful endovascular thrombectomy (EVT), functional independence remains suboptimal. Blood pressure (BP) management post-EVT is crucial, but the optimal BP target remains unclear.
Objectives: This study aimed to analyze BP parameters, thresholds, and their association with clinical outcomes.
Methods: This post hoc analysis of the OPTIMAL-BP trial included patients with successful EVT randomized to intensive (< 140 mm Hg) or conventional (140–180 mm Hg) BP management. Systolic BP (SBP) parameters, variability, and threshold exceedance durations were analyzed. Outcomes included the modified Rankin Scale (mRS) at 3 months and symptomatic intracranial hemorrhage (sICH) within 36 h.
Results: A total of 302 patients were analyzed with 11,461 BP measurements recorded during the first 24 h after EVT. SBP below 100 mm Hg for prolonged continuous durations was associated with worse mRS outcomes (adjusted OR [aOR] 1.18 per hour, 95% CI [1.01–1.42]; P = 0.047) and increased sICH risk (aOR 1.36 per hour, 95% CI [1.11–1.74]; P = 0.009). SBP surges above 190 mm Hg were linked to mRS worsening (aOR 2.90, 95% CI [1.17–7.28]; P = 0.022), but upper thresholds were not significantly associated with sICH.
Conclusions: Prolonged hypoperfusion below 100 mm Hg and extreme surges above 190 mm Hg, rather than overall BP variability, were associated with poor outcomes. These findings highlight the need for a threshold-based BP management approach post-EVT to minimize prolonged hypotension and excessive surges.

a+b: total duration below the lower threshold
b: continous duration below the lower threshod
c: maximum SBP decrease from the mean SBP
d: maximum SBP decrease from the SBP at enrollment
e: maximum SBP increase from the mean SBP
f: maximum SBP increase from the SBP at enrollment
g: total and continous durations exceeding the upper threshold

The schematic graph displays each patient's SBP at enrollment, lowest SBP, highest SBP, and the 24-h mean SBP (green dotted line). It illustrates the differences between mean SBP and lowest SBP (c) as well

as highest SBP (e). Additionally, it shows the differences between SBP at enrollment and lowest SBP (d) as well as highest SBP (f). The total duration (a + b) and the continuous duration (b) during which SBP remained below the lower threshold (blue dotted line) are depicted, along with the total duration and continuous duration (g) during which SBP remained above the upper threshold (red dotted line).

Intensive care Medicine Experimental 2025* 13(1):*000201.

Introduction: Fulminant Clostridioides difficile infection (FCDI) is characterized by severe symptoms such as hypotension, shock, ileus, and toxic megacolon, leading to high mortality rates in critically ill patients. Current guidelines recommend vancomycin plus metronidazole for FCDI. In non-severe and severe CDI, current treatment guidelines recommend fidaxomicin over vancomycin and metronidazole due to higher clinical cure rates and lower CDI recurrence. However, fidaxomicin has not been extensively studied for FCDI, so it is unknown if fidaxomicin would be as effective as vancomycin in this population.
Objectives: We aimed to compare clinical outcomes of fidaxomicin treatment versus vancomycin in critically ill patients with FCDI.
Methods: This clinical effectiveness study utilized the Premier database and included ICU patients > 18 years old admitted to one of over 900 US hospitals between January 1, 2016 and December 31, 2021 who were treated with fidaxomicin or vancomycin therapy for a diagnosis of FCDI. Patients were placed into fidaxomicin or vancomycin groups based on the first 2 days of FCDI treatment. The primary outcome was hospital mortality. Secondary outcomes included clinical cure (survival to discharge), clinical failure (escalation of treatment or mortality), and readmission within 60 days for CDI. Outcomes were compared between vancomycin and fidaxomicin groups. Multivariable logistic regression was used to adjust for differences in baseline covariables.
Results: A total of 81,227 patients were evaluated, 1,355 in the fidaxomicin group and 79,872 in the vancomycin group. Patients were 65 ± 15 years old, 52% female, and 75% white. The most common comorbidities were diabetes (43%), pneumonia (16%), COPD (15%), and respiratory failure (90%). Proton pump inhibitor use was present in 68% of patients and all received broad spectrum antibiotics and vasopressor therapy for shock during their ICU stay. Sixty percent of patients were being treated for an initial episode of CDI. Fidaxomicin patients were more likely to be treated for a recurrent CDI episode compared to vancomycin (27% vs 8%, $p < 0.01$). Metronidazole was co-administered in 48% of fidaxomicin patients and 58% of vancomycin patients ($p < 0.01$). In hospital mortality was similar between groups (15.2% fidax vs. 16.8% vanc, $p = 0.1$). Clinical failure occurred in 16% of fidaxomicin versus 17% of vancomycin patients ($p = 0.34$). Bezlotoxumab use (0.66% fidax vs 0.03% vanc, $p < 0.01$) and fecal transplantation (0.22% fidax vs 0.06% vanc, $p = 0.01$) were used in a small number of patients. Readmission for recurrent CDI occurred more frequently in the fidaxomicin group (5% vs. 2.4%, $p < 0.01$). No difference in mortality, clinical failure, or readmissions were observed after adjustment for covariables ($p > 0.05$ for all).
Conclusions: Fidaxomicin is uncommonly used in critically ill patients with FCDI and was more frequently utilized in patients with a recurrent CDI episode. Fidaxomicin was associated with similar outcomes when compared to treatment with vancomycin. Fidaxomicin may be a reasonable alternative to vancomycin for the treatment of patients with FCDI. Further research is needed.

Intensive care Medicine Experimental 2025* 13(1):*000209.

Introduction: Blood gas analyzers (BGA) deliver hemoglobin (Hb) concentration results in a shorter time than laboratory hematology analyzers (LHA). Potential clinical benefit of faster results is conditioned by the agreement between these two techniques.
Objectives: To assess the concordance of Hb values as measured on a BGA and a LHA during management of gastrointestinal bleeding.
Methods: Prospective monocentric study.
Comparison of Hb values measured on a LHA (SYSMEX XN) and on a BGA (Radiometer ABL90 FLEX) on two simultaneous samples drawn in patients undergoing an esophagogastroduodenal endoscopy for suspected gastrointestinal bleeding.
Results: 164 paired samples obtained in 133 patients.
(SAPS II 46.8 ± 17.4; age 64.9 years ± 14.9).
The mean Hb concentration measured on laboratory hematology analyzer (HbLHA) was 7.75 ± 1.5 (g/dL).
The mean Hb concentration measured on BGA (HbBGA) was 8.3 ± 2.16 (g/dL).
Bias (average of differences) was—0.5 ± 1.5.
Correlation coefficient R2 = 0.54 HbBGA = 0.161 + 1.5 HbLHA.
Agreement between HbLHA and HbBGA is represented in figure.
Conclusions: Among patients with suspected gastrointestinal bleeding, concordance between Hb values measured on a HLA and a BGA is low. Results from these two techniques cannot be used indifferently for diagnosis and clinical management.

Agreement between HbLHA and HbBGA.

Signature of impaired efferocytosis early after coronary artery bypass grafting (CABG) marks patients with increased tissue damage and risk for acute kidney injury (AKI)

K. Laurent[1]; A. Cattini[1]; M. Elbaz-Kanner[2]; K. Welzenbach[1]
[1]Immunology, Novartis Biomedical Research, Bâle, Switzerland; [2]Biomarker Development, Novartis Biomedical Research, Bâle, Switzerland.

Intensive care Medicine Experimental 2025* 13(1)*:000210.

Introduction

- AKI is a common complication in CABG and increases morbidity, risk for chronic kidney disease (CKD) and mortality [1, 2]. Impaired efferocytosis (clearance of dying cells/ debris) has been implicated in the pathogenesis of AKI while promotion of efferocytosis has been beneficial in preclinical models of AKI [3-5]. To date there is no study assessing biomarkers suggestive for impairment of efferocytosis and their relationship with AKI in adult CABG patients.

Objectives

- Assess the longitudinal trajectories of biomarkers of biomarkers for impaired efferocytosis in an exploratory cohort of CABG patients and investigate their relationship with markers of tissue injury, extracellular vesicles (EVs), coagulation and AKI.

Methods

- Plasma and urine from 10 patients with risk for AKI (CKD and type 2 diabetes) undergoing CABG were prospectively sampled (-24 h, + 2 h, + 6 h, + 24 h, + 48 h post-surgery). Markers for impaired efferocytosis (increased soluble Mer or AXL and reduced MFG-E8) were quantified and integrated into a novel arbitrary *Efferocytosis Impairment Score* EIS: sAXL x sMer)/sMFG-E8/1000. Cell/tissue damage (dsDNA, AST, ALT, LDH), D-Dimer and AKI markers (pCrea, uNGAL) and *AKIRISK™ Score* = (TIMP-2 * IGFBP-7)/1000, NephroCheck™) were assessed. EVs were assessed by flow cytometry for 39 surface markers, including phosphatidylserine (PS), CD11b and CD235ab.

Results: Biomarkers of impaired efferocytosis were extensively changed in 3 of 10 patients (30%) at 2 h post CABG surgery. These 3 patients had an EIS score of 19.8 ± 10.6 (EIShigh; n = 3) vs 0.7 ± 0.65 (EISlow; n = 7). Besides, EIS high patients showed significantly elevated levels of cell free dsDNA, PS + , CD11b + and CD235ab + EVs, and D-Dimer (> 8 µg/mL) compared to patients with EISlow at 2 h post-surgery implying higher rates of cell death, prothrombotic EV and higher fibrinolysis. These markers preceded LDH and AST which raised substantially in EIS high patients but only marginally in EIS low patients at later timepoint (> 6 h). In urine samples taken 6 h post-surgery, EIShigh patients showed increased uNGAL (234.8 ± 91.5 ng/mL EIShigh vs 7.2 ± 7.3 ng/mL EISlow) and an AKIRISK™ Score of 0.9 ± 0.2 EIShigh vs 0.06 ± 0.05 EISlow, both readouts marking for high risk to develop AKI. Indeed, in two of the EIS high patients pCrea increased > 100% from baseline 24 h post-surgery defining AKI stage 2 (KIDIGO). AKI markers including pCrea declined 48 h post-surgery suggesting a transient episode of AKI in these patients.
Conclusions: 30% of CAGB patients showed pronounced elevated biomarkers of impaired efferocytosis early post-CABG surgery. These preceded tissue injury and transient AKI suggesting involvement in the pathogenesis of AKI post-CABG. Confirmation prospective studies and applicability of early efferocytosis impairment for identifying AKI risk patients are required, also to support the development of efferocytosis-promoting therapies to protect and treat AKI.

SomaScan™ proteomic profiling in coronary artery bypass grafting (CABG) reveals a patient subgroup with impaired efferocytosis, increased tissue damage, and higher risk of acute kidney injury (AKI)

S. Pfister[1]; K. Laurent[1]; M. Elbaz-Kanner[2]; K. Welzenbach[1]
[1]Immunology, Novartis Biomedical Research, Basel, Switzerland; [2]Biomarker Development, Novartis Biomedical Research, Basel, Switzerland
Correspondence: K. Welzenbach
Intensive care Medicine Experimental 2025* 13(1)*:000212.

Introduction: Acute kidney injury (AKI) is a common complication after CABG associated with increased morbidity and mortality [1, 2]. Early stratification of patients at risk for AKI post-CABG may help develop effective therapies. We hypothesized that early proteomic profiles after CABG could identify patients at risk for AKI and relate to insufficient clearance of dying cells (efferocytosis), which contributes to AKI pathogenesis [3].
Objectives: Assess proteomic trajectories and investigate relationship to markers of efferocytosis, tissue injury and AKI in a cohort of CABG patients.
Methods
Plasma and urine from 10 patients with risk for AKI (CKD and type 2 diabetes) undergoing CABG were prospectively sampled (-24 h, + 2 h,

+ 6 h, + 24 h, + 48 h post surgery). SomaScan™ proteomics dataset (7596 analytes) [4] was analysed using *limma-voom* in R. Patients with signature of impaired efferocytosis (increased soluble *Mer* or *AXL* and reduced *MFG-E8*) were identified using a novel Efferocytosis Impairment Score "*EIS*" (sAXL x sMer)/sMFG-E8/1000. AKI (risk) biomarkers *pCrea*, *uNGAL* and AKIRISK™ Score = [(*TIMP-2* * *IGFBP-7*)/1000, NephroCheck™] were assessed. AKI was defined by > 100% rise of pCrea over pre-surgery levels.

Results: Significant biomarker changes were observed a*t* 2 h (plasma) and 6 h (urine) post-surgery. Plasma biomarkers (such as *LPR1b, ANK2, Siglec11, CCPG1*) were notably elevated in 9/10 patients at 2 h post-surgery and preluded typical acute phase proteins (*SAA1, SAA2, CRP*) by several hours. 3/10 patients had an efferocytosis impairment score of > 5 (EIShigh). This group differed from EISlow (EIS < 5) by increased proteomic pathway signatures for acute phase responses/myocardial damage (plasma), and signatures of impaired efferocytosis and kidney damage (urine). Proteomics detected increased markers for cell damage (*actinine alpha2*), neutrophil activation (*MPO*) and vascular leakage (*FGFBP3*) in the EIShigh group at 2 h post-surgery. Novel urine markers of tissue damage such as *biliverdin reductase A*, *apolipoprotein B,* and *mRNA editing enzyme TOR signaling pathway regulator* were highly elevated in EIShigh patients 6 h post-surgery. Indeed, *uNGAL* and NephroCheck™ were markedly increased in urine of EIShigh group with 2/3 exhibiting a transient rise of pCrea to > 100% over baseline at 24 h (AKI stage 2).

Conclusions: SomaScan proteomics facilitated the clustering of patients into a subgroup with impaired efferocytosis pathways as early as 2 h post-CABG surgery. This subset (EIShigh) exhibited increased markers related to cell damage, immune system activation, and biomarkers for AKI. The novel biomarkers identified may assist in early identification of AKI risk patients post-CABG, but larger cohorts are needed for validation. Such studies are necessary to also support the development of new therapies targeting AKI, including those promoting efferocytosis.

Interrater reliability and predictive modeling of nutritional assessment tools in critically Ill COVID-19 patients: a secondary data analysis of a cohort study

P. Mohammadi[1]; M. Mohammadi[2]; HA. Varpaei[3]
[1]Pain Research Center, Tehran University of Medical Science (TUMS), Tehran, Islamic Republic of Iran; [2]Anesthesiology department; medicine faculty, Tehran University of Medical Science (TUMS), Tehran, Islamic Republic of Iran; [3]College of nursing, Michigan State University, East Lansing, United States of America.
Correspondence: M. Mohammadi
Intensive care Medicine Experimental 2025* 13(1)*:000213.

Introduction: COVID-19's inflammatory responses increase the risk of malnutrition in patients admitted to intensive care patients. Reported malnutrition rates vary markedly—from 28.2% to 67.3%—depending on the assessment tool used, underscoring data gaps and variability. Recognizing that essential nutritional data are not always available for every patient, this study employs a secondary analysis to evaluate the interrater reliability among common nutritional scoring systems. In addition, we aimed to develop equations that establish quantitative relationships between these nutritional assessment tools, enhancing their comparability and practical application.

Methods: The present study was a secondary data analysis of prospective cohort. The study was obtained institutional review board approval from Tehran University of Medical sciences (IR.TUMS.IKHC.REC.1400.229). We performed a secondary analysis on data from 110 COVID-19 patients admitted to the intensive care unit (59.1% men; mean age 52 ± 15). Four assessment tools were evaluated: Nutritional Risk Screening 2002 (NRS2002), Mini Nutritional Assessment (MNA), modified Nutrition Risk in Critically Ill (mNUTRIC) score, and Prognostic Nutritional Index (PNI). Pearson correlation and Cohen's Kappa coefficients were calculated to assess interrater reliability. Additionally, curve estimation models were developed to explore the relationships among scores from different tools.

Results: Linear curve estimation was applicable for most pairs, except for the PNI–mNUTRIC pair, which was best modeled by a quadratic equation. Notably, the predictive model for NRS2002 based on the MNA score resulted in the highest R-squared value (R^2 = 0.636). The NRS2002 showed fair to moderate agreement with the MNA (κ = 0.289, p < 0.001) and with mNUTRIC (κ = 0.244, p = 0.001), but only slight and non-significant agreement with the PNI (κ = 0.114, p = 0.255). In contrast, the MNA demonstrated moderate to substantial agreement with mNUTRIC (κ = 0.348, p < 0.001) and a trend toward agreement with the PNI (κ = 0.135, p = 0.089).

Conclusions: Our findings support a linear association between several nutritional assessment tools in COVID-19 patients admitted to ICU. Promising results show an adequate predictive model for NRS2002 based on the MNA score. It is recommended to utilize the most comprehensive nutritional scoring system suitable for the clinical setting. Nonetheless, in scenarios where laboratory data or time are limited, these tools may be employed interchangeably, leveraging their predictive capabilities to ensure effective nutritional assessment.

Table 1 (abstract 000213) Curve estimates and equation modeling

	Test statistics	R^2	Equation model
mNUTRIC predicted by PNI	F =7.218, p=.001	.119	mNUTRIC= 8.92 - .207(PNI) + .002 $(PNI)^2$
PNI predicted by MNA	F= 5.672, p=.019	.050	PNI= 19.793+1.271 (MNA)
mNUTRIC predicted by MNA	F=23.476, p<.001	.179	mNUTRIC=10.991 - .604 (MNA)

Intensive care Medicine Experimental 2025* 13(1):*000215.

Introduction: Ketoacidosis is a metabolic state where ketone bodies increase with decreasing serum bicarbonate levels and pH. Starvation is one of its causes. Starvation ketoacidosis (SKA) may occur in children after traumatic brain injury (TBI) due to metabolic adaptation to fasting. This setting may potentiate cerebral microinfarctions leading to altered cerebral metabolism. This eventually leads to worsening coagulopathy and acidosis,(1) Literature is sparse in highlighting the effect of SKA in children with TBI.
Objectives: The primary objective is to find the incidence of SKA. Secondary objectives are the effect of SKA on outcome, its relation to the time from injury to admission, and evaluation of the Glasgow Outcome Score extended (GOS-E) at 3 months.
Methods: After ethics approval and trial registration, a prospective observational study was conducted after written and informed consent. Inclusion criteria: children aged 2 years to 12 years with moderate to severe isolated TBI. GCS < 5, hospital admission > 24 h of injury, known pre-existing metabolic disorders that may cause ketoacidosis, known neurodevelopment delay, and injury severity score (ISS) > 25 were excluded. All patients received standard of care as per formulated guidelines. At the time of assessment, arterial blood samples were collected for serum ketone levels and were measured by point-of-care testing using ketone strips. SKA was defined as serum ketone > 0.6 mmol/L along with pH < 7.30, HCO3-values < 18 meq/dl, normal lactate levels, and blood glucose level ≤ 80 mg/dl. Outcomes were assessed as death and/or ventilator-free days on or before 7 days post-admission and GOS-E at 3 months.
Results: 456 patients were screened out of whom 121 were analysed as per inclusion criteria (Fig. 1). Table 1 shows the baseline characteristics, ketone levels, ABG values, outcomes, and complications of the study.

Particulars	Total	SKA (40)	Non-SKA(81)	p-value

RBS	87.98 ± 26.2	60.85 ± 12.66	102.5 ± 18.93	0.00 β
GCS at discharge	9(7,10)	9(7,10)	9(7,10)	0.97μ
GCS motor	5(4,6)	4(3,5)	6(4.5,6)	0.01 μ
Death %(n)	7.4 (9)	12.5 (5)	4.9(4)	0.27α
Ventilator-free days	3.41 ± 1.78	2.79 ± 1.81	3.66 ± 1.72	0.01β
GOS-E	5 (4,6)	5 (4,6)	6 (4,6.5)	0.31μ
Neuro worsening %(n) GCS motor	14(17)	30(12)	6(5)	0.00 α
Seizure %(n)	5(7)	15(6)	1(1)	0.01 α
Hemiparesis %(n)	2.5(3)	7.5(3)	0(0)	0.00 α
VAP %(n)	11.5(14)	25(10)	5(4)	0.01 α

Conclusions: In our study, incidence of SKA was 33% with more mortality, fewer ventilator-free days, and more complications than non-SKA. Time to injury, number of referrals, and consumption of last meal may be predisposing factors for developing SKA in children with TBI.

Intensive care Medicine Experimental 2025* 13(1):*000216.

Introduction: The pathophysiology of sepsis-induced acute kidney injury remains elusive. Although mitochondrial dysfunction is often perceived as the main culprit, data from preclinical models yielded conflicting results so far. The aim of this study was to assess the immune-metabolic background of sepsis-associated renal dysfunction using sequential biopsy approach with mitochondria function evaluation in a large clinically relevant porcine models mimicking two different paces and severity of sepsis and couple this approach with traditional parameters of renal physiology.
Methods: In this randomized, open-label study, 15 anaesthetized, mechanically ventilated and instrumented (renal artery flow probe and renal vein catheter) pigs were randomized in two disease severity groups—low severity (LS) sepsis (0.5 g/kg of autologous faeces intraperitoneally) and high severity (HS) sepsis (1 g/kg of autologous faeces intraperitoneally). Sequential cortical biopsies of the left kidney were performed and a pyramid-shaped kidney specimen with cortex, medulla and renal papilla was resected and processed at the end of the experiment. Oxygraphic data and western blot analysis of proteins involved in mitochondrial biogenesis and degradation were obtained.
Results: In contrast to increased mitochondrial activity observed in LS sepsis, a significant decrease in the oxidative phosphorylation capacity together with an increase in the respiratory system uncoupling was observed during the first 24 h after sepsis induction in the HS group. Those changes preceded alterations of renal haemodynamics. Furthermore, serum creatinine rose significantly during the first 24 h, indicating that renal dysfunction is not primarily driven by haemodynamic changes. Compared to cortex, renal medulla had significantly lower oxidative phosphorylation capacity and electron-transport system activity. PGC-1-alfa, a marker of mitochondrial biogenesis, was significantly decreased in HS group.
Conclusions: In this experimental model, unique sequential tissue data show that the nature and dynamics of renal mitochondrial responses to sepsis are profoundly determined by the severity of infectious challenge and resulting magnitude of inflammatory insult. High disease severity is associated with early and stepwise progression of mitochondria dysfunction and acute kidney injury, both occurring independently from later renal macro-haemodynamic alterations. Our data may help explain the conflicting results of preclinical studies and suggest that sepsis encompasses a very broad spectrum of sepsis-induced acute kidney injury endotypes.

Introduction: Cardiac arrest in ICU settings is associated with high mortality despite advances in resuscitation techniques [3,4]. While cardiopulmonary resuscitation (CPR) duration is a well-established predictor of survival [5,6], the independent impact of ROSC timing remains underexplored [7]. Achieving ROSC earlier may reduce ischemic injury and improve outcomes, but confounding with CPR duration often limits interpretation. This study investigates whether shorter time to ROSC independently predicts survival in ICU cardiac arrest patients after adjusting for illness severity and resuscitation duration [3,5,8].
Objectives: This study aimed to evaluate the association between time to return of spontaneous circulation (ROSC) and survival to hospital discharge in intensive care unit (ICU) patients with cardiac arrest.
Methods: A retrospective cohort study was conducted in the ICU of a secondary-care hospital in Saudi Arabia. Medical records of adult patients (≥ 18 years) who experienced cardiac arrest and received CPR between January 2023 and December 2024 were reviewed. Patients with documented ROSC times were included. Variables collected included age, sex, CPR duration, ROSC time, Simplified Acute Physiology Score II (SAPS II), and survival to discharge. Multivariate logistic regression was used to identify independent predictors of survival, adjusting for CPR duration and SAPS II.
Results: Among 111 patients, the overall survival-to-discharge rate was 32.43%. Survivors had significantly shorter ROSC times compared to nonsurvivors (mean: 9.8 ± 3.4 vs. 17.5 ± 6.1 min; $p < 0.001$). Time to ROSC was independently associated with survival (adjusted OR = 1.32 per minute reduction; 95% CI: 1.12–1.55; $p < 0.001$). Longer CPR duration was negatively associated with survival (adjusted OR = 0.85 per minute increase; 95% CI: 0.78–0.92; $p < 0.001$). Age, sex, and SAPS II were not significantly associated with survival.
Conclusions: A shorter time to ROSC is a strong and independent predictor of survival in ICU cardiac arrest. These findings support implementing structured resuscitation protocols focused on minimizing ROSC time through timely interventions and optimized CPR delivery. Further multicenter studies are needed to validate these results and assess long-term neurological outcomes [9,11].

Discharge destination as a predictor of ED revisit: a study on survivors of the emergency ICU

GS. Wang[1]; SY. Lee[2]; YS. Jung[3]
[1]Emergency medicine, Seoul National University Hospital, Seoul, Republic of Korea; [2]Public Healthcare Center, Seoul National university hospital, Seoul, Republic of Korea; [3]Emergency medicine, critical care medicine, Seoul National University Hospital, Seoul, Republic of Korea
Correspondence: G.S. Wang
Intensive care Medicine Experimental 2025* 13(1)*:000218.

Introduction: While ICU survival has improved, survivors are at increased risk of frailty and higher healthcare utilization, including ED visits, due to post-intensive care syndrome (PICS). Individualized discharge planning is increasingly important, yet direct discharge to home is becoming more common due to patient preference, bed shortages, and transfer delays. This study aimed to analyze post-discharge trajectories and factors associated with 30-day ED revisits among survivors from an emergency ICU (EICU).
Methods: This retrospective single-center cohort study included 611 patients admitted via the ED and discharged alive from the EICU between June 1, 2021, and June 30, 2023, excluding those who died in the ICU or after transfer to general wards. Patients were grouped by discharge destination: direct home (DH), ward-to-home (WH), and transfer to another hospital (TF). The primary outcome was ED revisit within 30 days; the secondary outcome was revisit within 14 days. Multivariable logistic regression was performed to identify independent risk factors for early ED revisits.
Results: Among 611 patients, 80 (13.1%) were in the DH group, 294 (48.1%) in WH, and 237 (38.8%) in TF. The TF group was older ($p < 0.001$), and unmarried patients were more likely to be discharged directly home. Solid tumors ($p = 0.028$), diabetes ($p = 0.008$), dementia ($p < 0.001$), and cerebrovascular disease ($p = 0.008$) were more common in TF. Hematologic malignancies were more frequent in WH ($p = 0.011$). The TF group had higher rates of sepsis ($p < 0.001$), cardiac

arrest ($p = 0.036$), mechanical ventilation ($p = 0.003$), ICU delirium ($p = 0.006$), and POLST completion ($p < 0.001$), with longer hospital and ICU stays ($p < 0.001$ for both). Toxicologic admissions were more frequent in DH ($p < 0.001$).
At discharge, tracheostomies, home ventilators, nutritional tubes, urinary catheters, and drainage devices (e.g., PTBD, PCD) were significantly more common in TF.
There were no significant differences in 30-day ($p = 0.989$) or 14-day ($p = 0.267$) ED revisit rates among the groups. However, tracheostomy (OR 2.48) and drainage catheter (OR 4.85) were significantly associated with increased ED revisit risk.
Conclusions: Discharge destination was not associated with short-term ED revisit risk among EICU survivors. However, the presence of a tracheostomy or drainage catheter significantly increased revisit risk, indicating the need for tailored post-discharge planning. Further research is warranted to develop structured ICU discharge protocols.

A service evaluation of extubation failure in a major trauma critical care unit in the United Kingdom

W. Leeson[1]; V. Macbean[2]; S. Ledger[3]; C. Hill[2]
[1]Critical Care, University Hospitals Birmingham, Birmingham, United Kingdom; [2]College of Health, Medicine and Life Sciences, Brunel, London, United Kingdom; [3]1nspire Physiotherapy, Denham Street, Allenstown, Rockhampton, Queensland, Australia.
Correspondence: W. Leeson.
Intensive care Medicine Experimental 2025* 13(1)*:000219.

Introduction: Extubation failure is associated with poor health outcomes for patients and various studies have identified multiple risk factors and causes (Li et al.,2023; Torrini et al., 2021).
Objectives: The aim of this study was to evaluate local risks and causes of extubation failure via a retrospective service evaluation in a trauma critical care unit over a 6-month period.
Methods: Extubation failure, defined as re-intubation within 72 h, was assessed in patients aged ≥ 18 years who were mechanically ventilated (MV), electively extubated, and survived 72 h post-extubation. Patients who had a tracheostomy, or were extubated for palliative purposes were excluded. Independent t-tests were used to determine between-group differences in length of stay, days MV prior to extubation, age and APACHE II score. A risk ratio was used to determine the probability of a failed extubation based on whether the patient was extubated on a weekday or weekend, and during the daytime or overnight. The documented cause of extubation failure was also recorded.
Results: Of 208 patients electively extubated, 38 (18.4%) failed. Primary documented causes were poor cough with retained secretions (31.6%), agitation/delirium (23.7%), hypoxia (15.8%) and airway obstruction (10.5%). There were no significant differences in age (-1.48; 95% CI, -6.81, 3.84, p = 0.58) or APACHE II score (-0.95; 95% CI, -3.11, 1.23, p = 0.39) between successful and failed extubations. However, patients who experienced extubation failure had a significantly longer MV duration prior to extubation (10.1 ± 6.2 vs 3.7 ± 3.3 days; 95% CI 4.9, 7.8; p < 0.001) and a significantly longer critical care length of stay (mean difference 15.6 days; 95% CI, 12.9, 18.4; p < 0.001) compared to those successfully extubated. Following extubation, the risk ratio of a failed extubation occurring overnight vs daytime was 1.03 (95%CI 0.9 to 1.2), and the risk ratio of a failed extubation occurring on the weekend vs weekday was 1.0 (95%CI 0.9 to 1.2).
Conclusions: Extended duration of MV was associated with failure. Factors such as age, APACHE II score, time of day, and day of the week were not identified as being associated with extubation failure. Primary reasons for failure were poor cough or delirium. The results of this service evaluation provide a rationale for undertaking a quality improvement initiative, to implement a protocol and standardised assessment pathway for extubation. Future research should include a qualitative approach to explore clinicians' decision-making processes around extubation. This service evaluation has highlighted that clinicians should carefully consider all potential risk factors before trialling an extubation, particularly being cognizant of patients who have been MV for a prolonged period.

Intensive care Medicine Experimental 2025* 13(1)*:000220.

Introduction: Following vvECMO initiation, the intensity of mechanical ventilation is typically reduced, but the optimal ventilation strategy during vvECMO remains a matter of debate [1].
Previous studies describing ventilator adjustments upon vvECMO initiation were limited to daily recordings of ventilatory parameters. However, rapid adjustments may have a particularly pronounced effect on survival [2,3], creating the need to analyze granular data. In this, mechanical power (MP), estimating the risk of ventilator-induced lung injury (VILI) by combining several parameters, can serve as an appealing tool to quantify the de-escalation of ventilatory intensity during vvECMO initiation. The contribution of individual ventilatory adjustments on MP reductions during vvECMO initiation has yet to be assessed.
Objectives: To assess immediate changes in MP upon vvECMO initiation and the contribution of individual ventilatory parameters.
Methods: Adult patients undergoing vvECMO from 2019 to 2025 at Charité—Universitätsmedizin Berlin, Berlin, Germany, with available ventilatory parameter data, were eligible for inclusion. Median ventilatory parameters (respiratory rate [RR], tidal volume [Vt], peak-inspiratory pressure [Ppeak], positive end-expiratory pressure [PEEP]) and arterial blood gases measured during the ± 4 h of vvECMO initiation were used to calculate changes. MP was calculated using the previously published simplified equation $MP = 0.098 \times RR \times Vt \times (Ppeak - 0.5 \times (Ppeak - PEEP))$ [3,4]. Changes upon vvECMO initiation were assessed using the Wilcoxon rank-sum or signed-rank test, as appropriate. This study was approved by Charité's Ethics Committee (*EA2/139/20*).
Results: 417 patients (27.3% female, median [interquartile range] age 57.8 [50.1,63.8]) were included. Hospital mortality was 44.6% (n = 186). The median SOFA Score before vvECMO was 14.0 (12.0,17.0), and the median P/F ratio was 111.7 mmHg (81.9,156.8).
Pre-vvECMO MP was lower (p < 0.001) in survivors (16.8 J/min [10.6,23.6]) vs. non-survivors (21.6 J/min [16.0,27.4]). Pre vvECMO, RR was 22 bpm (18.0,25.0) in survivors and 23 bpm (20.0,25.0) in non-survivors (p = 0.034), PEEP was 14.0 cmH2O (10.0,17.0) in survivors and 16.0 (14.0,18.0) in non-survivors (p < 0.001). No significant differences were observed for Vt (5.8 ml/kg predicted body weight [4.8,7.1], p = 0.10) and dynamic driving pressure (DP = Ppeak-PEEP; 17.0 cmH2O [14.0,19.5], p = 0.06) among both groups.
Upon vvECMO initiation, MP decreased by a median of -8.4 J/min (-13.5,-4.1) in survivors and -11.8 J/min (-17.4,-6.7) in non-survivors (p < 0.001, Fig. 1). This was mainly attributable to DP, RR, and Vt, while PEEP remained clinically unchanged (Fig. 1, Fig. 2).
In survivors, 96.7% (-100.0%,-86.5%) of MP decreases occurred within the first two hours, while in non-survivors 94.0% (-100.0%,-75.0%) of changes occurred during this period (p = 0.025).
Prior to vvECMO P/F ratio was higher among survivors than non-survivors (Fig. 3). After vvECMO initiation, P/F ratio increased, mainly driven by a decreased fraction of inspired oxygen (FiO2), with no significant post-vvECMO differences by survivor status (Fig. 3). Arterial partial pressure of carbon dioxide (PaCO2) decreased by -13.6 mmHg (-24.7,-6.6) with no significant differences between both groups (p = 0.23).
Conclusions: The initiation of vvECMO resulted in a significant overall reduction in MP by 61.5%. This decrease was primarily driven by reductions in DP, Vt, and RR, while PEEP remained clinically comparable. Changes predominantly occurred during the first two hours post-vvECMO and were more pronounced among non-survivors. At the same time, the PF ratio increased, primarily due to a reduction in FiO2. These findings highlight the importance of vvECMO in providing lung-protective ventilation while ensuring adequate gas exchange, even in patients with severely compromised lungs.

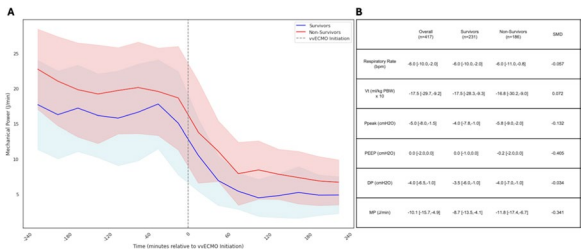

Fig. 1 (abstract 000220) Adjustment of ventilator parameters during vvECMO initiation. (A) MP trends in survivors vs. non-survivors from 4 h before to 4 h after the start of vvECMO. The X-axis represents time (in minutes), while the Y-axis indicates median MP (J/min) and IQR, which was calculated every 30 min. (B) Changes in ventilatory parameters during the last 4 h before and 4 h after start of vvECMO. Medians and interquartile range were calculated for the 4-h period before and the 4-h period after vvECMO initiation. *Abbreviations: bpm = breaths per minute, Vt = tidal volume, PBW = predicted body weight, Ppeak = peak inspiratory pressure, DP = dynamic driving pressure, MP = mechanical power, SMD = standardized mean difference.*

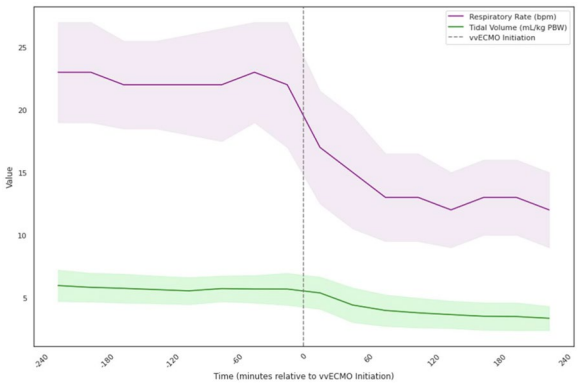

Fig. 2 (abstract 000220) Adjustment of tidal volume (Vt) and respiratory rate during vvECMO initiation. Overall trends in ventilatory parameters from 4 h before to 4 h after start of vvECMO. The X-axis represents time (in minutes), while the Y-axis indicates median values of ventilatory parameters (Vt in ml/kg PBW and respiratory rate) and IQR, which were calculated every 30 min. *Abbreviations: bpm = breaths per minute, PBW = predicted body weight.*

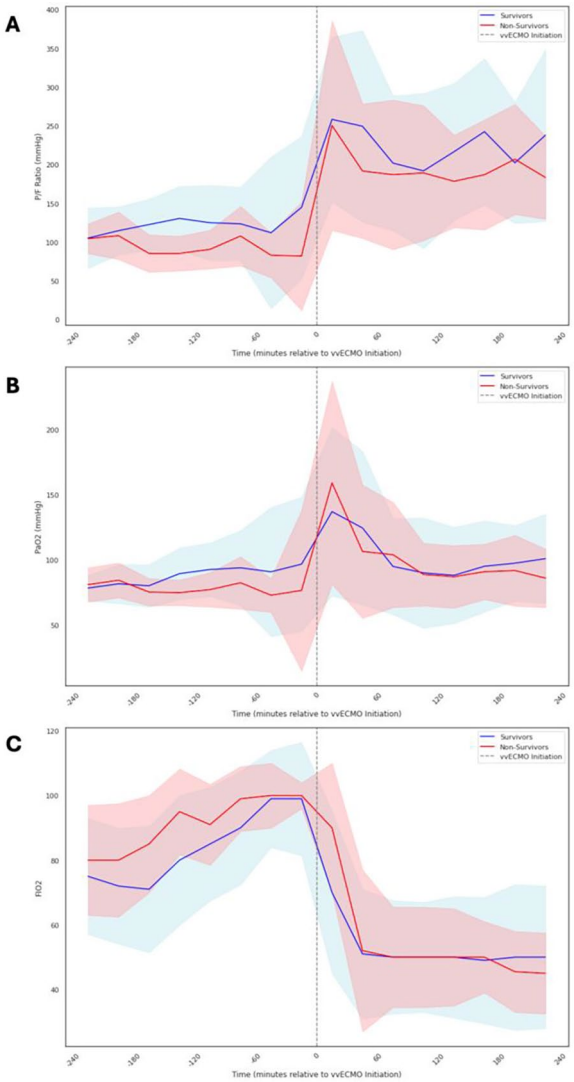

Fig. 3 (abstract 000220) Gas exchange during vvECMO initiation. (A) Line graph depicting P/F ratio trends in survivors vs. non-survivors from 4 h before to 4 h after the start of vvECMO. The median P/F-ratio pre vvECMO was 125.5 mmHg (91.8,180.4) in survivors and 95.6 mmHg (73.9,130.4) in non-survivors ($p < 0.001$). The median P/F ratio post vvECMO was 213 mmHg (142,302.6), with no significant differences between both groups ($p = 0.06$). (B) Line graph depicting arterial partial pressure of oxygen (PaO2) trends in survivors vs. non-survivors from 4 h before to 4 h after start of vvECMO. The median PaO2 pre-vvECMO was 87.8 mmHg (74.1,116.7) in survivors and 80.3 mmHg (68.8,92.3) in non-survivors ($p < 0.001$). The PaO2 post-vvECMO median was 99.6 mmHg (76.2,144.2) with no significant differences between both groups ($p = 0.22$). (C) Line graph depicting fraction of inspired oxygen (FiO2) trends in survivors vs. non-survivors from 4 h before to 4 h after start of vvECMO. The median FiO2 pre-vvECMO was 80% (55.5,99.2) in survivors and 88.5% (70.2,100.0) in non-survivors ($p < 0.001$). The median FiO2 post-vvECMO was 50.0% (40.0,70.0) with no significant differences between both groups ($p = 0.92$)
In all graphs, the X-axis represents time (in minutes), while the Y-axis indicates median values for (A) P/F ratio (mmHg), (B) PaO2 (mmHg), and (C) FiO2 (%), all with IQRs, which were calculated every 30 min.

Introduction: Accurate assessment of fluid responsiveness is crucial for effective hemodynamic resuscitation. Current methods primarily rely on cardiac output (CO) monitoring, often requiring invasive techniques. The VASCOVID project, a collaborative European initiative, has recently validated a non-invasive device for continuous microvascular flow monitoring. This platform integrates Diffuse Correlation Spectroscopy (DCS) and Time-Resolved Near-Infrared Spectroscopy (TR-NIRS) to measure microvascular metabolic and flow-related parameters.
Objectives: To evaluate dynamic changes in microvascular flow and CO during a passive leg raising (PLR) maneuver.
Methods: This proof-of-concept observational study included both healthy subjects and ICU patients undergoing a PLR maneuver. Local microvasculature was assessed with the VASCOVID platform on the brachioradialis muscle, deriving the microvascular blood flow index (BFi) and tissue oxygen saturation (StO2). In healthy subjects, CO was estimated using the volume-clamp method (Finapres®, Finapres Med). In ICU patients, CO was assessed via an invasive hemodynamic monitor based on pulse waveform analysis with internal calibration (ProAQT®, Getinge), connected to the patient's arterial line. Subjects were classified as "responders" (CO-R) if their CO increased by at least 10% within 60 s of PLR. Continuous variables are reported as median (IQR), while categorical variables are expressed as absolute numbers (percentage). The predictive ability of microvascular variables for CO-R was assessed using Receiver Operating Characteristic (ROC) analysis.
Results: A total of 24 healthy subjects (32, 30–42 years) and 13 ICU patients (64, 61–72 years) were included. All ICU patients were receiving mechanical ventilation, and 10 (77%) required vasopressor support (Norepinephrine dose 0.25, 0.1–0.4 mcg/kg/min). Changes in CO during the PLR were effectively tracked by both BFi and StO2 (Figure). Thirteen (56%) healthy subjects, and 4 (31%) patients were CO-R. BFi changes showed an AUC of 0.74 (95% CI 0.6–0.9; $p < 0.01$), while StO_2 changes had an AUC of 0.80 (95% CI 0.64–0.96; $p < 0.001$) for predicting CO-R. The combination of both signals exhibited strong predictive performance for CO-R detection (AUROC 0.90, 95% CI 0.7–1; $p < 0.001$).
Conclusions: Non-invasive monitoring of peripheral microvascular flow using diffuse optics may serve as a valuable tool for assessing fluid responsiveness, potentially minimizing the need for invasive

Methods: Further research is needed to evaluate its effectiveness, particularly in complex ICU patients.

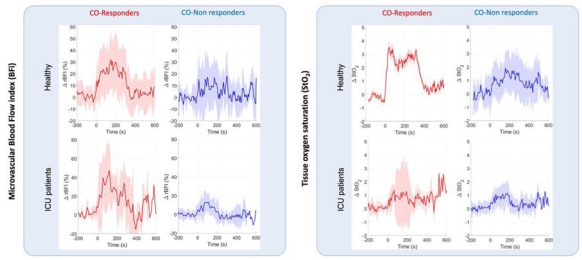

Figure. BFi and StO2 traces in responders and non-responders to the PLR maneuver in healthy volunteers and ICU patients. Solid lines represent average values, while shaded areas indicate the standard deviation. Time 0 represents the initiation of the PLR maneuver.

Intensive care Medicine Experimental 2025* 13(1):*000225.

Introduction: Refractory septic shock, defined as persistent low MAP despite fluid resuscitation and vasopressors infusion, is characterized by high morbidity and mortality. In the last years, some drugs with alternative pathways than catecholamines, have been proposed as additional therapy. Ang II in combination with NE have proven to be effective in achieve adequate MAP in refractory septic shock patients [1].

Objectives: In our study, we wanted to verify first hour Ang II adding effects on MAP, C.O., Pmsf, venous return resistances, RVr, and vasopressors requirement in refractory septic shock patients without any direct volume intervention.

Methods: We collected data from eight consecutive patients affected by refractory septic shock admitted to our general ICU, treated with association NE + Ang II and monitored by transpulmonary thermodilution with PiCCO instrument.

All patients received, before enrollment, fluid resuscitation of almost 30 ml/kg over two hours and showed inadequate MAP despite NE infusion at ≥ 0,3mcg/kg/min. We analyzed MAP, C.O. and vasopressors infusion rate during NE treatment and 1 h after Ang II adding. By continuous C.O. monitoring and performing two series of end-inspiratory hold maneuvers at 15, 25 and 35 cmH2O, we constructed two venous return curves for each of the six ventilator dependent patients and computed Pmsf and RVr during NE and NE + Ang II therapy without any fluid bolus infusion between measurements (Fig. 1) [2]. Data were analyzed using t paired rank test.

Results: After the first hour of Ang II treatment, all patients showed statistically significant MAP increase from 58 (± 9,8) to 92 (± 11,4) mmHg (p < 0,0001) and C.O. rise from 5,3 (± 1,6) to 5,8 (± 1,4) l/min (p = 0,06) (Fig. 1).

Pmsf increased from 14,8 (± 11,8) to 19,5 (± 6,8) mmHg (p = 0,07) without any CVP variation. Pmsf-CVP increased accordingly from 7,5 (± 9,1) to 11,8 (± 5) mmHg (p = 0,09).

RVr increased from 2,5 (± 1,4) to 4 (± 1,8) mmHg.min/l (p = 0,04).

Excluding data from a patient with profuse diuresis (> 500 ml) between measurements, C.O. increased from 5,2 (± 1,7) to 5,9 (± 1,5) l/min (p = 0,001), Pmsf from 10,4 (± 4,2) to 17 (± 3,3) mmHg (p = 0,002) and Pmsf-CVP from 3,5 (± 1,3) to 10,2 (± 2,9) mmHg (p = 0,007), (Fig. 2).

All patients showed NE dosage reduction after 1 h of Ang II treatment from 0,46 (± 0,15) to 0,3 (± 0,17) mcg/kg/min, (p = 0,0005). The average Ang II dose to reach MAP target was 31,6 ng/kg/min, higher dosages, till 80 ng/kg/min, was necessary in three patients chronically exposed to angiotensin receptor blockers [3].

Six patients were discharged alive from ICU, three needed RRT.

Conclusions: Although several results did not reach statistical significance due to the small sample size analyzed, in our series of refractory septic shock patients, Ang II infusion as second vasopressor proved to be effective in achieving of adequate MAP, in Pmsf and Pmsf-CVP increasing with consequent C.O. growth. After Ang II adding, NE dosage rapidly and significantly decreased.

Measurement of microcirculation by laser Doppler flowmetry is useful for the physiological monitoring of the chest compression rate during cardiopulmonary resuscitation: a pilot study

K. Sakaguchi[1]; G. Tomita[1]; R. Yokoyama[1]; M. Takada[1]; T. Kobayashi[1]; M. Nakane[1]
[1]Department of Emergency and Critical Care Medicine, Yamagata University Hospital, Yamagata, Japan

Intensive care Medicine Experimental 2025 13(**Suppl 1**)***:000227***.

Introduction: High-quality cardiopulmonary resuscitation (CPR) performed by all rescuers, including bystanders, improves patient outcomes. Physiological monitoring of CPR, such as end-tidal carbon dioxide, is thought to be useful for improving CPR quality, but physiological monitoring cannot be performed rapidly or easily. Pocket LDF (JMS, Japan), a laser Doppler flowmetry (LDF) device, is currently used for non-invasive clinical assessment of the flow and tempo of the microcirculation. Microcirculatory monitoring might be useful for physiological monitoring during CPR, but this has not been investigated. We hypothesized that physiological monitoring of the microcirculation during CPR would reflect CPR quality.
Objectives: This pilot study investigated whether the microcirculation tempo is useful for physiological monitoring of the chest compression rate during CPR.
Methods: This observational study was conducted between September 2023 and February 2025. Patients with out-of-hospital cardiac arrest who arrived at the emergency department (ED) of Yamagata University Hospital, Japan, and whose microcirculation was measured using pocket LDF during CPR were included in this study. For monitoring, the LDF probe was placed on the patient's earlobe and used to measure the microcirculation tempo and flow every 1 s during CPR. The primary outcome was the percentage of 2 min average tempo values that were > 80/min, because high-quality CPR is considered to be achieved at a tempo of 100–120/min and chest compression fraction (CCF) of 60%–80%. The secondary outcome was the percentage of the tempo per second ≥ 100/min, as the CCF measured by LDF (CCFLDF), per case of cardiac arrest. Statistical analyses were performed using R version 4.4.0.
Results: Eighteen patients were included. The median age was 84.0 (interquartile range [IQR]: 67.8–87.8) years and 61.1% were male. The median (IQR) no-flow time was 9 (0–76) min, 50.0% had witnessed cardiac arrest, and the initial waveform was asystole in 55.6%, pulseless electrical activity in 33.3%, and ventricular fibrillation in 5.6%. Return of spontaneous circulation was achieved in the ED in 33.3% of patients. According to LDF, the median (IQR) mean tempo and flow were 97.7 (93.4–99.8)/min and 3.4 (2.2–9.7) mL/min, respectively. We obtained 91 records of the average tempo every 2 min, yielding a median of 98.3 (95.9–99.7)/min. The percentage of the average tempo > 80/min every 2 min was 95.6%. The median CCFLDF was 63.6% (52.9%–79.7%). The numbers of cases of CCFLDF > 80% or > 60% were 4 (20.0%) and 12 (60.0%), respectively.
Conclusions: The percentage of average tempo > 80/min every 2 min was 95.6%, indicative of high-quality CPR. On the other hand, few patients had CCFLDF > 60%. We consider that the tempo measured by LDF during CPR adequately reflects chest compression. Physiological monitoring of the microcirculation by LDF could guide the chest compression rate during CPR. However, the utility of CCFLDF remains unknown, and further studies are needed to determine the most appropriate analysis method and optimal cut-off values.

Correlation of pulse oximeter saturation measurements and smart wearable devices: a prospective observational study

M. Kovar[1]; V. Kratka[2]; M. Navratil[2]; A. Natália[1]; H. Zelinkova[3]; H. Harazim[1]; J. Malaska[1]; P. Stourac[1]
[1]Department of Paediatric Anesthesiology and Resuscitation, Masaryk University and University Hospital Brno, Brno, Czech Republic; [2]Faculty of Medicine, Masaryk University, Brno, Czech Republic; [3]Institute of Biostatistics and Analyses, Masaryk University, Brno, Czech Republic

Intensive care Medicine Experimental 2025 **13(1)***:000230*

Introduction: Peripheral venous blood oxygen saturation (SpO2) and clinical status play crucial roles in the early detection of patients at risk of respiratory failure. Smart Wearable Devices can be designed to include SpO2 measurement capabilities (1). With sufficient sensitivity, these devices could help identify deterioration in a patient's condition and signal the need for escalation of care, such as hospitalisation, activating early warning systems (EWS), or admitting patients to the intensive care unit (ICU).
Objectives: To evaluate the accuracy of SpO2 measurements from smart wearable devices by comparing them to readings from a calibrated pulse oximeter in a paediatric ICU setting.
Methods: In a mixed paediatric ICU, the SpO2 levels of 30 paediatric patients were measured using a reference-calibrated pulse oximeter, the Masimo Rad-8 (MR8). Additionally, measurements were obtained with several smart wearable devices, specifically the Samsung Galaxy S7 (SGS7), Samsung Galaxy S8 (SGS8), and Honor Band 7 (HB7). Each device was used to conduct six measurements (three on each hand).
Results: Pearson's test revealed a strong positive correlation in all cases, ranging from 0.413 to 0.783 ($p < 0.001$ to $p < 0.023$) (see Fig. 1). A paired t-test showed mean differences of -0.2 to -1.4 ($p < 0.002$ to $p < 0.511$) (see Fig. 2). The Bland–Altman plots indicated the following mean differences (± standard deviation): MR8-**SGS7**: 1.08% ± 1.91; MR8-SGS8: 0.03% ± 1.19; MR8-HB7: 0.85% ± 2.25 (see Fig. 3).
Some comparisons indicate statistically significant differences in average measurements, with the highest difference of 1.4% exceeding the SpO2 measurement error of ± 1%. The latest SGS8 device met the targeted criteria, but due to the limited number of devices tested, it is unclear if this represents a coincidence or greater accuracy in newer

devices. Typically, smart wearables record lower values than calibrated devices, making them suitable for activating EWS.
Conclusions: The newest smart wearable device we tested provides accurate measurements aligned with calibrated equipment. However, it is noteworthy that all devices tend to report lower values. This heightened sensitivity can be leveraged in EWSs and aid in making timely decisions to escalate critical care.

Introduction: Ventricular–arterial coupling (VAC) represents the interaction between ventricular contractility and the arterial load, serving as reflects cardiovascular performance and ventricular efficiency index. VAC uncoupling, a mismatch between contractility and afterload, has been previously described in septic shock patients.
Objectives: The aim of our work was to evaluate whether there is an the association between VAC and mortality in critically ill patients with sepsis, and to identify a VAC threshold measured by transpulmonary thermodilution (TPTD) that predicts increased mortality.
Methods: We conducted a prospective study was conducted in a 24- bed mixed intensive care unit ICU in Argentina. Adults patients with sepsis and cardiovascular dysfunction were included. VAC was calculated from the first TPTD measurement using the formulas: arterial elastance (Ea) = (MAP × 0.9) / SV and end-systolic elastance (Ees) = MAP /[(GEDVI/4) − SV]. Statistical analysis included Student's t-test or Mann–Whitney U test, as appropriate. Binary logistic regression identified independent predictors of mortality. Receiver operating characteristic (ROC) curve analysis was performed to determine the VAC threshold associated with increased mortality.
Results: We included 34 patients, 11 of whom were female. Mean age was 57 [40 – 68] (p = 0.53) Apache II and SOFA scores were 19 [13 – 27] and 8 [5 – 9]; (p = 0.02) (p = 0.53), respectively. Hemodynamic variables are shown in Table 1. ROC curve is shown in Table 2 AUC was 0.75. The cutt off VAC value that predicted higher mortality in this cohort was 1.27 (p = 0.02) with a sensitivity of 70% and specificity of 83%. It is important to note that these are preliminary Results:
Conclusions: In this cohort of septic patients VAC was independently associated with mortality. The cutt-off VAC value that predicted higher mortality in this cohort was 1.27 (p = 0.02) with a sensitivity of 70% and specificity of 83%

Introduction of a decision aid algorithm to rationalise blood gas analysis

D. Shroff[1]; R. Watts[1]; J. Powys-Lybbe[2]
[1]Adult Critical Care, St George's Hospital, London, United Kingdom; [2]General Intensive Care Unit, St George's Hospital, London, United Kingdom
Correspondence: D. Shroff
Intensive care Medicine Experimental 2025* 13(1):*000232.

Introduction: Blood gas analysis, particularly arterial blood, is one of the most used tests in critical care.(1) However, it is often lacks a clear indication and over 30% are performed unnecessarily.(2) The over-use of blood gas sampling is financially and environmentally costly, contributing to intensive care beds being responsible for three times the greenhouse gas emissions of a standard inpatient bed.(3) It is also a time-consuming burden on staff.
Objectives: A decision-aid algorithm was introduced across three intensive care units in a UK centre, with the aim of reducing the number of blood gas samples taken by 10–20%.
Methods: The blood gas analysis decision aid tool (from North Shore Hospital, Australia) (2) was introduced with an education campaign.
Data were collected on the number of patient samples analysed on point-of-care testing machines over the preceding year and savings predicted. An interim analysis was carried out 8 weeks after the intervention, then re-audited a further 6 months later.
Staff time savings were based on the average of time from decision to take a blood gas sample to test resulted.
Environmental savings were calculated using input–output emissions based on UK government databases (4,5).
Intermittent spot audits with mini educational interventions collected qualitative data and increased awareness.
Results: The total number of blood gas analyses reduced from average of 2274 to 1933 per week (14.98%) at interim analysis, then further to 1836 per week (19.25%) over 6 months. Figure 1 shows this and per each intensive care unit, with the greatest reduction (31.1%) in General ICU and High-dependency.
In total, this is estimated to be savings of £46,563.00 and environmentally 52.587 tonnes CO_2e per year.
It equates to 2190 min (36.5 h) of nursing time per week saved. Spot audits collected staff experience data and showed 100% of nurses surveyed were aware of the decision aid. It was on display at 81% of bed spaces.
However, spot audits also showed 18.6% of blood gas analyses had no clear indication as per the algorithm and 4.7% were performed on "wardable" patients.
Conclusions: The introduction of a decision aid tool has successfully rationalised blood gas sampling, leading to a reduction in samples taken, financial and environmental savings. It has also freed up staff time, to divert to other activities of patient care. The target of 20% reduction has been safely achieved.
This success has been limited in specialist units, especially Neuro-ICU, likely due to the need for tight electrolyte monitoring.
Data limitations include the seasonal variance in bed occupancy and acuity, and the samples run on our point-of-care analysers from neighbouring non-critical care wards.
The qualitative data highlight the challenges of changing mind-set and identified areas to target.
In summary, the introduction of a decision aid tool has rationalised blood gas analysis, leading to a reduction of unnecessary sampling, financial and environmental savings, without compromising patient safety.

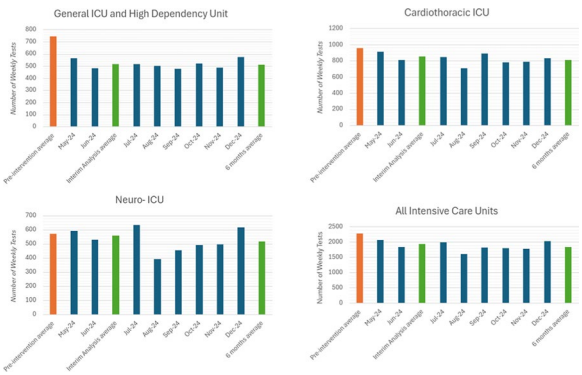

Fig. 1 (abstract 000232) Bar charts showing the average number of weekly point-of-care blood gas analyses before, 8 weeks after and a further 6 months after the introduction of the decision aid tool; separately in each unit and as a total across all intensive care units

Effect of high protein diet on weaning from mechanical ventilation in critically ill patients

O. Elgendy[1]
[1]Critical care, Alexanderia faculty of medicine, Alexanderia, Egypt
Correspondence: O. Elgendy
Intensive care Medicine Experimental 2025* 13(1)*:000237.

Introduction: An imbalance among intake and needs, the effects of catabolic hormones, and physical immobilization are the main causes of malnutrition and muscle atrophy throughout intensive care unit stays. (1).
The body's greatest protein pool is found in muscle. Significant proteolysis and muscle loss (up to 1 kg a day) are linked to critical illness and are linked to acquired weakness in the intensive care unit (3). Muscle wasting is more severe in individuals with multiple organ failure than in those with single organ failure, and it happens early and quickly in the 1st week of critical illness (3). Although there is little evidence to support these recommendations, current guidelines suggest that critically sick studied cases should consume more protein (1.2–2.0 g/kg/d) than the healthy, who should consume 0.80 g/kg/d. It is suggested that protein intake must be greater than 2.0 g/kg/d when 24-h nitrogen balances are utilized as an objective (4). Protein is the most crucial macronutrient for critically ill studied cases because it enhances immunological response, aids in the maintenance of lean body mass, and promotes recovery. There is mounting evidence that consuming enough protein may be more crucial for the body than consuming enough calories (5).
Several studies recommend using a method to evaluate malnutrition in the intensive care unit. Due to the rapid withering of lean tissues and fluid administration, it is challenging to assess weight changes in the intensive care unit. Sarcopenia and muscle loss must be identified in the intensive care unit. Unfortunately, sarcopenia and malnutrition cannot be accurately reflected by body mass index or real body weight (2).
Throughout an ICU stay, significant amounts of fat and lean body mass may be lost in a comparatively short period of time. Although there is no recognized method, lean body mass can be assessed using stable isotopes, bioelectric impedance, ultrasound, or computerized tomography scans (2). In critical care settings, ultrasonography provides a noninvasive, portable, affordable, and bedside tool for assessing muscle mass (6,7). When compared to previous tests used to evaluate muscular features, it has a number of advantages and enables a rapid screening of broad muscle sections at the patient's bedside (6).
Diaphragmatic dysfunction can be accurately and usefully diagnosed by diaphragmatic ultrasound. Additionally, a thickening proportion of thirty-to-thirty six percent enables both morphologic and functional examination of the muscle (1).
Objectives: To illustrate how a diet rich in protein affects: diaphragmatic thickness and diaphragmatic excursion by using ultrasound and its reflection on weaning from mechanical ventilation and mortality.
Methods: 60 patients in critical condition were involved in this single-center, randomized controlled research. Group I consisted of studied cases who were given a high-protein diet (2.0 g/kg/d) for seven days, whereas Group II consisted of studied cases who were given a standard-protein diet (1.2 g/kg/d) using enteral formula. Patients were recruited and assessed for eligibility from the intensive care units in Alexandria Main University Hospital.
Results: There had been a statistically significant increase in diaphragmatic thickness with inspiration, diaphragmatic thickening Fraction and diaphragmatic excursion between studied cases in group I compared with group II at day 3 and day 7. Meanwhile, there had been no significant difference between the studied groups at day0. There had been a statistically significant reduction in the number of studied cases weaned from mechanical ventilation among patients in group II compared with group I, and group II exposed higher mortality rate within 28 days.

Conclusions:
Patients with standard protein diet showed low diaphragmatic thickness with inspiration and low diaphragmatic thickening fraction and low diaphragmatic excursion compared to patients received high protein diet especially after 7 days. So, weaning from mechanical ventilation was higher among studied cases received high protein diet, but mortality rate throughout ICU stay was higher among patients with standard protein diet.

Fig. 1 (abstract 000237) view of the right subcostal region in B mode and M mode to measure diaphragmatic excursion

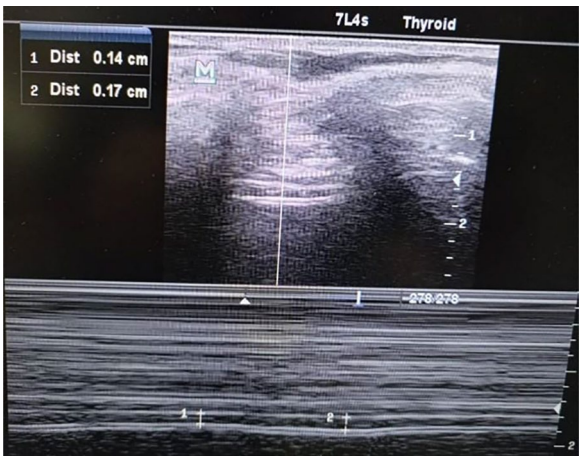

Fig. 2 (abstract 000237) Diaphragmatic thickness is measured by diaphragmatic ultrasound in B-mode and M-mode at the zone of apposition. End-expiration thickness is 1, while end-inspiration thickness is 2.

Determinants of ICU memory formation and the impact on long-term post-traumatic stress: a multicenter longitudinal cohort study

R. Kooken[1]; B. Tilburgs[1]; A. Slooter[2]; M. van den Boogaard[1]
[1]Department of Intensive Care Medicine, Radboud University Medical Center, Nijmegen, Netherlands; [2]Department of Intensive Care Medicine, University Medical Center Utrecht, Utrecht, Netherlands

Intensive care Medicine Experimental 2025* 13(1)*:000238.

Introduction: Patients admitted to an intensive care unit (ICU) can experience a wide array of recollections during recovery, ranging from complete amnesia to vivid delusional memories, with the latter being linked to poor short-term psychological outcomes [1, 2]. However, it is unclear which demographic and clinical determinants shape ICU memory formation and how different memory types contribute to long-term psychological distress.
Objectives: To identify determinants of ICU memory formation and the relationship between memory types and long-term symptoms of post-traumatic stress disorder (PTSD).
Methods: Adult patients from two Dutch University ICUs underwent a structured telephone interview using the ICU-Memory Tool (ICU-MT) three months after ICU discharge. Memories were categorized in three types: complete ICU amnesia, factual memories without delusions, and delusional memories. Symptoms of PTSD were assessed using the Impact of Event Scale (IES-6) at 3 and 12 months post-ICU. Determinants of ICU memory formation were identified in a multinomial logistic regression model. The impact of different memories on long-term PTSD symptoms was assessed in a linear mixed-effects model, using mean IES score as the outcome, adjusted for relevant covariates.
Results: Of the 428 included patients, 13.8% (n = 59) had complete amnesia for the ICU stay. Factual memories without delusions were reported by 47.4% (n = 203), while 38.8% (n = 166) experienced delusional memories, of whom 93.3% (n = 155) also had factual memories. ICU delirium was present in 41% of patients with delusional memories. Days with deep sedation and female sex were associated with amnesia for the ICU stay (adjusted odds ratio (aOR), 1.34, 95%CI 1.09 – 1.65 and aOR 2.01, 95%CI 1.05 – 3.83, respectively, Fig. 1), whereas presence of delirium and length of ICU stay were associated with delusional memories (aOR 1.94, 95%CI 1.04 – 3.61 and aOR 1.11, 95%CI 1.02 – 1.21, respectively, Fig. 1). Prevalence of PTSD symptoms increased significantly from 3 months to 1 year post-ICU in those with delusional memories (6.7% to 17.8%, p < 0.01, Fig. 2), while remaining stable in the other memory groups. Adjusted analyses revealed delusional memories as well as female sex as risk factors for long-term symptoms of PTSD (adjusted relative increase 13%, 95%CI 4.2% – 22%, and 8.9%, 95%CI 1.8% – 17%, respectively, Fig. 3).
Conclusions: Delusional memories occurred in over one third of ICU survivors, also in the absence of delirium. Delirium and more days in the ICU increased the likelihood of delusional memories, whereas deep sedation and female sex were associated with ICU amnesia. Both delusional memories and female sex contributed to the development and persistence of PTSD symptoms in the long term. These findings underscore the need for targeted interventions to mitigate memory disturbances and their psychological consequences, both during and after ICU admission.

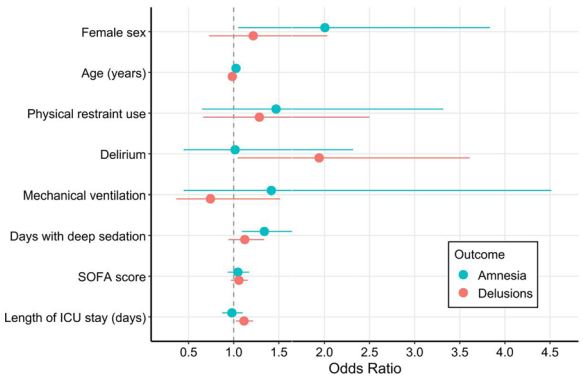

Fig. 1 (abstract 000238) Multinomial logistic model to identify determinants of ICU memory types. *The reference group is factual memories. Horizontal coloured lines represent 95% confidence intervals.*

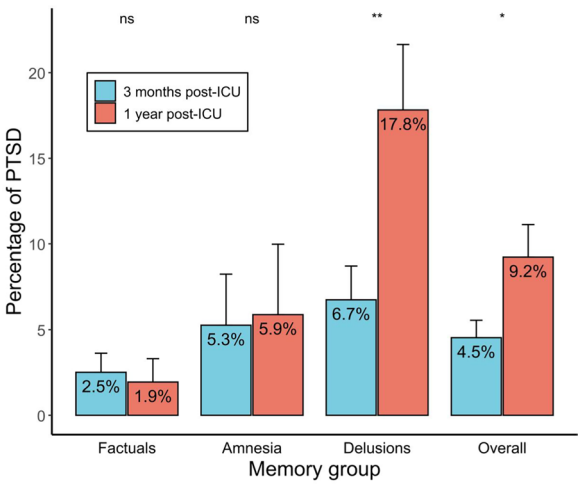

Fig. 2 (abstract 000238) Prevalence of PTSD symptoms per time-point and memory group. ** p < 0.05; ** p < 0.01. A mean IES-6 score of > = 1.75 was used as a cut-off to determine presence of PTSD symptoms [3].*

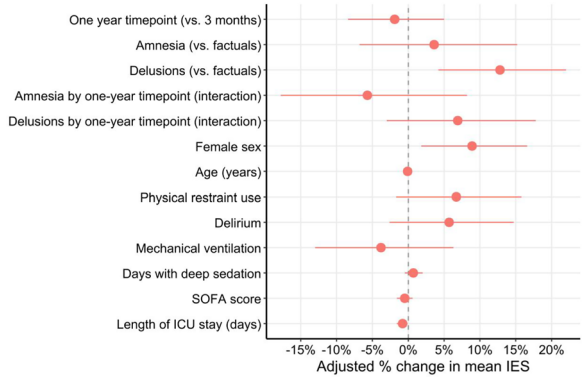

Fig. 3 (abstract 000238) The impact of different ICU memories on long-term PTSD symptoms (linear mixed-effects model). *The outcome variable mean IES-6 score was log-transformed to normalize the residuals. To enhance interpretability, estimates were exponentiated, allowing for the coefficients to be interpreted as % change per one-unit increase in the independent variable. Horizontal coloured lines represent 95% confidence intervals.*

User perceptions and time savings with a TPN calculator: a pilot survey among ICU clinicians

MT. bin jumah[1]; YJ. Lim[1]
[1]Pharmacy, tan tock seng hospital, singapore, Singapore
Correspondence: M.T. bin jumah
Intensive care Medicine Experimental 2025* 13(1):*000239.

Introduction: Prescribing total parenteral nutrition (TPN) is a detailed task that involves clinicians calculating patient-specific factors, nutritional elements, and dosage limits to meet individual needs while ensuring the stability of the TPN mixture. To support clinicians in this process, a web-based TPN calculator was created to improve the accuracy and efficiency of TPN order prescriptions. This study aims to outline the features of the TPN calculator and evaluate the usability, and impact of the calculator on productivity, collaboration, and decision-making in a professional context.
Methods: A TPN calculator was created using Google Sheets and shared with clinicians in the surgical intensive care unit at Tan Tock Seng Hospital. This tool utilized numerical formulas to perform multi-step calculations, determining the necessary macro- and micronutrient values for TPN prescriptions based on patient-specific inputs. A YouTube instructional video link was included to assist prescribers in navigating the calculator. To evaluate its effectiveness, a pilot survey was conducted, featuring 10 Likert-scale questions from the System Usability Scale (SUS) alongside qualitative feedback prompts, focusing on usability and the tool's influence on productivity, collaboration, and decision-making. Typically, an average SUS score of 70 or higher reflects a strong level of usability.
Results: Six clinicians who used the TPN calculator—comprising three medical doctors and three pharmacists—participated in a survey. These users had a median age of 31 years and professional experience ranging from 4 to 9 years. The pilot survey revealed a strong usability rating, with a median SUS score of 77.5 (70–90). Feedback highlighted the calculator's efficiency and ease of use, noting that it boosted confidence in the accuracy of TPN prescriptions. Additionally, it enhanced focus on tasks, improved team collaboration, minimized repetitive clarifications in the clinical decision-making process, and proved reliable. Users also reported a median time savings of 10 min per TPN prescription.
Conclusions: The TPN calculator exhibited strong usability and serves as a valuable tool for clinicians, enhancing accuracy, efficiency, and productivity in crafting TPN prescriptions within the ICU.

***Intensive care Medicine Experimental 2025* 13(1):*000240*.**

Introduction:
A spontaneous breathing trial (SBT) using pressure support ventilation (PSV) appears to be the strategy associated with the best clinical outcomes. However, the role of positive end-expiratory pressure (PEEP) during SBT remains unclear. Strategies such as reconnecting the patient to the ventilator after SBT or extubation with positive pressure may help prevent lung collapse during SBT and extubation. We hypothesized that a weaning strategy designed to prevent lung collapse during both SBT and extubation could result in higher successful extubation rates.

Objectives: Primary objective: To evaluate whether a lung volume preservation strategy during weaning increases the rate of successful extubation at 72 h compared to a standard weaning strategy.
Secondary objectives: To compare the extubation rates immediately after the SBT between both strategies. To assess the respiratory failure and reintubation rates within 72 h post-extubation. To evaluate the impact of each strategy on ICU mortality and hospital mortality.
Methods: Multicenter randomized clinical trial conducted in 30 Spanish ICUs. Patients meeting weaning criteria were randomized to either: 1. Lung volume preservation weaning strategy: SBT for 30 min with PSV 8 cmH_2O, PEEP 5 cmH_2O, and extubation maintaining PEEP; or 2. Standard weaning strategy: SBT for 30 min with PSV 8 cmH_2O, ZEEP, and extubation with continuous suction.
Results: A total of 1,692 patients were included, with a median age of 65 years (IQR 55–73) and a median duration of mechanical ventilation of 6 days (IQR 3–9); 639 (38%) were women.
A total of 840 patients were randomized to the standard strategy and 852 to the lung volume preservation strategy. After the SBT, 777 patients (92%) in the standard group and 809 patients (95%) in the lung volume preservation group were extubated ($p = 0.03$). Reintubation within 72 h was required in 101 patients (13%) from the standard group versus 129 patients (16%) from the lung volume preservation group ($p = 0.09$). Consequently, successful extubation at 72 h was achieved in 676 patients (81%) in the standard group and 680 patients (80%) in the lung volume preservation group ($p = 0.73$). ICU mortality occurred in 67 patients (8%) in the standard group and 45 patients (5%) in the lung volume preservation group ($p = 0.02$), while hospital mortality was 98 patients (12%) in the standard group and 90 patients (10%) in the lung volume preservation group ($p = 0.14$).
Conclusions: A lung volume preservation strategy for weaning from mechanical ventilation did not result in higher rates of successful extubation at 72 h compared to a standard weaning strategy. A higher percentage of patients were extubated following an SBT with PEEP compared to an SBT without PEEP. Reintubation rates were slightly higher with the lung volume preservation strategy, though the difference was not statistically significant. ICU mortality was higher in patients undergoing the standard strategy, but there were no differences in hospital mortality.

Table 1 (abstract 000240) Primary and secondary outcomes

	Total (n= 1692)	Standard group (n= 840)	Lung volume preservation group (n = 852)	p-value
Primary outcome:				
- Successful extubation at 72 h; n (%)	1356 (80)	676 (81)	680 (80)	0.73
Secondary outcomes:				
- Extubated after SBT; n (%)	1586 (94)	777 (92)	809 (95)	0.03
- Respiratory failure at 72h; n (%)	326 (21)	148 (19)	178 (22)	0.14
- Reintubation rate at 72 h; n(%)	230 (15)	101 (13)	129 (16)	0.09
ICU Mortality; n (%)	112 (7)	67 (8)	45 (5)	0.02
Hospital mortality; n (%)	188 (11)	98 (12)	90 (10)	0.14

Reducing mortality in cardiopathic ICU patients through an adapted early sepsis recognition protocol

S. Oliveira[1]; L. Sales[1]; A. Magalhães[1]
[1]ICU, Hospital Estadual Anchieta, Rio de Janeiro, Brazil
Correspondence: S. Oliveira
Intensive care Medicine Experimental 2025* 13(1)*:000241.

Introduction: Sepsis remains one of the leading causes of hospital mortality, particularly among patients with severe comorbidities. In cardiology hospitals, delayed recognition of sepsis in cardiopathic patients contributes significantly to adverse outcomes, due to the clinical complexity of this population. The absence of specific protocols for these patients frequently hampers timely diagnosis.
Objectives: To evaluate the impact of implementing a sepsis protocol adapted for early recognition in critically ill cardiopathic patients in a cardiology hospital, focusing on its effect on mortality reduction.
Methods: This was an observational study, both retrospective and prospective, conducted at a specialised cardiology hospital between January 2023 and December 2024. An adapted sepsis protocol was introduced, incorporating clinical and laboratory criteria tailored to the cardiology setting. A multidisciplinary team received structured training aimed at enhancing early recognition. Clinical indicators and outcomes were compared before and after implementation. The primary outcome was in-hospital mortality. Inclusion criteria encompassed patients aged 18 or older with a confirmed diagnosis of severe heart disease and sepsis.
Results: A total of 312 patients were assessed prior to protocol implementation and 329 afterwards. Early recognition of sepsis within the first six hours improved significantly (from 41 to 76%, $p < 0.001$). Prompt initiation of appropriate antibiotic therapy increased from 47 to 82% ($p < 0.001$). Hospital mortality showed a significant decrease from 38 to 24% ($p = 0.004$). The mean length of stay in the intensive care unit was reduced from 9.2 to 6.7 days ($p = 0.02$).
Conclusions: The implementation of an adapted sepsis protocol for critically ill cardiopathic patients led to earlier recognition, improved therapeutic response, and a statistically significant reduction in hospital mortality. These findings underscore the importance of developing patient-specific strategies in complex clinical settings and reinforce the value of tailoring institutional sepsis protocols.

Intensive care Medicine Experimental 2025* 13(1)*:000243.

Introduction: Aneurysmal subarachnoid hemorrhage (aSAH) is associated with high morbidity and mortality rates. Functional prognosis depends not only on the primary injury, but also on the secondary brain damage. Multimodal neuromonitoring can help prevent the secondary damage. In this study, we aim to analyze if there are differences in outcomes within our sample based on the type of advanced neuromonitoring used.
Objectives: To describe the characteristics and outcomes of patients admitted to critical care units with aSAH who require advanced neuromonitoring with an intracranial pressure (ICP) sensor or with an ICP and a brain tissue oxygen pressure (PbtO2) sensor. To analyze outcomes in terms of complications, mortality and hospital length of stay among patients with different types of advanced monitoring.
Methods: A retrospective observational study was conducted on patients admitted for aSAH to the critical care units of a tertiary hospital from March 2018 to December 2024. Demographic, clinical and mortality variables, as well as neuromonitoring data, were collected. In this sample, **vasospasm** was diagnosed by angiography and **delayed**

cerebral ischemia (DCI) was defined as the appearance of new focal deficits or a decrease of two points on the Glasgow Coma Scale for more than 1 h. **Cerebral infarction** was identified as the ischemic lesion detected by computed tomography or magnetic resonance imaging. Patients were classified according to neuromonitoring type: **group 1** (monitored with ICP) and **group 2** (monitored with both ICP and PbtO2). Results are expressed as numbers and percentages or as median and interquartile range (IQR), as appropriate.

Results: A total of 128 patients diagnosed with aSAH were included, with a median age of 61.7 years, 71.1% (n = 91) women. Of these, 44 patients did not undergo neuromonitoring with ICP or PbtO2, either due to the possibility of clinical evaluation (n = 31) or poor short-term vital prognosis (n = 13). The remaining 84 patients required neuromonitoring and were classified into Group 1 (n = 68) and Group 2 (n = 16). Both groups were homogeneous in terms of median age, gender distribution, and prognostic neurological scales. Although the incidence of rebleeding and intracranial hypertension was similar between the two groups, Group 2 had a higher incidence of vasospasm, DCI and cerebral infarction. The length of stay in both the critical care unit and the hospital was longer in Group 2. The results are detailed in Table 1.

Conclusions: In our sample, most patients with aSAH required advanced neuromonitoring. Patients monitored with both ICP and PbtO2 had a significantly higher incidence of cerebral infarction and a longer stay in critical care units, as well as a higher percentage of vasospasm and DCI, although the latter were not statistically significant. A larger sample size for Group 2 is needed to assess these differences.

Predicting intensive care unit readmissions, death or code blue events after discharge from intensive care

Y. wong[1]; J. Zhang[1]; YS. Heng[1]
[1]anaesthesia, Tan Tock Seng Hospital, Singapore, Singapore
Correspondence: Y. wong
Intensive care Medicine Experimental 2025* 13(1):*000245.

Introduction: Unplanned intensive care unit (ICU) readmissions, deaths, and medical emergencies following ICU discharge are significant adverse events that impact patient outcomes and healthcare resources. The decision to discharge patients from ICU is a complex clinical judgement that could benefit from additional decision support tools. Early recognition of at-risk patients using data-driven approaches could support clinicians' discharge decisions.

Objectives: This study aimed to develop a clinical decision support tool to predict ICU readmission, death, or code blue events as a multiclass outcome post-ICU discharge (within 48 h, after 48 h, or neither). We sought to: (1) leverage deep learning based on transformer architectures to process temporal clinical data; (2) compare deep learning against traditional machine learning approaches; and (3) identify key predictors of adverse events.

Methods: We conducted a retrospective analysis of adult patients transferred out from ICUs in Tan Tock Seng Hospital and National Centre for Infectious Diseases between August 2022 and July 2024. Patients were excluded if they: (1) died during their ICU stay, (2) were transferred to another hospital, (3) were under Palliative Medicine care, or (4) had Do Not Resuscitate or Comfort Care Only orders. For the remaining 3,210 ICU episodes, we extracted demographics, clinical attributes, and temporal physiological data.

For the machine learning approach, data were split into development (80%) and test (20%) sets, with nested tenfold cross-validation for hyperparameter tuning and model selection. SHapley Additive exPlanations (SHAP) analysis was conducted for feature importance.

For the deep learning approach using the Self-Supervised Transformer for Sparse and Irregularly Sampled Multivariate Clinical Time-Series (STraTS) model [1], data were split into training (60%), development (10%), validation (10%), and test (20%) sets. The test set was common across both approaches to evaluate model performance using macro-averaged F1 score.

Results: Of the 3,210 ICU episodes analysed, 5.6% experienced adverse events within 48 h, 11.6% after 48 h, and 82.8% had no events post-ICU discharge. Among traditional machine learning approaches, Random Forest achieved the best performance with a macro-averaged F1 score of 0.44 on the test set. The STraTS model demonstrated superior performance with a F1 score of 0.55. SHAP analysis identified current and cumulative ICU length of stay, oxygen device at ICU discharge, and latest laboratory values (urea, creatinine, haemoglobin) as the strongest predictors of post-ICU adverse events.

Conclusions: The transformer-based STraTS model outperformed traditional machine learning approaches in predicting post-ICU adverse events by effectively capturing complex temporal patterns in physiological data. This tool could provide objective decision support for ICU discharge planning and guide appropriate monitoring strategies for high-risk patients.

MIRACLE2 versus other cardiac arrest scores, and traditional severity scores to predict neurological consequence and hospital mortality: ten-year analysis in patients with out-of-hospital cardiac arrest

N. Sathaporn[1]; B. Khwannimit[1]
[1]Division of Critical Care Medicine, Department of Internal Medicine, Faculty of Medicine, Prince of Songkla University, Hat Yai, Thailand
Correspondence: N. Sathaporn

***Intensive care Medicine Experimental 2025* 13(1):*000246*.**

Introduction: The MIRACLE2 is a practical score with seven parameters accurately predicting neurological outcomes in out-of-hospital cardiac arrest (OHCA). Its effectiveness is comparable to cardiac arrest scores like the Cardiac Arrest Hospital Prognosis (CAHP) and Target Temperature Management (TTM) scores. Nonetheless, data on the performance of these specific scores in OHCA is limited compared to traditional severity scores such as Acute Physiology and Chronic Health Evaluation (APACHE) and Simplified Acute Physiology Score (SAPS), which require multiple variables.
Objectives: This study aims to comprehensively assess the efficacy of MIRACLE2, CAHP, and TTM with APACHE II, SAPS II, and SAPS-3 scores to predict neurological outcomes and hospital mortality in patients with OHCA from cardiac cause with return of spontaneous circulation (ROSC).
Methods: A retrospective study was conducted in a tertiary care hospital from 2015 to 2024. The primary outcome was the poor neurological outcome, defined by Cerebral Performance Category (CPC) 3–5 at hospital discharge. The secondary outcome was hospital mortality.
Results: A total of 158 cases were included. Hospital mortality was 53.2%. The unfavorable neurological outcome was 73.4%. The patients' good and poor neurological outcomes did not differ significantly according to gender, witness arrest, and bystander CPR. Acute myocardial infarction was the most common cause of cardiac arrest, and revascularization was not different between groups (69% and 73.3%). The patients in this study received veno-arterial extracorporeal membrane oxygenation (VA-ECMO) 6.3% and targeted temperature management (TTM) 50%. VA-ECMO and TTM were not performed differently in each group. Whereas, the parameters included the specific cardiac arrest score, such as age, initial shockable rhythm, cardiac arrest at home, no-flow time, low flow time, adrenaline dose before ROSC, reactive pupil at ROSC, GCS M1 at ROSC, and admission pH less than 7.2, which were significantly different between groups. The poor outcome substantially increased in patients with higher scores. The MIRACLE2, CAHP, TTM, APACHE II, SAPS II, and SAPS-3 scores presented an area under the receiver operating characteristic curve (AUROC) of more than 0.8 to predict poor neurological outcomes (Fig. 1). These results were in line with mortality prediction (Fig. 2). The TTM score revealed the highest AUROC of 0.899 and 0.854 to predict unfavorable neurological consequences and mortality, respectively. There was no significant difference in the ability of each cardiac arrest score to indicate a poor neurological outcome. However, the TTM score significantly outperforms APACHE II, SAPS II, and SAPS-3 in predicting unfavorable neurological outcomes, with p-value < 0.001. The AUROC and optimum cut-off point for each score to predict poor neurological outcomes were presented in Table 1.

Table 1 (abstract 000246) The performance of each score to predict poor neurological outcome

Score	AUROC (95%CI)	Cut-off point	Sensitivity (%)	Specificity (%)
MIRACLE2	0.832 (0.769–0.895)	5	69.0	90.5
CAHP	0.869 (0.808–0.930)	188	74.1	85.7
TTM	0.899 (0.852–0.946)	15	81.0	88.1
APACHE II	0.823 (0.750–0.896)	30	80.2	69.0
SAPS II	0.865 (0.799–0.931)	54	83.6	78.6
SAPS-3	0.837 (0.772–0.902)	66	75.0	83.3

Conclusions: The MIRACLE2, CAHP, and TTM scores can be used as part of patient assessment in the post-arrest state to identify unfavorable neurological consequences and mortality in OHCA. The TTM score could be considered because it is the most effective and is significantly superior to traditional severity scores.

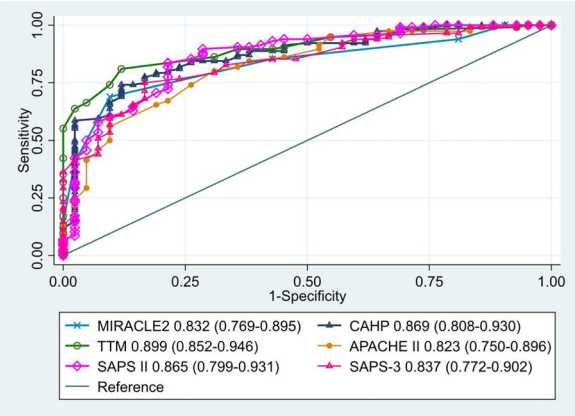

Fig. 1 (abstract 000246) Each score to predict neurological outcome in patients with OHCA from cardiac cause

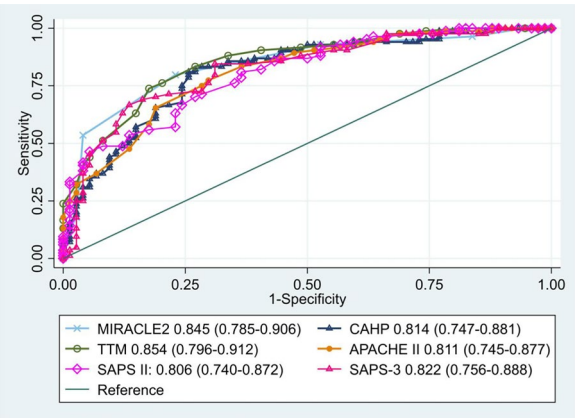

Fig. 2 (abstract 000246) Each score to predict hospital mortality in patients with OHCA from cardiac cause

Novel approach to assess metabolic load during ICU rehabilitation: evaluation of lactate response

J. Sommers[1]; E. Voorn[2]; J. Beek Van[3]; J. Horn[4]; M. Van Der Schaaf[5]
[1]Department of Physical Therapy, Erasmus MC, Rotterdam, Netherlands; [2]Department of Rehabilitation Medicine, Amsterdam UMC, location University of Amsterdam, Amsterdam Movement Sciences, Amsterdam, Netherlands; [3]Department of Rehabilitation Medicine, Amsterdam UMC, location University of Amsterdam, Amsterdam, Netherlands; [4]Department of intensive care medicine, Amsterdam UMC, location University of Amsterdam, Amsterdam, Netherlands; [5]Department of rehabilitation medicine, Amsterdam UMC, University of Amsterdam, Amsterdam Movement Sciences, Amsterdam, Netherlands
Correspondence: J. Sommers
***Intensive care Medicine Experimental 2025* 13(1):*000247*.**

Introduction: Early rehabilitation is advocated for ICU patients but clinical guidelines to guide exercise intensity are lacking. 1,2 Due

to low muscle strength and exercise capacity related to ICU-AW and mitochondria dysfunction, overexertion is a serious risk for this vulnerable population.1–5 To avoid overexertion, information on the metabolic load of rehabilitation interventions is warranted.2,6,7
Recent work in COVID-19 patients demonstrated high blood lactate levels at low exercise intensities, indicating a high metabolic load and mitochondrial dysfunction.8 Blood lactate levels may be a promising marker for assessing metabolic load during ICU rehabilitation.
Objectives: To investigate changes in blood lactate levels during active rehabilitation interventions in ICU patients.
Methods: This single-center observational cohort study was conducted in the ICU of Amsterdam University Medical Center. Mechanically ventilated ICU patients (> 48 h) who met the safety criteria for active exercise therapy were included.1 The primary outcome, blood lactate level was measured at three time points: before, at peak exertion, and 30 min after a rehabilitation intervention (defined as sitting on the edge of the bed).
For analysis, patients were stratified into two groups: those at potential higher risk of mitochondrial dysfunction (patients with sepsis, COVID-19, or acute respiratory distress syndrome (ARDS)) and those at potential lower risk of mitochondrial damage (patients after cardiac surgery, trauma, or cancer). Descriptive statistics were used to characterize the study population and lactate levels across time points as primary outcome.
Results: A total of 30 ICU patients were included (median age: 65 years [IQR 51–75]; 67% male). The median duration of mechanical ventilation was 12.5 days [IQR 7.8–24.3], and the median ICU stay was 15.5 days [IQR 9.8–29.5]. Thirteen patients were categorized into the potential higher risk of mitochondrial dysfunction group, while 17 were in the group at potential lower risk mitochondrial damage. Individual responses to exercise varied. The group with potential higher risk of mitochondrial dysfunction shows higher baseline lactate levels, an upward trend during exercise, and delayed recovery compared to the group at potential lower risk of mitochondrial damage (median lactate levels: before 1.4 vs 1.0; at peak exertion 2.1 vs 1.2; and 30 min after 1.8 vs.1.1, respectively) (figure).
Conclusions: This pilot study suggests that ICU patients who are at high risk for mitochondrial dysfunction exhibit an increased lactate response to exercise with delayed recovery, potentially indicating metabolic stress. Blood lactate may serve as a marker of metabolic response in this ICU subgroup. However, further research in a larger cohort is needed to determine the association between physical capacity and metabolic stress.

Response lactate to active exercise therapy.

Unlocking the predictive power of hematological indices of 30-day mortality in diabetic and non-diabetic stroke patients

R. Karasneh[1]
[1]Basic Medical Sciences, Yarmouk University, Faculty of Medicine, Irbid, Jordan
Correspondence: R. Karasneh
Intensive care Medicine Experimental 2025* 13(1):*000250.

Introduction: Stroke is a leading cause of disability and death worldwide with diabetes being a well-recognized risk factor associated with poor outcomes. Diabetes fosters a chronic low-grade inflammation that worsens stroke prognosis. Recently, hematological indices including neutrophil-to-lymphocyte ratio, and monocyte-to-lymphocyte ratio have emerged as prognostic inflammatory biomarkers for stroke outcomes. However, the impact of diabetes on the predictive power of these indices remains unclear.
Objectives: This study aimed to evaluate neutrophil-to-lymphocyte ratio and monocyte-to-lymphocyte ratio as potential predictors of 30-day mortality in diabetic and non-diabetic stroke patients, contributing to personalized risk assessment and therapeutic strategies.
Methods: We conducted a retrospective cohort study on 359 stroke patients admitted to the intensive care unit and assigned them to diabetic and nondiabetic groups. Neutrophil-to-lymphocyte ratio and monocyte-to-lymphocyte ratio were calculated from complete blood count upon admission. The association between the biomarkers and 30-day mortality was assessed using Spearman's correlation. The predictive ability of neutrophil-to-lymphocyte ratio and monocyte-to-lymphocyte ratio on short-term mortality was evaluated using univariate and multivariate regression, and the predictive performance was determined using receiver operating curve analysis.
Results: In the non-diabetic stroke group, neutrophil-to-lymphocyte ratio was significantly associated with 30-day mortality in both univariate (OR = 1.14, 95% CI: 1.075–1.206, $p < 0.001$) and multivariate analyses (OR = 1.12, 95% CI: 1.04–1.22, $p = 0.004$), with an optimal cutoff of 6.2 (sensitivity = 72%, specificity = 77%). Monocyte-to-lymphocyte ratio showed significance in univariate analysis (OR = 6.13, 95% CI: 2.40–15.6, $p < 0.001$) but not in multivariate analysis.
Conclusions: In the diabetic stroke group, neither neutrophil-to-lymphocyte ratio nor monocyte-to-lymphocyte ratio independently

predicted mortality. In conclusion, neutrophil-to-lymphocyte ratio only emerged as a reliable predictor for 30-day mortality in non-diabetic stroke patients. However, in diabetic stroke patients, its predictive ability is blunted.

Co-occurrence of hypomagnesemia and hypokalemia and their effect on 28-day mortality in critically ill patients, a retrospective cohort study

S. Al-Azzam[1]
[1]Clinical Pharmacy, Jordan University of Science & Technology (JUST), Irbid, Jordan
Correspondence: S. Al-Azzam
Intensive care Medicine Experimental 2025* 13(1):*000252.

Introduction: Among the various complications faced by critically ill patients, electrolyte disorders remain a significant complication associated with poor outcomes. Hypomagnesemia and hypokalemia are frequently encountered in critical care patients. Despite their clinical significance, data on their combined effect on mortality and ICU length of stay (LOS) is limited, especially in Middle Eastern populations.
Objectives: To assess the impact of hypomagnesemia and hypokalemia, individually and in combination, on 28-day mortality, overall mortality, and ICU length of stay among critically ill patients.
Methods: A retrospective cohort study in a tertiary hospital was conducted, and data were obtained from the medical records of all patients admitted to the ICU during the period of July 2012 to July 2022. The patients were divided into four major groups based on their magnesium and potassium levels. The 28-day mortality, mortality rate, and length of stay were measured as outcomes. SPSS software version 22 was used for data analysis.
Results: The prevalence of hypomagnesemia, hypokalemia, and their co-occurrence were 16%, 11.9%, and 4.2%, respectively. Hypomagnesemia was associated with a longer LOS (13.84 vs. 11.34 days, $p \leq 0.05$) but not with a significant increase in 28-day mortality (36%). Hypokalemia significantly increased 28-day mortality (42% vs. 36%, $p \leq 0.05$) and LOS (14.87 vs. 11.44 days, $p \leq 0.05$). Combined hypomagnesemia and hypokalemia significantly increased 28-day mortality (42.6% vs. 36.5%, $p \leq 0.05$) and LOS (17.44 vs. 11.6 days, $p \leq 0.05$).
Conclusions: Both hypomagnesemia and hypokalemia negatively impact ICU outcomes, with the combined disturbances showing the most significant effect on mortality and LOS. Early detection and correction are critical for improving patient outcomes.

Predictors of acute kidney injury in patients with diabetic ketoacidosis: a retrospective observational study

Y. Al-Azzam[1]
[1]Medicine, Jordan University of Science & Technology (JUST), الرمثا, Jordan
Correspondence: Y. Al-Azzam
Intensive care Medicine Experimental 2025* 13(1):*000253.

Introduction: Acute kidney injury (AKI) is a serious complication in patients with diabetic ketoacidosis (DKA), contributing to prolonged hospital stays, increased morbidity, and higher mortality rates. Identifying key predictors of acute kidney injury in diabetic ketoacidosis patients is essential for early risk stratification and intervention and improving patient outcomes.
Objectives: The study aimed to identify predictors of acute kidney injury in patients with diabetic ketoacidosis admitted to the Intensive Care Unit (ICU).
Methods: This retrospective observational study analyzed a cohort of all diabetic ketoacidosis patients admitted to the intensive care unit (ICU) from July 2012 to July 2022. Data were extracted from electronic health records, including demographic factors, prior acute kidney injury history, comorbidities, and clinical outcomes.
Results: A total of 152 patients with diabetic ketoacidosis admitted to the ICU were included in the analysis. Acute kidney injury was observed in 24 (15.5%) of patients. Significant predictors of acute kidney injury included hypertension ($p = 0.018$), prior acute kidney injury history ($p = 0.021$), human albumin administration ($p < 0.000$), and blood product transfusions ($p = 0.001$).
Conclusions: Hypertension, prior acute kidney injury, human albumin administration, and blood product transfusions were identified as significant predictors of acute kidney injury in diabetic ketoacidosis patients reflecting overall disease severity. Larger studies are needed to confirm these findings and explore the complex interplay between fluid management, hemodynamic stability, and acute kidney injury risk in critically ill diabetic ketoacidosis patients. Clinicians should remain cautious when managing fluid resuscitation and transfusion strategies in this population.

Effects or remote ischaemic preconditioning on contrast-associated nephropathy in diabetic patients and its relantionships to oxidative stress and inflammatory status

M. Galindo Martínez[1]; MD. Rodriguez Mulero[2]; F. Rodriguez Mulero[3]
[1]Intensive Care, Hospital General Universitario Santa Lucía, Cartagena, Spain; [2]Intensive Care, Hospital Universitario Santa Lucia, Cartagena, Spain; [3]Departamento de Fisiología Universidad de Murcia, Facultad Medicina Universidad Murcia, Cartagena, Spain.
Correspondence: M. Galindo Martínez
Intensive care Medicine Experimental 2025* 13(1):*000255.

Introduction: Remote ischaemic preconditioning (RIP) is a non-pharmacological strategies proposed to reduce the incidence of contrast-associated nephropathy (CN). Previous research describes protective effects in patients with risk factors, as in diabetic patients. This protective effect might be related to the activation of haemoxygenase-1 (HO-1) enzyme. HO-1 is a protein rapidly induced by various stimuli (such as RIP), which triggers vasodilator, anti-inflammatory and anti-apoptotic effects at the renal level.
However, some studies suggests that this mechanism may be altered in diabetic patients, in whom the protective effects by RIP may be attenuated.
Objectives: Evaluate if the manoeuvre of remote ischaemic preconditioning (RIP) exerts beneficial preventive effects on contrast-associated nephropathy (CN) through activation of antioxidant defence system haemoxygenase-1 (HO-1) dependent antioxidant and anti-inflammatory mechanisms, in diabetic patients undergoing preferential coronary intervention (CI).
Methods: A prospective randomized, single centre pilot trial was conducted at University Hospital Sta. Lucia, Spain. We analyzed 71 diabetic adult patients with acute coronary syndrome admitted to a medical intensive care unit, with a diagnosis of diabetes before admission, undergoing standard coronary intervention (CI).
We established two groups (random assignment): one of them received the RIP manoeuvre (RIPC group) trough intermittent upper-arm ischemia before CI, and the other one did not received it (control group). We recorded demographical, clinical, and analytical data of the patients, before and after 72 h of procedure. We analyzed the changes in the levels of HO-1, before and after RIP, and their relationship with the development of CN.

The effect of RIP on the temporal evolution of the inflammatory state was also studied by determining changes in the white series, C-reactive protein (CRP) and plasma ferritin levels, and their relationship with the development of CN.

Results: The incidence of CN in our sample was 32.4%.

Receiving the RIP manoeuvre was not associated with significant differences in this respect between groups and did not affect the time course of the antioxidant status.

There was no association between antioxidant status and the occurrence of CN.

Similarly, receiving the preconditioning manoeuvre did not affect the time course of the inflammatory markers analysed. There was also no association between inflammatory status and the occurrence of CN.

Conclusions: Based on our results we can describe the lack of efficacy of the RIP manoeuvre, in our diabetic patients, in terms of protecting them from developing CN, and the independence, of such a manoeuvre, of inflammatory and antioxidant behaviour.

Intensive care Medicine Experimental 2025* 13(1)*:000258.

Introduction: The impact of SDD in areas where multidrug-resistant bacteria (MDRB) are endemic is of great interest. Selective digestive decontamination (SDD) has been associated with a reduction in mortality and rates of nosocomial infections (NI).

Objectives: To analyze the impact on MDRB NI, antibiotic consumption and colistin and tobramycin colonization in an ICU after 13 years of SDD.

Methods: This study was conducted in a 30-bed medical-surgical ICU. All consecutive patients admitted to the ICU between October 1, 2011, and September 30, 2024, who were expected to require tracheal intubation > 48 h were administered SDD (SDD study group) with a 4-day course of intravenous cefotaxime plus enteral colistin, tobramycin, nystatin in an oropharyngeal paste and digestive solution. Oropharyngeal and rectal swabs were obtained on admission and once a week. We used ENVIN NI criteria. All patients admitted to ICU with NI in ICU between October 1, 2010, and September 30, 2011 (non-SDD group) were compared with the SDD study group. A univariate and a multivariate logistic regression analysis were performed. For each of the NIs, incidences per 1000 days of exposure in each cohort and the corresponding relative risks were obtained using Poisson regression. Statistical significance was $p \leq 0.05$. Colistin- and tobramycin-resistant colonization and antibiotic consumption as defined daily doses of antibiotics (DDD) were also analyzed.

Results: A total of 14.695 patients were admitted to ICU. We analyzed patients who developed NI, and 933 patients of them received SDD. There were no statistically significant differences between the two groups in terms of admission type or demographics. SDD patients had significantly fewer extended spectrum beta-lactamase (ESBL) infections $p = 0.007$, other Gram negative multidrug resistant bacteria (GNB-MR) $p = 0.004$ (Table 1) and *Acinetobacter spp*. infections $p < 0.001$ (Table 2). There was also a significant reduction in the rates of ventilator-associated pneumonia (VAP), urinary tract infections, other secondary bacteremia and MDRB NI in the SDD group versus the non-SDD group (Table 3). There was 2 *Clostridioides difficile* infection. Colistin-resistant colonization was 14.7% and tobramycin-resistant colonization was 21.% of samples. There was a decrease in DDD/100 ICU stays after SDD.

Conclusions: After 13 years of SDD application, there was a significant reduction in ESBL, other GNB-MR and *Acinetobacter* infections, as well as rates of VAP, secondary bacteremia, urinary tract infections and MDRB NI. There was a decrease in antibiotic consumption after SDD. Low rates of colonization by colistin- and tobramycin-resistant bacteria were also observed.

Intensive care Medicine Experimental 2025* 13(1)*:000258.

Introduction: Selective digestive decontamination (SDD) has been associated with a reduction in nosocomial infections (NI). The fact that critically ill patients have the highest susceptibility, coupled with the frequent disruption of their defense barriers by invasive devices, has long justified the rates. Identifying factors associated with the development of NI by multidrug-resistant Gram negative bacteria (MRGNB) in ICU patients may help us to reduce them.

Objectives: To identify factors associated with the development of NIs by MRGNB in an ICU after 13 years of selective digestive decontamination (SDD).

Methods: Prospective study including patients who developed NI from 1 October 2010 to 30 September 2024 in a polivalent ICU. SDD was applied to all admitted patients requiring mechanical ventilation for more than 48 h. Intravenous cefotaxime plus enteral solution and a paste with colistin, tobramycin, and nystatin were administered every 8 h until discharge for the first 4 days. Rectal and pharyngeal swabs were requested on admission and weekly. The risk factors associated with the development of NI by MRGNB described in the literature were analysed. The diagnostic criteria for NIs were those of the ENVIN-Helics program. Univariate analysis and multidimensional logistic analysis of MRGNB were performed. It was considered statistically significant if $p \leq 0.05$.

Results: A total of 14.695 patients were admitted to the ICU during this period and 356 (34.13%) developed NI due to MRGNB out of a total of 1043 patients with NI. In univariate analysis (Table 1), patients with MRGNB had longer length of stay ($p < 0.001$) and higher ICU mortality ($p = 0.002$). Among the MRGNB responsible for infections, extended-spectrum beta-lactamase (ESBL) (63.2%) and MR *Pseudomonas* (24.3%) were the most common. The most frequent MRGNB NI was ventilator-associated pneumonia. The independent factors for the development of MRGNB NIs in the multivariate analysis were secondary bacteremia: OR: 1.674 (1.273,2.200) with $p < 0.001$ and SDD itself: OR: 0.373 (0.249,0.558) with $p < 0.001$ (Table 2).

Conclusions: Selective digestive decontamination was a statistically significant independent protective factor for the development of MRGNB NIs in our ICU. Secondary bacteremia was also an independent factor. Patients with these NIs had higher ICU length of stay and mortality. ESBL and MR *Pseudomonas* MRGNB NIs were the most common.

Intensive care Medicine Experimental 2025* 13(1):*000264.

Introduction: Sepsis-induced cardiomyopathy (SICM) is myocardial injury induced by sepsis, with a high mortality rate, directly impacting the prognosis of sepsis[1–4]. Due to its complex pathogenesis, there is a lack of effective treatment strategies and early warning biomarkers. Lipoprotein associated phospholipase A2 (Lp-PLA2) is considered to be associated with the regulation of inflammatory responses and is an independent risk factor for many inflammation-related diseases[5–10]. The activity and expression of Lp-PLA2 are associated with poor prognosis in septic shock patients and are mainly secreted by macrophages, which are key cells in maintaining the inflammatory homeostasis of the heart. However, the role of Lp-PLA2 and macrophages in SICM is not yet clear.
Objectives: This study aims to explore the role and specific mechanisms of Lp-PLA2 in regulating macrophages in SICM and to identify potential specific targets for the treatment of SICM.
Methods: This study utilized cecal ligation and puncture surgery or intraperitoneal injection of LPS to establish a mouse model of SICM, and used LPS stimulation of macrophages to establish a cell model of SICM. Through both animal and cell levels, lentiviral overexpression/knockdown of Lp-PLA2 and the specific drug darapladib were used, combined with experimental techniques such as RT-PCR, Western blot, co-culture of cells, immunofluorescence staining, cardiac ultrasound, and ELISA, to validate the important role of Lp-PLA2 in driving macrophage inflammation in the occurrence and development of SICM. Subsequently, techniques such as COIP-MS, RNA-Seq, Western blot, and immunofluorescence staining were used to validate that Lp-PLA2 drives macrophage inflammation through the iNOS/NLRP3 signaling pathway.

Result

1. In the cardiac tissues of LPS/CLP-induced SICM mice, Lp-PLA2 expression is upregulated and primarily localized in macrophages.
2. Darapladib downregulates the expression of inflammatory factors *iNOS*, *Il-1β*, *Tnf-α*, *Il-6*, and *Il-10* in the cardiac tissues of SICM mice by inhibiting Lp-PLA2 expression and activity, and the intervention effect of 50 mg/kg darapladib is significant.
3. A dose of 50 mg/kg darapladib significantly reduces the mortality and the expression of cardiac injury markers ANP, BNP, CK-MB, and cTnI in SICM mice, and maintains normal EF and FS values at various time points.
4. Inhibiting Lp-PLA2 can downregulate the expression of macrophage activation markers CD68 and inflammatory factors *Tnf-α*, *Il-6* in LPS-treated macrophages, and alleviate the damage of the supernatant from LPS-treated macrophages to the viability of H9C2 myocardial cells.
5. iNOS is a downstream transcription factor of Lp-PLA2, and knocking down Lp-PLA2 in macrophages can inhibit the LPS-induced increase of iNOS.
6. Transcriptomic testing suggests that NLRP3 is a key molecule in Lp-PLA2-regulated macrophage inflammatory response. In SICM mouse heart tissue, NLRP3 is significantly positively correlated with Lp-PLA2, and darapladib can inhibit the expression of NLRP3.
7. MCC950 can significantly inhibit the expression of NLRP3. When used alone, both MCC950 and darapladib can inhibit the expression of NLRP3, iNOS, and IL-1β, and can significantly downregulate the transcription of the inflammatory factors *Tnf-α* and *Il-6*. The combined use does not have an additive effect.

Conclusions: Lp-PLA2 regulates macrophage inflammatory response through iNOS/NLRP3, contributing to the occurrence and development of SICM. Inhibiting Lp-PLA2 may improve the prognosis of SICM, and darapladib could potentially become a therapeutic drug for SICM patients.

Trajectories of 24-h heart rate and hemorrhagic transformation in acute ischemic stroke patient receiving intravenous thrombolysis

C. Hantrakul[1]; P. Korathanakhun[2]; V. Vattanavanit[3]
[1]Division of Internal Medicine, Prince of Songkla University, Hat Yai, Thailand; [2]Neurology Unit, Division of Internal Medicine, Prince of Songkla University, Hat Yai, Thailand; [3]Critical Care Medicine Unit, Division of Internal Medicine, Prince of Songkla University, Hat Yai, Thailand

Intensive care Medicine Experimental 2025* 13(1):*000265.

Introduction: Hemorrhagic transformation (HT) is a serious complication in patients with acute ischemic stroke (AIS) receiving intravenous thrombolysis (IVT) with recombinant tissue plasminogen activator (rtPA). Previous studies have shown that admission heart rate (HR) is associated with poor outcomes in AIS. Heart rate trajectory (HRT), which reflects autonomic nervous system regulation over time, may provide more comprehensive insights than single-point HR measurements. However, data on the association between HRT and HT in AIS patients receiving IVT remain limited.
Objectives: The primary objective was to evaluate the association between 24-h HRT patterns and hemorrhagic transformation in AIS patients treated with IVT. Secondary objectives included assessing the relationships between HRT patterns and in-hospital mortality, as well as functional outcomes at discharge, measured by the modified Rankin Scale (mRS).
Methods: This retrospective cohort study included AIS patients who received IV rtPA alone at Songklanagarind Hospital between January 2015 and February 2025. Patients aged over 18 years with confirmed AIS, complete 24-h HR data, and follow-up neuroimaging were included. Hourly HR values during the first 24 h were analyzed using latent mixture modeling to classify HRT patterns.

Results: A total of 164 AIS patients were included. Of these, 38 (23.2%) developed hemorrhagic transformation. Four distinct HRT groups were identified: low HR trajectory (T1; 7.3%), moderate-low HR trajectory (T2; 37.8%), moderate-high HR trajectory (T3; 40.9%), and high HR trajectory (T4; 14.0%). Compared with the low HR group, the high HR group was significantly associated with an increased risk of HT, with an adjusted odds ratio of 11.12 (95% confidence interval [CI]: 1.01–122.59; $P = 0.049$). While in-hospital mortality did not differ significantly across groups, discharge mRS scores varied significantly by trajectory ($P = 0.010$), suggesting a relationship between HRT pattern and functional outcome.
Conclusions: In AIS patients treated with IV rtPA, distinct 24-h heart rate trajectory patterns were significantly associated with the risk of hemorrhagic transformation and functional outcomes at discharge. Notably, a persistently high HR trajectory was correlated with a markedly increased risk of HT. Trajectory-based assessment may be a valuable tool for early risk stratification, and heart rate control could represent a future therapeutic target in AIS management during thrombolysis.

Trajectory groups of heart rate measured repeatedly during the first 24 h after rt-PA administration. Group 1 (7.3%), group 2 (37.8%), group 3 (40.9%) and group 4 (14%) were categorized as the low HR, moderate–low HR, moderate–high HR, and high HR groups, respectively.

The association between exposure to hypertonic albumin and mortality after traumatic brain injury

M. Salvagno[1]; JL. Vincent[1]; F. Taccone[1]
[1]Soins intensif, ULB Erasme, Brussels, Belgium
Correspondence: M. Salvagno.
Intensive care Medicine Experimental 2025* 13(1):*000267.

Introduction: Traumatic brain injury (TBI) is a leading cause of morbidity and mortality in critically ill patients and often requires fluid administration.[1] Previous studies have suggested a potential association between albumin administration and increased mortality after TBI; however, few data are available for hypertonic (25%) albumin administration.[2,3].
Objectives: This study aims to investigate the relationship between hypertonic albumin use and hospital mortality in TBI patients.
Methods: We conducted a retrospective analysis using the MIMIC-IV database via BigQuery. We identified Intensive Care Unit (ICU) admissions for TBI based on ICD-9 and ICD-10 diagnosis codes. Unique hospital admissions were used as the unit of analysis to account for patients with multiple encounters. Administration of albumin during the ICU stay was determined, and only administrations occurring between ICU admission and discharge were included. Patients were stratified based on whether they received hypertonic albumin. Clinical presentation was assessed using the first available Glasgow Coma Scale (GCS) score within six hours of ICU admission and SOFA score of the first 24 h. Demographic data, ICU length of stay, and hospital mortality were extracted and compared between groups. A multivariable logistic regression was conducted on the propensity score-matched cohort to assess the association between hypertonic albumin administration and hospital mortality.
Results: We identified 3.074 patients (62.5% male; median age 66 [IQR 48–82] years; median LOS 48 [IQR 25–105] hours) diagnosed with TBI who were admitted to the ICU. Among them, 28 (0.9%) received at least one administration of hypertonic albumin during their ICU stay. Of the 3.047 patients who did not receive albumin, 370 (12.1%) died, compared to 12 deaths (42.9%) in the hypertonic albumin group ($p < 0.001$). However, patients receiving hypertonic albumin had higher SOFA score during the first 24 h (7 [IQR 4–9] vs. 3 [IQR 2–4], p 0.04) and longer ICU stays (190 [IQR 59–347] vs. 48 [IQR 25–103] hours, $p < 0.001$), without differences in age and gender. After a multivariable logistic regression including first-day SOFA, conducted on the propensity score-matched cohort, the administration of hypertonic albumin was not independently associated with hospital mortality (OR 1.17; 95% CI: 0.37–3.72; $p = 0.79$).
Conclusions: In this cohort of ICU patients with TBI, administration of hypertonic albumin was not significantly associated with higher probability of in-hospital mortality.

Intensive care Medicine Experimental 2025* 13(1):*000268.

Introduction: Inflammatory subphenotypes of acute respiratory distress syndrome (ARDS) identify patients with distinct outcomes and may lead to possible individualized treatment (1). However, temporal evolution of the initial subphenotype is unclear (2,3), and may impact targeted treatment strategies (4).
Objectives: This study assessed the temporal stability of inflammatory subphenotypes of ARDS and potential clinical implications using the example of early corticosteroids.
Methods: Data and biomarkers from six multicenter randomized controlled trials (RCTs, n = 3,958: ARMA, ALVEOLI, FACTT, SAILS, ROSE, EPVent-2) were analyzed to develop and validate an open-source AI Clinical Classifier for classification of inflammatory subphenotypes of ARDS using routinely available data. Then, it was used to classify a retrospective cohort including 5,578 adult ARDS patients from the seven intensive care units at Beth Israel Deaconess Medical Center (Boston) between 2008 and 2024. A Bayesian Markov model was used to evaluate temporal stability at 3-day intervals until day 30 (5). Multivariable logistic regression models assessed the effect of early corticosteroids on 30-day mortality across subphenotypes.
Results: An open-source AI Clinical Classifier (https://bostonmontpellier.shinyapps.io/AIClarity) was developed and externally validated across six RCTs before longitudinal validation using biomarkers until day 7 (Fig. 1). In the retrospective cohort, 2,169 (39%) hyperinflammatory and 3,409 (61%) hypoinflammatory patients were identified. The 30-day mortality was 49% (1,053/2,169) and 24% (826/3,409, $p < 0.001$), respectively. Over 30 days, 1,072 (49%) hyperinflammatory patients at baseline transitioned to hypoinflammatory, compared to 229 (7%) hypoinflammatory patients at baseline transitioning to hyperinflammatory ($p < 0.001$). Every 3 days, patients initially classified as hyperinflammatory had a 51% probability of staying hyperinflammatory, and a 24% probability of transitioning to hypoinflammatory (Fig. 2). Every 3 days, patients initially classified as hypoinflammatory had a 62% probability of staying hypoinflammatory, and a 7% probability of transitioning to hyperinflammatory. Early corticosteroids were associated with a lower 30-day mortality (adjusted odds ratio, aOR = 0.76 [95% confidence interval (95%CI):0.59–0.99], $p = 0.040$) in hyperinflammatory patients at baseline, and a higher 30-day mortality (aOR = 1.46 [95%CI:1.17–1.82], $p < 0.001$) in hypoinflammatory patients (p-for-interaction < 0.001, Fig. 3). Only patients who stayed hyperinflammatory at day 3 exhibited a persistent response to corticosteroids (aOR = 0.51, 95%CI:0.32–0.80, $p = 0.004$).
Conclusions: While the hypoinflammatory subphenotype of ARDS remains stable over time, the hyperinflammatory subphenotype displays a more unpredictable trajectory. Early corticosteroids may benefit hyperinflammatory ARDS patients until transition to hypoinflammatory, supporting re-classification to ensure treatment success.

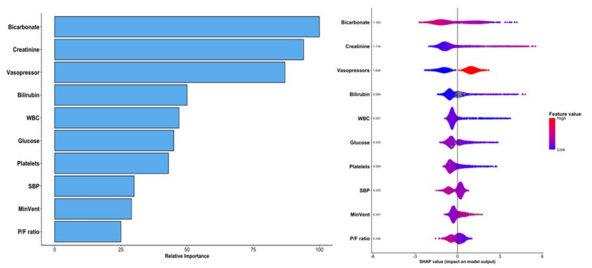

Fig. 1 (abstract 000268) Most important variables in the AI Clinical Classifier
Left panel: the variables used by the AI Clinical Classifier to make a prediction are organized by relative importance from top to bottom.
Right panel: each patient is represented by a dot. The color represents the value of the variable. Its position on the horizontal axis represents its SHAP value (its impact on the prediction). The farther to the right the dot is, the higher the probability of hyperinflammation.
WBC: white blood cell count, SBP: systolic blood pressure, MinVent: minute ventilation, P/F: PaO2/FiO2.

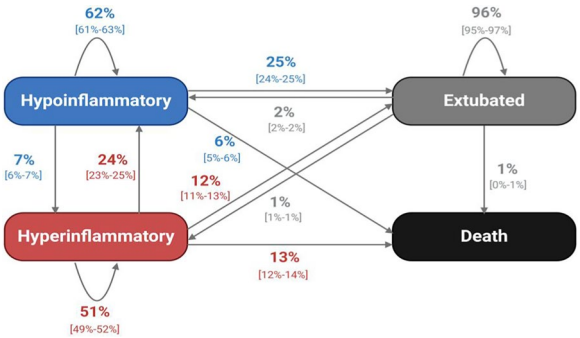

Fig. 2 (abstract 000268) Temporal transition probabilities per 3-day intervals and 95% credible intervals in the Bayesian Markov model
The numbers represent the probability of transitioning from one state to another every three days. Red numbers represent the probabilities for hyperinflammatory patients, blue numbers for hypoinflammatory patients, and grey number for extubated patients.

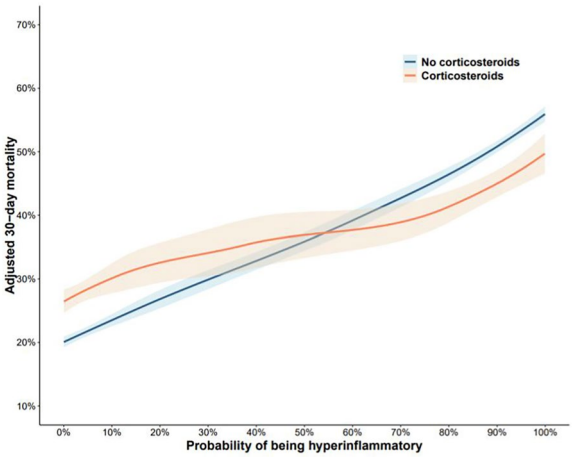

Fig. 3 (abstract 000268) Corticosteroids effect on 30-day mortality according to the probability of being hyperinflammatory at baseline
The probability of being hyperinflammatory at baseline is derived from the AI Clinical Classifier. Adjusted on age, sex, ethnicity, body mass index, hematologic malignancy, COVID-19, chronic obstructive pulmonary disease, PaO2/FiO2 ratio, Sequential Organ Failure Assessment score, neuromuscular blockade administration, and sedation depth.

Impact of the NHS Lothian Critical Care Recovery Service on post-ICU hospital stay and costs: a retrospective cohort analysis

G. Fleming[1]; J. Thompson[1]; J. Wilson[1]; B. Mcghee[1]; N. Cosette[1]; T. Jones[1]; R. Reagan[1]; E. Forbes[1]; S. Hobson[2]; D. Leanne[1]; L. Elliott[1]; H. Lousada[1]; L. Richards[1]; M. Johnston[1]; S. Macinnes[1]; A. Wilkinson[1]; Z. Jiwaji[1]

Correspondence: G. Fleming
Intensive care Medicine Experimental 2025* 13(1)*:000269.

Introduction: Survivors of critical illness frequently experience prolonged hospital stays and substantial healthcare costs due to complex rehabilitation needs. To address this, NHS Lothian implemented the Critical Care Recovery Service (CCRS) in 2021, providing a structured multidisciplinary pathway for post-ICU rehabilitation. This study evaluates the impact of CCRS on post-ICU hospital length of stay (LOS) and associated costs.
Methods: A retrospective cohort analysis was conducted at the Royal Infirmary of Edinburgh, comparing ICU survivors pre-CCRS implementation in 2019 with those managed by CCRS in 2024. Patients in the 2019 cohort were retrospectively triaged to ensure they met CCRS inclusion criteria. Exclusions included patients eligible for alternative rehabilitation pathways (e.g., major trauma, stroke, neurosurgery) and those who died during their hospitalisation. Cost estimates were derived from Public Health Scotland's Scottish Costs Book, calculating total post-ICU hospitalisation expenses.
Results: There were 99 patients in pre-CCRS implementation cohort (2019) and 95 patients in the post CCRS implementation cohort (2024). Implementation of CCRS was associated with a reduction in median post-ICU hospital LOS from 16 days (IQR 12–34) to 11.5 days (IQR 7–25.5), despite unchanged median ICU LOS (12 days) in both cohorts. The proportion of patients requiring prolonged hospitalisation (> 30 days post-ICU) significantly declined from 31 to 24% ($p < 0.05$). Cost analysis revealed a median per-patient reduction in post-ICU hospitalisation expenses from £21,000 to £12,650, leading to a total cost saving of £660,951 (£3,103,268 pre-CCRS vs. £2,442,317 post-CCRS).
Conclusions: The implementation of CCRS has contributed to significant reductions in hospital LOS and healthcare costs for post-ICU patients. These findings support the continued investment and expansion of CCRS services to optimise healthcare resources and improve patient outcomes. Future studies should assess patient centred measures of long-term recovery, hospital readmission rates and healthcare resource utilisation post CCRS implementation.

Pupil diameter in patients with a brain death clinic

A. Gritsan[1]; N. Dovbish[2]
[1]Anaesthesiology and Intensive Care, Krasnoyarsk State Medical University, Krasnoayrsk Regional Clinical Hospital, Krasnoyarsk, Russia; [2]Anaesthesiology and Intensive Care, Krasnoyarsk State Medical University, Krasnoyarsk Regional Clinical Hospital, Krasnoyarsk, Russia
Correspondence: A. Gritsan
Intensive care Medicine Experimental 2025 **13(1)**:00270.

Introduction: When deciding on the possibility of ascertaining brain death, it is mandatory to comply with existing national recommendations/orders. Russian recommendations, along with such mandatory criteria that make it possible to suspect brain death in a patient, such as complete and stable lack of consciousness (coma); atony of all muscles; lack of reaction to severe pain stimuli in the area of trigeminal points and any other reflexes closing above the cervical spinal cord; immobility of the eyeballs, lack of reaction of the maximally dilated pupils—for adults, the diameter of the pupils is more than 5 mm, to direct bright light; absence of corneal reflexes; absence of oculocephalic reflexes; absence of oculovestibular reflexes; absence of pharyngeal and tracheal reflexes. If all of the above criteria are met, an apnoeic oxygenation test is performed to determine the absence of spontaneous breathing. After passing this test, a clinical diagnosis of brain death is made and dynamic observation begins from 6 to 72 h, depending on the cause of the development of this condition. We noted that in a number of patients, in the presence of all the criteria that make it possible to establish the diagnosis of brain death, the diameter of the pupils does not reach 5 mm or more.
Objectives: To assess the effect of pupil diameter in patients with the absence of other clinical signs on the ascertainment of brain death in patients with primary brain injury.
Methods: The study included 95 patients with primary brain injuries (strokes, traumatic brain injuries) over 18 years of age, admitted to the Regional Clinical Hospital from September 4, 2023 to March 22, 2024 (201 days). Patients received standardised therapy, including mechanical ventilation. In the development of atonic coma and the absence of reaction to painful stimuli, the absence of pupils' reaction to light, the absence of corneal, oculocephalic, oculovestibular, pharyngeal and tracheal reflexes, as well as the absence of the pattern of own breathing (assessed by the absence of own breaths in the Adaptive Support Ventilation mode of the Hamilton-C2 device with a trigger sensitivity of 1 l/min), the pupil diameter was measured.
Results: 31 (33%) patients out of 95 developed atonic coma with no stem reflexes and no self-breathing pattern. When assessing the pupil diameter in 13 (37%) patients out of 31 patients, the pupil diameter was less than 5 mm, which did not allow for the ascertainment of brain death. Pupil diameter less than 5 mm remained in all patients until circulatory arrest, with no surviving patients in this group. The death of patients occurred within 48 h from the moment of the development of atonic coma with the absence of their own breathing.
The absence of an increase in pupillary diameter of 5 mm or more in patients with other signs of brain death is a common phenomenon in clinical practice. In reviewing the available literature, we found that in a retrospective study by Pavlina Lenga et al. (2024) in a group of 17 patients with established brain death, the mean diameter for the right pupil was 4.9 mm (± 1.3) and 5.2 mm (± 1.2) for the left pupil, i.e. half of the patients had pupil diameter less than 5 mm. In a study by Shlugman D. et al. (2001), 148 patients were diagnosed with brain death, several of whom had pupil diameters less than 4 mm. Khandelwal et al. (2019) described several cases where the pupil diameter of

the patients was less than 3 mm, which led to the question of the possibility of declaring brain death in these patients, but after a thorough assessment of the stem reflexes and confirmation of their absence, the pronouncement of death in these patients was carried out.
Conclusions: The presence of the phenomenon of absence of pupil diameter increase of 5 mm or more is a significant factor influencing the frequency of brain death determinations, with its mandatory presence in national clinical guidelines.

Intensive care Medicine Experimental 2025* 13(1):*000271.

Introduction: Intensive Care Unit (ICU) transport bags are vital for patient transfers and emergencies. They were designed nearly ten years ago with multiple carrying methods, which include: as a backpack, clipped onto the side of the bed or under the headrest (Van Zwanenberg, Dransfield and Juneja, 2016). Despite their robustness, concerns about their ergonomics promote an evaluation of their design.
Objectives: This study aimed to assess staff knowledge, utilisation, and satisfaction regarding these bags, focusing on potential safety impacts.
Methods: A cross-sectional study with one hundred staff, across three intensive care units, completed an online survey on frequency, awareness of recommended usage, actual practices, and overall satisfaction. This involved an image of intended use. We collected feedback on main concerns. Staff included nurses, doctors, porters, etc.
Results: Results revealed that while staff used the bags regularly, 79% were unaware of recommended transport Methods: Only 34% were satisfied with current bag deployment, with concerns about weight and strap design. Lack of education and musculoskeletal injury were commonly identified themes.
Conclusions: Poor awareness of recommended transport, coupled with low satisfaction rates, highlight a gap between intended use and actual practice. Failure of intended use demonstrates the need for staff education. Concerns raised were related to the strap design, weight and a high risk of associated potential injury and days lost to sickness. The intersection of human factors and ergonomics suggests that addressing these issues could improve staff safety. Future research should focus on exploring innovative designs for ICU transfer bags to improve staff experience and safety.

Intensive care Medicine Experimental* 2*025* 13(1):*000279.

Introduction: The COVID-19 pandemic had become a global emergency, with nearly 200 countries facing the crisis. Healthcare workers (HCWs) are at high risk, especially during aerosol-generating procedures. Proper training helps HCWs follow safety precautions, protecting themselves and their teams. Simulation-based training has proven effective in improving protocol adherence and helping HCWs perform procedures while wearing personal protective equipment (PPE). This method has also been successful in past epidemics, providing essential skills and overcoming technical challenges faced in high-risk environments.
Objectives: • Education of health care workers (HCW) to protect themselves and the team from acquiring infections while doing procedures on patients with COVID-19, that have the potential to generate aerosol.
• Training of HCWs to perform procedures with simulated personal protective equipment (PPE), to understand the technical difficulties that might be encountered and improve self-confidence.
Methods: The study, conducted by the Department of Anaesthesiology, Pain Medicine, and Critical Care, involves simulated training for COVID-19 management using mannequins. Participation in the study is voluntary, with full training provided regardless of participation. The intervention study follows a single-group pre–post design. Residents from various departments handling COVID-19 patients are eligible. A sample size of 200–250 residents is expected, with analysis after 50 trainings. The online teaching module (OTM) includes a standard operating procedure, audiovisual demonstration, and reading material. Simulation sessions will involve PPE simulation, mannequin practice, and procedure demonstrations. Participants will complete pre- and post-test questionnaires. Feedback will be provided by assessors, and materials will be discarded after each session.
Results: The study involved 51 Anaesthesia Residents over six months, including Junior Residents and those with 1–3 years of experience. A pre-test on bronchoscopy showed a mean score of 7.72 ± 1.0, improving to 8.66 ± 1.06 in the Post-Test ($P < 0.0001$). Similarly, pre-test intubation scores were 6.92 ± 1.39, rising to 9.45 ± 1.10 post-test ($P < 0.0001$). Post-simulation checklists revealed that 55% of participants scored ≥ 11 correct answers in bronchoscopy, and 57% did so in intubation. Feedback indicated 41% were very happy with the program, 80% understood it well, and 57% rated the content highly. Overall, the study demonstrated significant knowledge improvement and positive participant feedback.
Conclusions: Simulation-based training significantly improved healthcare workers' skills and knowledge in performing high-risk procedures like bronchoscopy and intubation while using PPE during the COVID-19 pandemic. The positive results and participant feedback demonstrate that this approach effectively enhances technical abilities and confidence, making it a valuable tool for training in high-risk environments. This method can be a key component of residency programs to ensure better preparedness and safety in future healthcare crises.

Methodology of the study.

Impact of awake prone positioning on lung aeration during high-flow nasal oxygen and continuous positive airway pressure: a prospective physiologic study

Y. Wang[1]; J. LI[2]; M. Zhong[3]
[1]Critical Care Medicine, Zhongshan Hospital, Fudan University, Shanghai, China; [2]Respiratory care, RUSH University Medical Center, Chicago, United States of America; [3]Department of Critical Care Medicine, Zhongshan Hospital, Fudan University, Shanghai, China

Introduction: Awake prone positioning (APP) has been reported to improve oxygenation for non-intubated patients with acute hypoxemic respiratory failure (AHRF) (1–3), particularly for patients with COVID-19 induced AHRF, APP has been shown to decrease the need of intubation(4, 5). However, a recent meta-analysis has revealed that the benefits of APP are more pronounced in patients who receive advanced respiratory support, including high-flow nasal cannula (HFNC) oxygen therapy, continuous positive airway pressure (CPAP), and noninvasive ventilation (NIV)(6), while no significant differences in intubation risk were observed between APP and supine position for those on conventional oxygen therapy. Furthermore, a subgroup analysis from a multi-center randomized controlled trial comparing APP with standard care has highlighted an increased risk of endotracheal intubation in patients receiving NIV or CPAP, while those undergoing HFNC therapy showed a decreased risk (7).
On the other hand, the consistent positive end-expiratory pressure (PEEP) delivery inherent in CPAP and NIV distinguishes them from the variable PEEP levels generated by HFNC. CPAP and NIV have been shown superior over HFNC in terms of oxygenation improvement(8, 9). Additionally, helmet NIV effectively reduced inspiratory effort and mitigated pendelluft effects, setting it apart from HFNC(9). Correspondingly, in a multi-center randomized controlled trial involving COVID-19 patients, Perkins and colleagues highlighted CPAP's superiority over HFNC and conventional oxygen therapy in reducing intubation rates(10).
However, the synergistic effects of APP combined with CPAP, as well as the potential for more effective alveolar recruitment and improved ventilation homogeneity, remain unclear when compared to the combination of APP and HFNC. Thus, we aimed to explore the impact on ventilation homogeneity and alveolar recruitment of different respiratory support—conventional oxygen therapy, HFNC, and CPAP—in both supine and prone positions among COVID-19 patients with AHRF.
Objectives: Awake prone positioning (APP) has shown potential in improving oxygenation and reducing intubation rates in patients with acute hypoxemic respiratory failure (AHRF). This study aimed to evaluate the effects of APP on ventilation distribution during high-flow nasal cannula (HFNC) and continuous positive airway pressure (CPAP).
Methods: Thirty-four AHRF patients underwent 30-min phases of HFNC, high-flow oxygen mask (HFOM), and CPAP in both supine and prone positions in a random order. Ventilation was assessed using electrical impedance tomography (EIT).
Results: The pulse oximetry of saturation/fraction of inspired oxygen (SpO2/FiO2) and ROX index (defined as [SpO2/FIO2]/respiratory rate) were greater with CPAP compared to HFOM and HFNC in both supine and prone positions (all $P < 0.05$). APP significantly improved the SpO2/FiO2 and ROX index across all devices (all $P < 0.05$). In the supine position, center of ventilation (CoV) with CPAP was higher compared to both HFOM ($P = 0.015$) and HFNC ($P = 0.030$). However, during APP, CoV with CPAP decreased significantly compared to supine position ($P = 0.001$). Regardless of the type of respiratory support, APP did not significantly affect ΔZ but significantly reduced global inhomogeneity (GI) and pendelluft. In contrast, CPAP, regardless of the position (supine or prone), significantly increased ΔZ and global inhomogeneity (GI) but had no effect on pendelluft, when compared to other respiratory support Methods: Regarding comfort, both APP and CPAP resulted in lower comfort levels compared to the baseline.
Conclusions: Compared to HFOM and HFNC, CPAP significantly improved oxygenation but may cause global ventilation inhomogeneity. APP reduced GI and pendelluft; whereas, using APP during CPAP facilitated homogeneous ventilation distribution, further improving oxygenation.

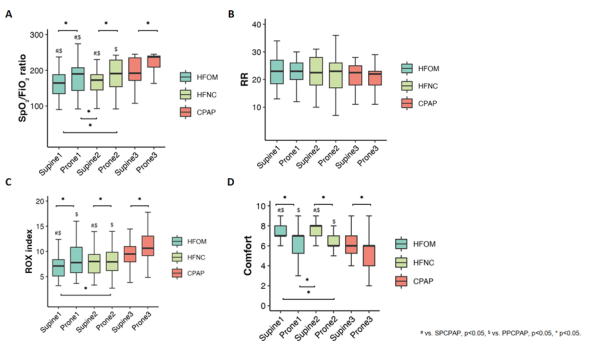

Fig. 1 (abstract 000280) Evolution of SpO2/FiO2 (A), RR(B), ROX index (C) and comfort (D) with HFOM, HFNC and CPAP in supine and prone position. # vs. SPCPAP, p < 0.05, $ vs. PPCPAP, p < 0.05, * p < 0.05. The difference of outcomes in cardiac arrest patients post targeted temperature management between patients with and without diabetes mellitus: the nationwide multicenter TIMECARD study

CH. Chiang[1]; WT. Hung[2]; YT. Wu[1]; KC. Lin[3]; WC. Huang[4]
[1]Cardiovascular Medical Center, Kaohsiung Veterans General Hospital, Kaohsiung City, Taiwan; [2]Department of Critical Care Medicine, Pingtung Veterans General Hospital, Pingtung City, Taiwan; [3]Department of Critical Care Medicine, Kaohsiung Veterans General Hospital, Kaohsiung City, Taiwan; [4]Department of Cardiovascular Medicine, Pingtung Christian Hospital, Pingtung City, Taiwan
Correspondence: C.H. Chiang
Intensive care Medicine Experimental 2025* 13(1):*000282.

Introduction: Targeted temperature management (TTM) reduces mortality rates and improves neurological function in patients who experience cardiac arrest. However, the differences in responses to TTM between patients with and without diabetes mellitus (DM) require further investigation.
Objectives: We therefore aimed to examine the outcomes of TTM therapy for patients with and without DM who were treated for cardiac arrest.
Methods: This multicenter observational study included patients who experienced cardiac arrest and received TTM therapy between January 2013 and September 2019. Comparisons were made between DM and non-DM patient groups.
Results: A total of 580 patients were enrolled. The DM group had a worse survival rate (45.3% vs. 32.0%, $p = 0.0016$) and worse neurological outcomes (GCS score > 8: 67.5% vs. 53.2%, $p = 0.0318$) at hospital discharge. In the multivariate logistic regression analysis, it revealed that DM was a negative predictor for survival in patients who underwent cardiac arrest and were treated by TTM (OR = 1.51, 95% CI: 1.03–2.21, $p = 0.0366$). In the DM group, coronary intervention (OR = 0.262, 95% CI: 0.11–0.64, $p = 0.0034$) was a positive predictor for survival. In the non-DM group, prehospital return of spontaneous circulation (OR = 0.444, 95% CI: 0.24–0.83, $p = 0.0108$) was a positive predictor for survival, whereas old age > 65 years (OR = 2.15, 95% CI: 1.30–3.56,

$p = 0.003$) and mean arterial pressure < 65 mmHg (OR = 2.957, 95% CI: 1.49–5.86, $p = 0.019$) were negative predictors.
Conclusions: This study showed that DM is significantly associated with worse survival and neurological outcomes in patients who experience cardiac arrest and are treated by TTM. Additionally, patients with DM who had cardiogenic etiologies and initial shockable rhythms had a higher mortality rate. Some positive factors for survival, such as witness collapse and prehospital return of spontaneous circulation, were reduced in patients with DM.

Impact of recurrent enteral feeding intolerance on 30-day mortality in critically ill patients: a retrospective cohort study
CY. Wang[1]; CH. Wang[2]; PK. Fu[3]; CY. Hsu[4]
[1]Department of critical care medicine, Taichung Veterans General Hospital, Taichung, Taiwan; [2]Graduate institute of education, National Changhua University of Education, Changhua, Taiwan; [3]Department of Medical Research, Taichung Veterans General Hospital, Taichung, Taiwan; [4]Biostatistics task force, Taichung Veterans General Hospital, Taichung, Taiwan
Correspondence: C.Y. Wang
Intensive care Medicine Experimental 2025* 13(1)*:000283.

Introduction: Feeding intolerance (FI) is a prevalent and significant challenge in critically ill patients, often contributing to adverse clinical outcomes. While previous studies have established an association between a single episode of enteral feeding intolerance (EFI) and poor prognosis, the impact of multiple EFI episodes on patient outcomes remains inadequately explored. Given the potential prognostic significance of recurrent EFI in intensive care unit (ICU) patients, this study aims to evaluate its relationship with patient survival.
Objectives: We conducted a retrospective study of ICU patients requiring mechanical ventilation from July 2021 to September 2022.
Methods: Inclusion criteria comprised patients aged ≥ 20 years, requiring mechanical ventilation, and with an ICU stay exceeding three days. Patients with contraindications to enteral nutrition were excluded. EFI was defined as an interruption of enteral feeding with difficulty achieving the target intake due to any of the following: high gastric residual volumes, increased abdominal girth, distension, subjective discomfort, emesis, or diarrhea. A single episode of EFI was defined as meeting EFI criteria for one day, whereas multiple episodes of EFI indicated recurrent occurrences.
Results: Among 447 patients (mean age 69 years; mean APACHE II score 25), 15% experienced a single episode of EFI, while 29% experienced multiple episodes. The average daily enteral nutrition intake during the first 7 days was 692 kcal/day in patients with EFI, compared to 889 kcal/day in those without EFI. In multivariable Cox regression analysis, multiple EFI episodes were independently associated with increased 30-day mortality (hazard ratio [HR]: 1.66; 95% confidence interval [CI]: 1.10–2.49), as were higher APACHE II scores (HR: 1.08; 95% CI: 1.04–1.12). A single EFI episode was not significantly associated with mortality.
Conclusions: Multiple EFI episodes are linked to increased 30-day mortality in critically ill patients, highlighting the need for proactive management to prevent recurrent EFI.

Impact of pharmacist interventions on antimicrobial use in ICU
D. Mendes[1]; D. Videira[1]; M. Falcão[1]; F. Falcão[1]
[1]Pharmacy, Unidade Local de Saúde de Lisboa Ocidental, Lisbon, Portugal
Correspondence: D. Mendes
Intensive care Medicine Experimental 2025* 13(1)*:000288.

Introduction: Optimizing antimicrobial therapy in critically ill patients is essential to improving clinical outcomes and minimizing the emergence of antimicrobial resistance. Pharmacists play a crucial role in antimicrobial stewardship. This study aims to evaluate the relevance of pharmacist-led interventions on antimicrobial prescriptions in Intensive Care Units (ICU) with limited pharmacist support.
Objectives: Evaluate pharmacist interventions and how often they were accepted by doctors, regarding antimicrobial prescriptions in critically ill patients, in a setting where there is only one supporting pharmacist who is not exclusively dedicated to the ICU.
Methods: Pharmacist interventions regarding antimicrobial drugs were collected retrospectively in both ICUs of a tertiary hospital, using electronic prescribing system CPC-Glintt, between 2024 January 1st and 2024 December 31st. The interventions occurred in person or by written message in the prescription. They were classified according type of recommendation and acceptance by medical team. Patient data were collected anonymously. Antibiotics prescribed for gastroparesis were excluded.
Results: During the study period, there were 759 inpatients with antimicrobials prescribed. There were 186 registered interventions about antimicrobials, mainly regarding antibiotics (79%), followed by antifungals (12%), antivirals (6%), and antituberculous agents (2%). The types of interventions were as follows: dosing or frequency (69), duration (36), stopping (20), de-escalating (20), pharmacokinetic monitoring (13), interactions (3), IV to per os transition (1), and other (24). Approximately 10% of the interventions did not require acceptance to take place. Of the remaining interventions, 64% were accepted by the medical team in less than 24 h, and 5% after that.
Conclusions: Pharmacist interventions contributed to more appropriate use of antimicrobials in critically ill patients. The high rate of timely acceptance by the medical team reinforces the importance of integrating pharmacists into antimicrobial stewardship efforts, even when they are not exclusively dedicated to the ICU.

Intensive care Medicine Experimental 2025* 13(1)*:000289.

Introduction: Sepsis-associated cognitive impairment (SACI) lacks targeted therapies, with unresolved debates on the peripheral origins of cerebral amyloid-β (Aβ) pathology. We hypothesized that sepsis reprograms myeloid progenitors to drive Aβ dysregulation through "trained immunity". Integrated scRNA-seq analysis of sepsis, AD, and healthy cohorts identified dynamic expression of MAFG, FOXO3, NFIL3, and RGS10 in sepsis-derived CMPs, later enriched in AD DCs/platelets.

Objectives: Emerging evidence suggests that peripheral inflammation impacts the central nervous system (CNS) and may contribute to the pathophysiology of neurodegenerative diseases such as Alzheimer's disease (AD). Our objectives were to: (1) identify dynamically expressed myeloid-derived conserved genes shared between sepsis and AD; (2) validate their potential as biomarkers for sepsis-associated cognitive impairment (SACI) prognosis and Aβ pathology; (3) define their roles in cognitive deficits using murine sepsis models; (4) explore clinical relevance through survival analysis and functional enrichment.

Methods: Data integration: scRNA-seq analysis of sepsis, AD, and healthy controls (public datasets) to identify sepsis-enriched CMPs and AD-enriched DCs/platelets.

Biomarker validation: ROC analysis of gene expression in sepsis blood (GSE65682, n = 802) and brain tissue (GSE135838, CERAD-stratified, n = 24).

Murine models: cognitive assessment (Y-maze, novel object recognition) and RT-qPCR in CLP sepsis and APP/PS1 AD mice.

Functional annotation: GSEA (MSigDB pathways) and survival analysis (Kaplan–Meier).

Statistical analysis: ANOVA, Spearman correlation, ROC (AUC > 0.7) via R stats.

Results: Integrated analysis of single-cell transcriptomes from sepsis, AD, and healthy controls identified 13 core genes co-upregulated in sepsis-derived common myeloid progenitors (CMPs) and AD dendritic cells (DCs)/platelets (Fig. 1A-B), including myeloid regulators (MAFG, FOXO3, NFIL3) and neuroinflammatory mediators (RGS10). Literature mining expanded the signature to 28 AD-associated peripheral biomarkers (Fig. 1C), with pathway overlap observed for known AD risk genes (e.g., TREM2, APOE).

Validation in in-house sepsis and brain tissue cohorts demonstrated specific overexpression of MAFG, FOXO3, NFIL3, and RGS10 in SAE patients, showing robust diagnostic power (AUC > 0.7) for SAE subtyping, CERAD scores, and Braak staging (Fig. 2C, E). Single-cell resolution revealed dynamic cellular tropism: these genes localized to CMPs during sepsis but shifted to DCs/platelets in AD, suggesting myeloid phenotypic switching facilitates Aβ "periphery-to-CNS" transmission (Fig. 3C-E).

CLP-induced septic mice exhibited significant cognitive deficits at day 7: decrease in new object recognition index and time spent exploring the novelty arm of the Y maze, mirroring human SAE phenotypes (Fig. 4B-I). Survival analysis linked high FOXO3 and MAFG expression to increased 28-day mortality, while NFIL3/RGS10 showed no prognostic significance (Fig. 5A). Functional annotation revealed: (1) peripheral blood: FOXO3 enriched in keratinization/neurotransmission, MAFG in platelet activation, NFIL3 in IL-6/chemokine signaling, RGS10 in GPCR pathways (Fig. 5B); (2) brain tissue: MAFG/FOXO3 dominated synaptic plasticity, NFIL3 in neuroinflammation, RGS10 in microglial TYROBP networks (Fig. 5C).

Dynamic expression profiling showed acute-phase upregulation of MAFG/FOXO3/NFIL3/RGS10 in peripheral leukocytes, which normalized by day 21 but remained elevated in APP/PS1 mice, suggesting their role as "immune memory" markers driving post-sepsis Aβ pathology (Fig. 5D-G).

Conclusions: This study reveals that sepsis reprograms myeloid cells via MAFG, FOXO3, NFIL3, and RGS10—genes dynamically activated in sepsis progenitors (CMPs) and enriched in AD dendritic cells/platelets—to drive amyloid-β (Aβ) pathology through myeloid phenotypic switching and periphery-to-CNS transmission. These genes demonstrate diagnostic utility for sepsis-associated encephalopathy and predict mortality. Targeting the "myeloid-neurovascular unit" offers therapeutic promise for sepsis-related cognitive decline.

Intensive care Medicine Experimental 2025* 13(1):*000290.

Introduction: Since 2020 in the United States (US), the incidence rate of TB cases been increasing after nearly 30 years of decline.1 Respiratory tuberculosis (TB) rarely causes acute respiratory failure requiring invasive mechanical ventilation (IMV). Mortality ranges from 24–81% for patients with TB requiring IMV, however current evidence is limited to single-center studies with small sample sizes.2,3 Large population-based studies on outcomes associated with TB and IMV in the developed world are needed to understand the epidemiology and outcomes of TB acute respiratory failure on a national scale.
Objectives: To examine the incidence and outcomes of acute respiratory TB requiring IMV in the US.
Methods: We conducted a retrospective cohort analysis including all adults (^{3}18 years) admitted to hospital in the US wTabarith tuberculosis that required IMV between 2006–2022. IMV and TB were identified using ICD9/10 codes. The Nationwide Inpatient Sample (NIS), a national in-patient database capturing 20% of all US hospitalizations was utilized for this analysis. The database is structured to produce national estimates of in-patient care across the US. Multivariate logistic regression modelling was used for the primary outcome of in-hospital mortality on IMV.
Results: We identified 41,975 hospitalizations for TB, of which 2,896 (6.9%) were treated with IMV. All-cause mortality for patients on IMV was 42.5%. The mean age was 58.1 years (SD 18.1). Patients treated with IMV were more likely to be male (66.9%) and of lower socioeconomic status (39.1% from lowest income quartile, 22.3% from second lowest). Human immunodeficiency virus (HIV) infection was present in 311 IMV patients (10.8%), solid organ cancers in 303 (10.5%), and lymphoma/leukemia in 50 (1.7%). The median hospital length of stay was 17 days (IQR 8–32) and tracheostomy was performed in 593 patients (20.5%). After multivariate adjustment, risk factors associated with increased mortality included: age (Odds Ratio (OR) 1.34 per 10-year increase, 95% confidence interval (CI) 1.21–1.45, $p < 0.01$), Hispanic race (OR 1.43, 95% CI 1.11–1.83, $p < 0.01$), lymphoma (OR 2.29, 95% CI 1.25–4.20, $p < 0.01$), and liver failure (OR 1.81, 95% CI 1.45–2.26, $p < 0.01$). HIV infection was not associated with worse mortality (OR 1.26, 95% CI 0.95–1.67, $p = 0.10$). The incidence of TB treated with IMV fell from 0.39 cases/100,000 persons in 2006 to 0.16 cases/100,000 persons in 2022 ($p < 0.01$).
Conclusions: The incidence of acute respiratory TB treated with IMV has decreased in the US, however the mortality remains high.

Intensive care Medicine Experimental 2025* 13(1):*000291.

Introduction: A hemodynamic framework encompassing 'Doppler quadrants' and the 'Doppler Starling curve' has been proposed to conceptually integrate surrogates of stroke volume (SV) and right atrial hemodynamics from common carotid artery and internal jugular vein Doppler measures, respectively; how these Doppler quadrants associate with the probability of preload responsiveness (PR) and patient outcome is unknown.
Objectives: 1.) Describe the association between initial Doppler quadrant and the frequency of preload responsiveness in fluid-naïve patients presenting to the emergency department (ED) with suspected sepsis.
2.) Describe the association between initial Doppler quadrant and the frequency of adverse clinical outcome defined as a composite score of rapid response activation, intensive care unit admission, or mortality.
Methods: We enrolled a convenience sample of fluid-naïve, adult patients with suspected sepsis presenting to the ED of a quaternary care hospital as a prospective cohort study. Patients were excluded if they were intubated, on vasopressors, in whom there was known bilateral severe carotid stenosis or patients who were deemed at high risk for receiving intravenous fluids (e.g., overt pulmonary edema, volume overload).
In the semi-recumbent position, a wearable, wireless Doppler ultrasound system (Flosonics Medical, Sudbury, Canada) was placed on the neck over the common carotid artery and internal jugular vein; patients were allocated into Doppler quadrants based upon their baseline internal jugular Doppler morphology and absolute common carotid corrected flow time (ccFT) (Q1— 'warm-dry'; Q2—'warm-wet'; Q3—'cold-dry'; Q4— 'cold-wet'). Then, a rapid fluid challenge (RFC) consisting of 250—300 mL of crystalloid was delivered at a rate of at least 100 mL/min. PR, the primary outcome, was identified as a ccFT change (ccFTΔ), of at least + 7 ms between baseline and RFC.
The secondary outcome was whether adverse outcome (i.e., defined as a composite score of rapid response activation, intensive care unit admission, or mortality) differed between the 4 Doppler quadrants.
Results: Among 80 patients analyzed, 52.5% began in Doppler quadrant 3 (Q3 or 'cold-dry'); 26.0% of these patients were preload unresponsive. Patients who began in quadrant 2 (Q2 or 'warm-wet') more frequently developed adverse outcome compared with patients who began in Q1 ($p = 0.03$; 83.3% vs. 33.3%), Q3 ($p = 0.02$; 83.3% vs 40.5%), or Q4 ($p = 0.02$; 83.3% vs 27.3%)). Q4 patients had the highest in-hospital mortality (27%) though this was not statistically significantly different.
Conclusions: Most ED patients needing fluid resuscitation begin in Doppler quadrant Q3; nevertheless, a clinically significant proportion of these patients are fluid unresponsive. Patients presenting Q2, have a significantly increased risk of adverse outcome. Simultaneous internal jugular and common carotid Doppler may help direct fluid management and triage of septic patients in the ED.

Clinical profile of tetanus patients treated in tertiary ICU in Indonesia: a retrospective observational study

I. Hanafi[1]; CFR. Wisudarti[1]
[1]Department of Anesthesiology and Intensive Therapy, Medical Faculty, Universitas Gadjah Mada—Sardjito Hospital, Yogyakarta, Indonesia

Intensive care Medicine Experimental 2025* 13(1):*000293.

Introduction: Tetanus is a worldwide health problem, especially in developing countries. It occurred particularly in rural-agricultural areas, warm-humid environments, easy contact with soil or animal feces, and made worse by inadequate immunization among adult (Table 1). In 2020, more than 11.750 cases worldwide were reported, with the majority reported from Africa and Southeast Asia, where Indonesia is located. Besides the mortality problem, tetanus often requires advanced technology with high costs. The long course of tetanus requires prolonged supportive care in the ICU which can have a significant impact on survival and health system.
Objectives: In this study, we identify the clinical profile of adult patients with severe tetanus requiring intensive care at one of the tertiary referral hospitals in Indonesia. We aim to obtain data on clinical characteristics and mortality risk of tetanus patients to plan further studies with a larger scope by including several regional hospitals.
Methods: We analyzed retrospectively observational data of tetanus cases in tertiary ICU from 2020 to 2024. Adult patients diagnosed with tetanus were included in this study. Data on clinical features, therapies, and complications were recorded from medical records from the time the patient was admitted to the hospital. Descriptive analysis and mortality risk relationships were carried out using statistical Methods:
Results: This study included 12 patients with the immunization history of all patients unknown. The mean age of the patients was 62.9 ± 9.8 years and 75% were male. Eleven patients suffered from severe or very severe tetanus (Ablett's classification). Wounds on the lower extremities and cavities were the most common sources of infection (41.7%). Trismus and generalized spasm were the most common presenting symptoms, 58.3% and 66.7%, respectively. In survived patients, the mean length of stay in the ICU was 26 ± 9.19 days, while the median days on mechanical ventilation was 19.5 [17–40]. Continuous sedation and vasopressors were required in 83.3% of patients. Complications that often occur were pneumonia (100%), shock (66.7%), and AKI (66.7%). The overall mortality rate was 50%. Statistical analysis of factors that predicted to affect mortality (age, SAPS II score, AKI, and vasopressor use) showed not significant differences ($p > 0.05$) (Table 2).
Conclusions: The small number of cases we get is probably because our hospital is a tertiary referral hospital so that cases that came are only cases with severe conditions. The long duration of ventilator use and ICU stay indicate that tetanus has an impact on complications and high costs so that it requires financing support. Moreover, tetanus is a preventable disease so that re-immunization efforts need to be strengthened. The results of this study provide important initial insights. Further research with a wider population in regional hospitals is important to be carried out to identify risk factors that can affect mortality so that improvements can be made to the overall health system.

Table 1 (abstract 000293) Profile of tetanus that can cause problems in Indonesia

Profile of tetanus
▪ Most cases in Africa and Southeast Asia
▪ Most common in rural and agricultural areas
▪ Contact with soil or animal feces
▪ Warm and humid environments
▪ Inadequate tetanus immunization
▪ Requires sophisticated technology at high cost
▪ Requires long intensive care in the ICU
▪ Limited health funding

Table 2 (abstract 000293) Identification of factors associated with mortality

Identification of factors associated with morality			
Parameters	**Not survived**	**Survived**	**p value**
Age	63.67 ± 11.45	62.17 ± 8.95	0.806
SAPS II score	45 [35 – 84]	39.5 [37 – 70]	0.422
Shock	6 (75)	2 (25)	0.061
Acute kidney injury	5 (62.5)	3 (37.5)	0.545
Vasopressor use	6 (75)	2 (25)	0.061
Tracheostomy	3 (33.33)	6 (66.67)	0.182
Length of ICU stay	7.83 ± 5.78	26.00 ± 9.19	0.002
Length of hospital stay	9.50 ± 7.48	37.17 ± 9.95	0.000

Influence of time-varying fluid parameters on progression of acute kidney injury in septic patients requiring vasopressors: an international cohort study

W. Li[1]; H. Chen[2]; Y. Yang[1]
[1]Department of Critical Care Medicine, Southeast University, Nanjing, China; [2]Critical care unit, Zhongda hospital, Nanjing, China
Correspondence: W. Li
Intensive care Medicine Experimental 2025* 13(1):*000295.

Introduction: Fluid management is a fundamental treatment for septic patients and exerts a substantial influence on renal function [1]. Previous studies have proved that certain fluid parameters can guide fluid management in sepsis, but they are limited and mostly static, making them insufficient to estimate prognosis [2–5].
Objectives: This study aimed to evaluate the association between time-varying fluid parameters and acute kidney injury (AKI) progression in septic patients, and identify the most critical fluid parameter.
Methods: This multicenter study analyzed data from the Chinese Database in Intensive Care (CDIC) and the Medical Information Mart for Intensive Care IV (MIMIC-IV), which included adult septic patients requiring vasopressors. Patients with ICU stays < 24 h, AKI stage 3 at ICU admission, or undergoing hemodialysis were excluded. The exposures of interest were various time-varying fluid parameters, including fluid balance, fluid intake, fluid output, and the fluid accumulation index, defined as the ratio of fluid balance to fluid intake. The primary outcome was AKI progression, defined as the new onset of AKI or a worsening of AKI by at least one Kidney Disease: Improving Global Outcomes (KDIGO) stage within 7 days of enrollment [6]. Multivariable Cox regression models were employed to explore the association between different time-varying fluid parameters and AKI progression.
Results: A total of 824 septic patients from the CDIC cohort and 7918 from the MIMIC-IV cohort were included, with AKI progression rates of 34.6% and 49.8%, respectively. After adjusting for confounders, Cox regression analysis demonstrated that all time-varying fluid parameters were associated with AKI progression in both cohorts (Fig. 1). Compared with other fluid parameters, the fluid accumulation index had the best-fit Cox regression model, with the lowest Akaike information criterion (AIC) and highest C-index (Fig. 2). The impact of fluid parameters on AKI progression was primarily presented in patients with AKI progression to stage 3 (Fig. 3). In addition, fluid accumulation index was correlated with AKI progression in the early and middle phases (days 1–5), but not in the later phase (days 6–7) in CDIC cohort.
Conclusions: All time-varying fluid parameters demonstrated independent associations with AKI progression in septic patients, with the fluid accumulation index emerging as the strongest predictor.

Performances of the Day 1 SOFA and modified SOFA score in predicting ICU mortality across varying levels of respiratory support: insights from the MIMIC-IV cohort

SY. Lee[1]
[1]Department of pulmonary and critical care medicine, Asan Medical Center, Seoul, Republic of Korea
Correspondence: S.Y. Lee
***Intensive care Medicine Experimental 2025* 13(1):*000296*.**

Introduction: The Sequential Organ Failure Assessment (SOFA) score is widely used to predict ICU mortality. However, the predictive performance of the SOFA score for ICU mortality in patients treated with non-invasive ventilation (NIV) or high-flow nasal cannula (HFNC) remains unclear.
Objectives: In this study, we evaluated whether the Day 1 SOFA score accurately predicts ICU mortality in patients receiving various types of respiratory support, comparing the original SOFA score with a modified version that incorporates the SpO_2/FiO_2 ratio and allows for higher respiratory sub-scores in non-intubated patients.
Methods: This retrospective cohort study used the MIMIC-IV database (2008–2019). Patients receiving invasive ventilation, NIV, or HFNC on ICU day 1 were included. Two cohorts were defined: Cohort 1 for the original SOFA score using only the PaO_2/FiO_2 ratio, and Cohort 2 for the modified SOFA score incorporating both PaO_2/FiO_2 and SpO_2/FiO_2 ratios and allowing respiratory sub-scores ≥ 3 in non-intubated patients. The predictive performance of Day 1 SOFA scores for ICU mortality was assessed using the area under the receiver operating characteristic curve (AUC).
Results: A total of 10,302 and 12,353 patients were included in Cohort 1 and 2, respectively. In both cohorts, the predictive performance of Day 1 SOFA and modified SOFA was highest in invasively ventilated patients (AUCs: original 0.774; modified 0.778). In non-intubated patients, the AUCs were 0.698 (original) and 0.723 (modified) for NIV; 0.621 (original) and 0.635 (modified) for HFNC. Patients who required subsequent intubation had higher mortality with OR 2.33 (1.68 – 3.20, $p < 0.001$), while those who remained on non-invasive support during ICU stay had the lowest mortality with OR 0.62 (0.50 – 0.76, $p < 0.001$). The trajectory of SOFA scores varied according to intubation status, showing a marked upward trend in patients who were eventually intubated after initial non-invasive support.
Conclusions: The Day 1 modified SOFA score showed similar predictive performance to the original score overall. However, its ability to predict ICU mortality was limited in non-intubated patients, particularly those treated with HFNC. These results highlight the need to consider clinical trajectory in addition to early SOFA scores when assessing prognosis in patients receiving non-invasive respiratory support.

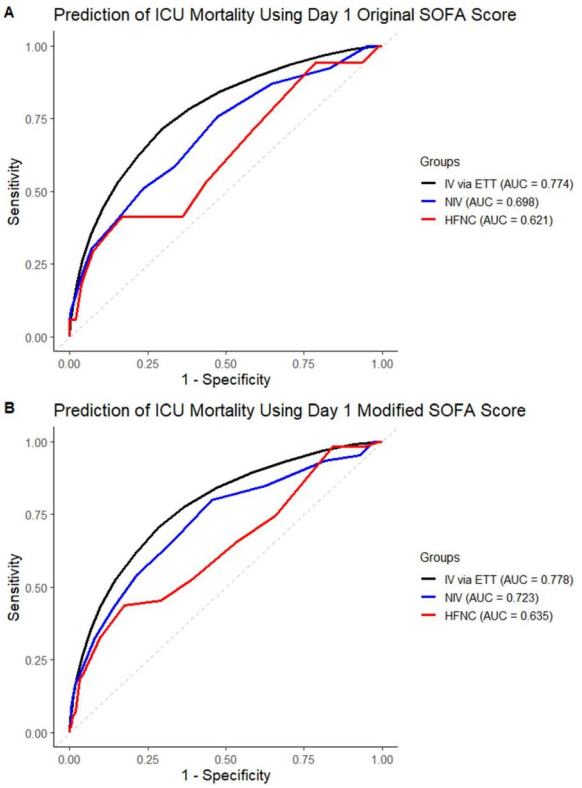

Fig.1 (abstract 000296) Comparison of day 1 original and modified SOFA scores for predicting ICU mortality across oxygen devices (Abbreviations: SOFA, sequential organ failure assessment; ICU, intensive care unit; IV via ETT, invasive ventilation via endotracheal tube; NIV, non-invasive ventilation; HFNC, high-flow nasal cannula)

Topic: Acute respiratory failure and mechanical ventilation

Introduction: Sepsis requires stratification for host-directed therapies through the discovery of adequate biomarkers enabling prediction of outcomes and treatment responses. Adrenomedullin contributes to endothelial homeostasis and has previously demonstrated potential for prognostic enrichment.
Objectives: This study aimed to assess associations of bioactive adrenomedullin (bio-ADM) levels at ICU admission and sepsis outcomes and to evaluate the potential value of bio-ADM as marker to identify subgroups of patients with moderate disease severity that might benefit from hydrocortisone treatment.
Methods: We used data from the HYPRESS trial (NCT00670254; 317/353 patients) to investigate, if bio-ADM is useful to predict sepsis outcomes (septic shock, 90- and 180-day mortality) and benefit or harm by hydrocortisone treatment. Optimal cut-offs for outcome predictions were determined by Youden's index. Logistic regression was used to assess bio-ADM subgroups and treatment interaction, and predictive enrichment for hydrocortisone therapy.
Results: Bio-ADM levels differed significantly in patients with or without septic shock within 14 days ($p = 0.011$). While the area under the ROC curve (AUC) was only 0.603 (CI 0.531–0.676), patient subgrouping according to an optimal bio-ADM cut-off level of 37 pg/mL (primary endpoint) showed significantly higher cumulative incidence of septic shock within 14 days in the subgroup of patients with bio-ADM levels ≥ 37 pg/mL ($p < 0.001$). The odds ratio for the development of septic shock in this bio-ADM group was 4.67 (95% CI 1.53, 20.3, $p = 0.016$). A bio-ADM cut-off of ≥ 136 pg/mL was predictive for 90-day (OR 6.51, 95% CI 2.04–20.6, $p = 0.001$) and 180-day mortality (OR 3.82, 95% CI 1.23–11.6, $p = 0.017$). Hydrocortisone therapy did not significantly reduce the incidence of septic shock (OR 1.59, 95% CI 0.37–8.15, $p = 0.54$) regardless of bio-ADM stratification (p-value for interaction test = 0.58). Likewise, hydrocortisone neither reduced 90- nor 180-day mortality (OR 1.53, $p = 0.22$ and OR 1.41, $p = 0.25$, respectively), irrespective of bio-ADM group (interaction term $p = 0.31$ for 90-day mortality and 0.58 for 180-day mortality).
Conclusions: Whereas bio-ADM levels are associated with sepsis outcomes, our data do not indicate usefulness of the marker to identify patients potentially benefitting from hydrocortisone therapy.

Intensive care Medicine Experimental 2025 **13(1)**:***000298***.

Introduction: Obstetric hemorrhage is the leading cause of maternal mortality worldwide.
Objectives: We present a case of a patient with placenta percreta who suffered massive blood loss of 6 L due to intra-aortic balloon rupture during REBOA and subsequent atonic bleeding.
Methods: Patient R., 34 weeks of pregnancy, BMI = 27 kg/m2, underwent combined anesthesia and lower midline laparotomy, corporal cesarean section. The balloon catheter in the aorta was dilated for 23 min. Metroplasty was performed, but excessive bleeding was observed due to balloon rupture (blood during desufflation, visually complete rupture of the balloon).
Results: The volume of blood loss was 2000 ml. Reinfusion of autoblood 600 ml, donor erythrocytes 600 ml, FFP 600 ml (FFP: erythrocytes ratio 1:2). ROTEM was performed: EXTEM: CT = 69, CFT = 154, A10 = 39; INTEM: = CT 313, CFT = 141, A10 = 42; HEPTEM: CT = 197, CFT = 127, A10 = 42; FIBTEM A10 = 5 mm. Additionally, fibrinogen concentrate 3 g was administered until FIBTEM A10 = 10 mm was reached.
Within 10 min after the end of the operation, rapid one-time blood loss from the vagina of more than 1000 ml led to unstable hemodynamics (SI—Allgower shock index = 2), against the background of infusion therapy with crystalloids, the norepinephrine rate was increased to 0.7 μg / kg / min, Gelofusine 1000 ml was added. Blood loss severity class according to ATLS is IV (BE = -12 mmol/l, lactate = 1.3 mmol/l, Hb = 64 g/l, Ht = 20, pH = 7.2). The situation was assessed as critical, a red code was declared, which made it possible to immediately activate the protocol of massive transfusion into three venous accesses with repeated administration of 1 g of tranexamic acid against the background of relaparotomy and extirpation of the uterus in order to stop atonic bleeding. Then 10 doses of cryoprecipitate lyophilisate and 1000 IU of prothrombin complex concentrate were administered. The ratio of the administered transfusion products was 1:2 (FFP = 1110 ml:donor erythrocytes—1520, autoblood—700 ml). Hypocalcemia was corrected with CaCl2 2 g.
Further treatment was carried out purposefully under the control of the acid–base state, clinical blood test (Hb = 102 g/l, Ht = 29, PLT = 44 × 109/l ROTEM: EXTEM: CT = 54, CFT = 184, A10 = 34; INTEM: = CT 184, CFT = 175, A10 = 37, FIBTEM A10 = 12 mm. Additionally, 8 donor doses of platelets were administered. The operation lasted 6 h, the total blood loss was 6000 ml, the total infusion-transfusion therapy intraoperatively was 6830 ml, diuresis was 1000 ml.
For 9 h after the operation, mechanical ventilation was performed, after which the patient was transferred to spontaneous breathing. In the postoperative period, multimodal analgesia was performed: paracetamol and 0.1% ropivacaine epidurally. Prevention of thromboembolic complications was started after 8 h with low molecular weight heparin (fragmin 2500 IU). On the 10th day the patient was discharged home.
Bleeding management should involve mobilization of a multidisciplinary team, which is facilitated by the implementation of color codes, including in the operating room and debriefing after emergencies [1,2].
Conclusions: This case shows the importance of communication between team members for rapid implementation of a massive blood loss protocol in the treatment of obstetric emergencies such as placenta accreta or inadvertent balloon rupture. The use of thromboelastometry helped to control bleeding, conduct targeted treatment, reduce the volume of transfusion media, and avoid potential complications of massive blood transfusion [3]. Consent to publish had been obtained.

Introduction: Approximately 30% of patients with aneurysmal subarachnoid hemorrhage (SAH) suffer delayed cerebral ischemia (DCI), which is the leading cause of death and treatable disability in these patients. Several studies have proposed markers to predict this complication, and numerous radiologic risk scales have been developed, although their predictive ability has been poorly studied and compared.
Objectives: To prospectively evaluate the risk factors for DCI in patients with SAH who are admitted to a neurotrauma intensive care unit (ICU).
Methods: Prospectively collected data of SAH patients admitted to a 10-bed neurotrauma ICU from October 2013 to December 2024. We analyzed: major diagnosis at admission; demographics, including sex and race; neurological data (clinical examination, pupil reactivity and size, and Glasgow Coma Score: GCS; aneurysm location and size; presence of intracranial hematoma (ICH); presence and volume of intraventricular hemorrhage; days to development of vasospasm; development of DCI; Fisher Scale (FS), Modified Fisher Scale (MFS), Hunt and Hess Scale (HHS), Word Federation of Neurosurgeons Scale (WFNS); presence of vasospasm on Doppler or arteriography; delayed ICU admission; aneurysm treatment; complications including infection; Glasgow Outcome Scale (GOS) at ICU discharge and 6 months after ICU discharge; and several other risk factors. A univariate analysis of DCI was performed, and variables that showed a significant association in the univariate analysis were entered into the multivariate logistic regression analysis. To obtain a prediction rule for DCI, a prediction model was obtained using the Classification and Regression Trees (CART) method [1]. CART classifies data using a sequence of if–then rules. The basis of decision tree algorithms is the recursive binary partitioning of the data. First, the most discriminative variable is selected to partition the data set into child nodes. The partitioning continues until a stopping criterion is reached. At each terminal node, the probability of DCI was estimated as the proportion of patients belonging to that node who developed the event. The tree was constructed according to the following algorithm: in the first step, the tree grows until all cases are correctly classified, and in the second step, we used the tenfold cross-validation method of successive pruning [1]. Finally, the tree that minimized the error measure (deviation) was selected. For this predictor, the corresponding ROC curve was obtained and the AUC was estimated using a 95% CI.
Results: We enrolled 291 patients with SAH and 66 (22.6%) developed DCI. APACHE II and SOFA on admission, as well as the FMS, HHS, and WFNS scales were significantly higher in patients with DCI, but the Fisher scale was not. Patients with DCI also had significantly lower GCS on admission to the emergency department and intensive care unit. Posterior communicating artery aneurysm was significantly associated with the development of DCI. The most common complications in these patients were: cerebral infarction 47 (71.2%), hydrocephalus 35 (53.0%), and ventriculitis 10 (15.2%). Patients with SAH with delayed admission after the bleeding, requiring clipping, and those with stuporous neurological status and pupillary anisocoria were associated with more DCI. In the ICU, 12 (18.2%) patients with SAH and DCI died, but there was no significant difference in mortality among patients who developed DCI (Tables 1a and 1b). The decision tree showed that the probability of developing DCI is 23%. However, this probability decreases to 6.2% in patients with a FM < 3, while it increases to 27% in patients with a FM of at least 3. In these patients, if the HH scale is < 2, the probability of DCI remains at 17%, while in the 151 patients with at least a HH scale of 2, the probability of DCI increases to 32% (Fig. 1). The AUC was 0.662 (0.602–0.722) (Fig. 2).
Conclusions: Our data show that 22.6% of our SAH patients developed DCI. Patients with SAH with delayed post-bleeding admission, who required clipping, those with stuporous neurological status and pupillary anisocoria were associated with greater development of DCI. The decision tree showed that in patients with SAH and FM scale ≥ 3 and HH > 2, the probability of DCI increased to 32%. Finally, mortality was not significantly higher compared to those who did not develop DCI.

Intensive care Medicine Experimental 2025* 13(1):*000301.

Introduction: Since the introduction of angiotensin II (AT2), multiple mechanistically distinct vasopressors are available to treat septic shock, but limited data exist regarding which patients are most likely to benefit from each agent. Dipeptidyl peptidase 3 (DPP3), a component of the alternative arm of the renin–angiotensin–aldosterone system, has been proposed to be a potentially useful biomarker to guide AT2 use in septic shock (1–3).
Objectives: To determine whether baseline plasma DPP3 levels may be used to identify patients with vasodilatory shock most likely to respond to AT2 therapy.
Methods: This was an investigator-initiated industry-funded, open-label, single-center randomized controlled trial of the use of AT2 versus standard of care (SOC) vasopressor therapy in patients with vasodilatory shock requiring norepinephrine ≥ 0.1 mcg/kg/min for ≥ 30 min. Of 40 enrolled subjects, 36 with available baseline DPP3 measurements are included in this preliminary analysis. The primary outcome was the ability of DPP3 to predict responsiveness to AT2, as measured by change in total norepinephrine equivalent dose (NED) (4,5) of vasopressors at 3 h post-drug initiation or the equivalent time-point in the SOC arm as assessed by linear regression. Secondary outcomes included in-hospital mortality. The trial protocol is registered at clinicaltrials.gov (NCT05824767) and was previously published (2).
Results: Baseline data and outcomes are shown in Table 1. Baseline DPP3 values and changes in NED at 3 h are plotted in Fig. 1. Higher baseline DPP3 was associated with an increase in NED at 3 h (β = 0.0022, 95% confidence interval [CI] 0.00022–0.0041, p = 0.031), though this association was attenuated when adjusting for baseline Sequential Organ Failure Assessment (SOFA) score (β = 0.0015, 95% CI −0.00056–0.0036, p = 0.15). When stratified by treatment arm, DPP3 was associated with an increase in NED at 3 h in the AT2 arm (β = 0.0062, 95% CI 0.0025–0.0098, p = 0.0025) but not the SOC arm (β = −0.00052, 95% CI −0.0012–0.00021, p = 0.15). In-hospital mortality was 11.1% in the AT2 arm and 22.2% in the SOC arm (p = 0.37). Across the full cohort, baseline DPP3 was associated with in-hospital death (β = 0.0050, 95% CI 0.0017–0.0083, p = 0.0043), an association which was partly attenuated by adjustment for baseline SOFA (β = 0.0034, 95% CI 0.0000014–0.0068, p = 0.050).

Time from pressor start to baseline, h	19.0 [13.5–27.9]	20.8 [13.5–34.4]	19.0 [13.6–24.3]	0.56
Baseline NED, mcg/kg/min	0.18 [0.13–0.24]	0.19 [0.14–0.24]	0.15 [0.12–0.23]	0.53
Change in NED at 3 h, mcg/kg/min	0 [−0.083–0.02]	−0.025 [−0.09–0.04]	0 [−0.04–0]	0.056
Baseline DPP3, ng/mL	27.7 [18.2–38.3]	27.7 [20.1–33.3]	27.7 [15.1–45.0]	0.72
In-hospital mortality	6 (16.7%)	2 (11.1%)	4 (22.2%)	0.37

Conclusions: In these preliminary data, baseline DPP3 was associated with an increase in NED at 3 h among subjects randomized to AT2 but not in the SOC arm. Thus, elevated DPP3 did not identify those with increased vasopressor responsiveness to AT2. Rather, our results suggest that lower circulating DPP3 may increase the efficacy of AT2, consistent with prior data showing that DPP3 cleaves and inactivates AT2 (6). As in multiple prior critically ill cohorts (1,3,7), baseline DPP3 was independently associated with an increased risk of mortality.

Intensive care Medicine Experimental 2025* 13(1):*000303.

Introduction: Invasive pulmonary aspergillosis (IPA) is a common cause of fungal infection acquired in intensive care. Although the SARS-CoV-2 infection has recently emerged as a significant risk factor for these events, the clinical landscape of IPA according to SARS-CoV-2 infection status remains poorly explored.
Methods: We included all mechanically ventilated patients hospitalized for at least 48 h from January 2018 to January 2024 in participating Intensive Care Units (ICUs) of the French REA-REZO network. Baseline characteristics and clinical course, including survival after IPA according to COVID-19, were assessed. Then, we aimed to identify variables associated with ICU survival in IPA patients using a Cox proportional hazard model. Finally, incidence rates of IPA according to SARS-CoV-2 status, as well as factors associated with IPA, were assessed using a Fine–Gray competing risk regression.
Results: A total of 120,993 patients were included during the study period. An IPA was diagnosed in 254 patients (2.1%). Of those, 149 were COVID-19-associated pulmonary aspergillosis (CAPA), while 105 IPAs occurred in non-COVID-19 (NC) patients. In competing risk regression, immunosuppression (either neutropenia or other kinds of immunosuppression) (sdHR = 3.41 [95% CI: 1.81–6.45]; p < 0.001 and sdHR = 2.14 [95% CI: 1.61–2.855]; p < 0.001), medical reasons for ICU admission (sdHR = 2.34 [95% CI: 1.41–3.89]; p < 0.001), antibiotherapy ± 2 days before or after ICU admission (sdHR = 1.83 [95% CI: 1.32–2.53]; p < 0.001), and the need for a central venous catheter (sdHR = 9.27 [95% CI: 1.29–66.46]; p = 0.027) were found to be

independent risk factors for IPA. Finally, the incidence rate of IPA was higher in COVID-19 patients (incidence rate 0.7 per 1,000 patient-days versus 0.08 per 1,000 patient-days; incidence rate ratio: 8.45 [95% CI: 6.59–10.87]; p < 0.001). CAPA patients were significantly older (median age 69 [IQR 62–73] years versus 63 [56–70] years; p < 0.001), less frequently immunocompromised (0.7% of CAPA patients with neutropenia and 23.5% of CAPA patients with other immunosuppression versus 8.6% and 32.4%, respectively; p = 0.001), and less severe at baseline compared to NC-IPA patients (median SAPS II score 45 [35–54] versus 55 [39–65]; p < 0.001) (Table 1). During their stay, CAPA patients had a longer duration of mechanical ventilation and ICU length of stay compared to NC-IPA patients (Table 2). Despite variations in baseline characteristics and clinical trajectories, the mortality rate was similar between CAPA and NC-IPA patients (56.4% versus 58.1%; p = 0.886) (Table 2, Fig. 1). Finally, the ICU mortality rate of patients with IPA was higher compared to patients without IPA (57.1% versus 24.9%; p < 0.001).

Conclusions: In this large multicenter cohort of mechanically ventilated ICU patients, IPA had a similar impact on survival depending on SARS-CoV-2 infection status, even though baseline characteristics and clinical trajectories varied between CAPA and NC-IPA patients.

Intensive care Medicine Experimental 2025* 13(1)*:000304.

Introduction: Post-ICU syndrome (PICS) is defined as "New or worsening of existing health problems related to the critical illness that persist at discharge in the survivor or family member." And financial toxicity (FT) is defined as "the perception of subjective financial hardship as a result of an objective financial burden", understanding objective financial burden as direct and indirect costs related to health care. In oncologic patient, FT is a risk factor for worse clinical outcomes, including death and diminished quality of life. In critically ill patient the impact of FT on the development and intensity of PICS is unclear.
Objectives: To determine the prevalence of PICS, quantify the development of FT and evaluate its impact on the intensity of PICS, particularly on post-traumatic stress disorder (PTSD), 3 months after hospital discharge.
Methods: Multicenter prospective observational cohort study in ICU survivors' patients, older than 18 y/o, connected to mechanical ventilation for at least 48 h, with deep sedation. All patients were evaluated after 3 months after discharge. Patients were considered as suffering PICS if any of its dimensions were impaired: the applied tests evaluated physical (dynamometry, maximum inspiratory pressure, Barthel, WHODAS and frailty scores), cognitive (Montreal Cognitive Assessment) and emotional (HADS, PTSD and pain) dimensions. Patients were classified as having no, moderate or severe FT using the FACIT-COST test. All tests were applied in person by home visits or by citation to the originating hospital. The study was performed from January 2024 to January 2025. For data analysis sample size was calculated to observe a 40% increase in the rate of PTSD associated with increased FT (power of 80%, type I error 0.05). Data were analyzed considering a normal distribution. The study was approved by Clinica Santa María Ethic committee (Code approval 080705-24) and all recruited patients have their informed consent.
Results: 40 patients were included, age of 57 ± 19 y/o, 52% were women with an APACHE II score of 15.9. 49% were admitted for respiratory failure and 30% for sepsis. 88% were independent prior to ICU stay (Barthel > 90 points). 49% of patients were on 3 sedation drugs at some point during their ICU stay. Only 9% of the population had completed university studies and the average income level of the family group was U$1377. 66% of patients were not working at 3 months, 61% were main providers, and 90% had public health insurance. 88.5% of the patients presented PICS in one or more of its dimensions. A total of 62.7% of the patients presented FT, 29% of whom had severe FT. Patients with FT, with respect to those without FT, presented significantly higher risk of PTSD (Fig. 1, p = 0.003), higher risk of depression (p = 0.04) and anxiety (p = 0.01), with a prevalence of 37% vs. 7% and 64% vs. 15%, respectively. 68% of patients with FT presented possible cognitive impairment, compared to 46% in patients without FT (p = 0.2). 80% of all patients presented some degree of muscle weakness by dynamometry, with no difference between groups.
Conclusions: In ICU patients who required MV and deep sedation for at least 48 h, the prevalence of PICS is very high in any of its dimensions. FT is associated with increased risk of PTSD, anxiety and depression. Further studies are required to evaluate the impact of FT on morbidity and mortality in the medium and long term.

PTSD prevalence according to FT.

Diabetic ketoacidosis management in a Portuguese intensive care unit: a retrospective analysis of current practices

MB. Dias Vieira[1]; M. Almeida[1]; T. Vieira[1]; E. Ribeiro[1]; M. Melo[1]; A. Oliveira[1]
[1]Intensive Care Unit, Unidade Local de Saúde da Região de Aveiro, Aveiro, Portugal

Intensive care Medicine Experimental 2025* 13(1)*:000306.

Introduction: Diabetic ketoacidosis (DKA) is a life-threatening complication of diabetes mellitus (DM) that may require admission in Intensive Care Units (ICU) in up to 50% of cases, mostly due to severe metabolic derangements. Although its mortality rate remains low, DKA still represents a substantial burden to individuals, families and healthcare systems. Moreover, clinical guidelines on this subject lack consensus when it comes to choice of fluids for resuscitation, insulin therapy and correction of metabolic disorders, leading to heterogeneous clinical practice and potentially slower resolution of DKA. Therefore, it is essential to assess if the management of this condition is being conducted according to ICU protocols, developed based on the best available evidence. In this context, Jozwiak and colleagues (2024) conducted an ESICM-endorsed international survey with the aim of evaluating the clinical management of adult patients with DKA in ICU comparing the results with existing literature.
Objectives: Building on Jozwiak's work, this study aimed to assess the treatment strategies employed for DKA in a Portuguese ICU and compare them with the latest available evidence.
Methods: A retrospective study was performed based on data from electronic clinical records of adult patients admitted to a Portuguese ICU with the main diagnosis of DKA, between January 2021 and March 2025. Recorded data included length of ICU stay, pre-existing DM with or without complications, DKA classification, type of resuscitation fluid, intravenous insulin therapy, sodium bicarbonate administration, timing of subcutaneous insulin introduction, use of glucose solution, resolution of DKA and ICU general outcome.

Results: A total of 44 patients were included, with 38.6% being male. The mean age was 45.6 ± 18.9 years, and the average length of ICU stay was 5.9 days. In 31.8% of cases, patients were admitted with their first episode of DKA. Of the 30 patients with a previous diagnosis of DM (68.2%), 36.7% had type 1 and 63.3% had type 2. Among these 30 patients, 43.3% had developed complications due to DM, with 20% presenting with both micro and macrovascular diseases. The most common factors for decompensation were non-compliance with therapy (40.9%) and infectious conditions (38.6%), mainly respiratory. DKA was considered severe in 50% of patients and moderate in 45.5%. The 2 patients with mild disease were admitted to the ICU due to the severity of the underlying causes of DKA, namely septic arthritis and moderate-risk pulmonary thromboembolism. For fluid resuscitation, 52.3% of patients received isotonic saline, 40.9% Plasma-Lyte 148, and only 6.8% were given both. 38.6% of patients received an initial intravenous bolus of insulin. Of the 44 patients, 63.3% started insulin infusion based on the ICU blood glucose protocol, while 31.8% initiated insulin administration with a fixed dose of 0.1 IU/kg/h. The remaining 2 patients started insulin infusion with initial fixed doses of 2 IU/h and5 IU/h. 79.5% of the patients started intravenous insulin at the same time as fluid resuscitation, with only 3 patients starting insulin administration after ICU admission. Sodium bicarbonate (8.4% solution) was administered to 52.3% of patients, 69.5% of whom had a pH < 7. For over half of the patients, resolution of DKA was determined by pH (> 7.3), bicarbonate (≥ 18 mmol/L), and blood ketone (< 0.6 mmol/L) levels, which was achieved within 12 to 24 h (40.9%) and 24 to 48 h (38.6%) after ICU admission. Subcutaneous insulin was resumed in the ICU in 84% of patients, usually after a 2-h period of overlapping continuous intravenous insulin and subcutaneous insulin boluses. Plasma-Lyte 148 + Glucose 5% was the most commonly used glucose solution (93.1%), for threshold blood glucose values lower than 250 mg/dL (45.5%), 200 mg/dL (36.4%), and 180 mg/dL (18.1%). A favorable outcome was achieved in 93% of patients, with 4 of them being discharged directly home. The remaining 3 were older and fragile, and eventually died in the ICU due to infectious complications.
Conclusions: This study's results align with Jozwiak's, particularly regarding variability in DKA management decisions. For instance, contrary to international trends, our clinical practice has shown a more frequent use of normal saline rather than balanced solutions like Plasma-Lyte 148. These findings highlight the need for better education, protocol adherence, and personalized approaches in DKA care in the ICU, as standardizing care could potentially improve outcomes, reduce hospital stays, and lower morbidity and mortality.

Single-use versus multiple-use endotracheal suction catheters in mechanically ventilated patients: a feasibility randomised controlled trial

M. Eid[1]; K. Hambridge[1]; P. Schofield[1]; J. Latour[1]
[1]School of Nursing and Midwifery, Faculty of Health, University of Plymouth, Plymouth, United Kingdom
Correspondence: M. Eid
Intensive care Medicine Experimental 2025* 13(1):*000307.

Introduction: In resource-limited settings, reusable equipment is more commonly used, especially in low- and middle-income countries where healthcare resources are constrained. One example of such equipment is the single-use open endotracheal suctioning catheters, which are used multiple times for endotracheal suctioning in resource limited Intensive Care Units (ICUs) [1,2]. The current evidence of this practice on ventilator-associated pneumonia (VAP) among mechanically ventilated patients remains unclear [3].
Objectives: The aim of this study was to evaluate the feasibility of single-use and multiple-use endo-tracheal suction catheters flushed with chlorhexidine versus standard care (multiple-use endo-tracheal suction catheters flushed with normal saline) to reduce VAP in resource-limited ICUs and to inform study methods for the design of a future definitive randomized controlled trial (RCT).
Methods: A three-armed feasibility RCT was conducted in three ICUs at a university hospital in Egypt. Sixty mechanically ventilated patients were randomized into three groups: single-use catheters (Intervention I group; n = 20), multiple-use catheters flushed with chlorhexidine (Intervention II group; n = 20), and standard care group (n = 20). Data on feasibility parameters, intervention adherence, and patient outcomes were collected. Ethical approvals were obtained from two ethical committees. The study was prospectively registered on ClinicalTrials.gov (identifier: NCT06207513).
Results: Recruitment and retention rates were high across all groups, with 100% (n = 58) of participants completing the 3-day follow-up and 96.6% (n = 56) completing the 6-day follow-up. Adherence to intervention protocols was excellent, with 100% of participants receiving the designed interventions. No adverse events were reported. Chlorhexidine flushing and single-use catheters were practical and successfully implemented, however, challenges of budget constraints, supply shortages, and the need for additional staff training was observed (Table 1). The incidence of VAP was 31.6% in Intervention I group, 26.3% in Intervention II group, and 40% in the standard care group (95% CI: 0.723–0.740). Secondary outcomes, including ICU length of stay and modified clinical pulmonary infection score (MCPIS), were comparable across groups, with no differences observed (Table 2).
Conclusions: This feasibility RCT demonstrated that a full-scale RCT comparing single-use and multiple-use catheters with chlorhexidine flushing is feasible in resource-limited ICUs. While the study was not designed to assess efficacy, it provided valuable insights into the trial design, intervention feasibility, and potential improvements for future research. Further investigation into the effectiveness of the interventions on VAP prevention is needed in future definitive RCTs.

Table 1 (abstract 000307) Intended feasibility measures and findings

Parameter	Intended Measurement	Findings
Chlorhexidine flushing feasibility	Assess use of chlorhexidine for suction flushing	Feasible; nurses successfully used it and found it practical.
Single-use suction catheters	Evaluate practicality of single use of the suction catheter	Feasible; accepted with adequate supply.
Resource availability	Assess availability of supplies	Constraints required purchasing additional supplies.
Patient recruitment & retention	Track enrolment and withdrawals	60 enrolled, 2 withdrawn, 58 retained.
Confounding factors	Assess impact of age, disease severity, or underlying conditions	No differences between groups.
Mortality	Evaluate intervention impact on mortality	No difference; 1 death per each group

Table 2 (abstract 000307) Secondary outcomes

Variable	Intervention I	Intervention II	Control	95 % CI
	n	n	n	
Length of ICU stay (days)				
• 3 – 4 days	1 (5.3%)	3 (15.8%)	0 (0%)	
• 5 – 6 days	5 (26.3%)	1 (5.3%)	8 (40%)	0.354 – 1.298
• ≥ 7 days	13 (68.4%)	15 (78.9%)	12 (60%)	
MCPIS (Mean; SD)				
• Day 1	19 (1.53; 1.50)	19 (1.42; 0.96)	20 (1.55; 1.28)	
• Day 3	19 (4.73; 1.82	19 (3.74; 1.73)	20 (4.70; 1.89)	0.612 – 0.874
• Day 6	14 (5.29; 2.52)	14 (4.86; 1.83)	18 (6.05; 2.63)	
Incidence of VAP				
• VAP	6 (31.6%)	5 (26.3%)	8 (40%)	0.723 - 0.740
• Not VAP	13 (68.4%)	14 (73.7%)	12 (60%)	

Modified clinical pulmonary infection score (MCPIS), Ventilator associated pneumonia (VAP), Data are presented as numbers (n) and frequency (%), Significance was assessed using Fisher's exact test, with a 95% confidence interval (CI).

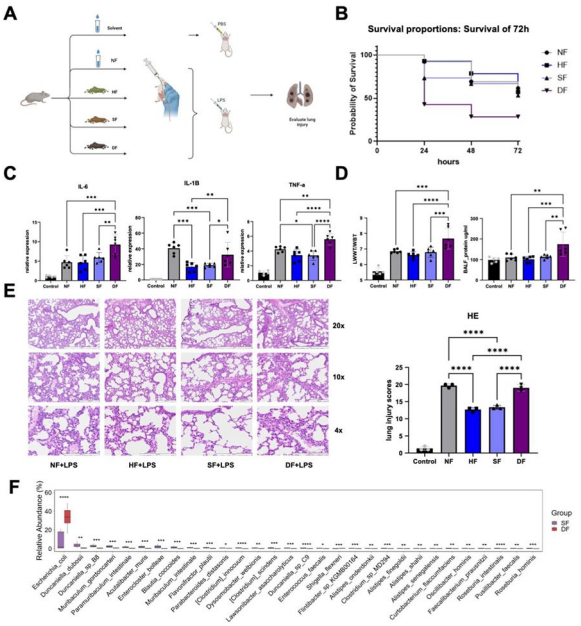
Intensive care Medicine Experimental 2025* 13(1):*000312.

Introduction: Acute respiratory distress syndrome (ARDS) represents a critical challenge in intensive care medicine, with mortality rates persistently exceeding 30% despite advancements in ventilatory support1,2. While structural compromise of the alveolo-capillary unit and dysregulated cytokine storm remain pathognomonic features, emerging translational evidence implicates the gut–lung axis in orchestrating pulmonary immune homeostasis, with enteric commensals emerging as pivotal immunomodulators. This investigation elucidates the pathophysiological mechanisms through which intestinal microbial consortia and their biotransformation metabolites govern ARDS trajectories, building upon foundational evidence of bidirectional microbiome–immune signaling across visceral organ systems.
Introduction: Acute respiratory distress syndrome (ARDS) represents a critical challenge in intensive care medicine, with mortality rates persistently exceeding 30% despite advancements in ventilatory support1,2. While structural compromise of the alveolo-capillary unit and dysregulated cytokine storm remain pathognomonic features, emerging translational evidence implicates the gut-lung axis in orchestrating pulmonary immune homeostasis, with enteric commensals emerging as pivotal immunomodulators. This investigation elucidates the pathophysiological mechanisms through which intestinal microbial consortia and their biotransformation metabolites govern ARDS trajectories, building upon foundational evidence of bidirectional microbiome–immune signaling across visceral organ systems.
Objectives: This study aims to investigate the role of gut microbiota in the progression of acute respiratory distress syndrome (ARDS) through the gut–lung axis.
Objectives: This study aims to investigate the role of gut microbiota in the progression of acute respiratory distress syndrome (ARDS) through the gut–lung axis.
Methods: A murine ARDS model was established through intratracheal lipopolysaccharide (LPS) administration (5 mg/kg), with subsequent stratification of animals into survival and non-survival groups based on 72-h outcomes. Donor microbiota from both cohorts were transplanted into antibiotic-pretreated recipients via oral gavage for seven days prior to ARDS induction. Comprehensive assessments included: histopathological evaluation of lung injury using H&E staining and semi-quantitative scoring quantification of alveolar-capillary leakage via bronchoalveolar lavage fluid (BALF) protein levels and pulmonary edema measurement (lung wet weight/whole body weight); cytokine profiling of TNF-α, IL-1β, and IL-6 in BALF using ELISA. Additionally, metagenomic and metabolomic analyses were conducted on fecal samples from the survival and non-survival groups to explore differences in microbial composition and metabolite profiles between the two groups.
Methods: A murine ARDS model was established through intratracheal lipopolysaccharide (LPS) administration (5 mg/kg), with subsequent stratification of animals into survival and non-survival groups based on 72-h outcomes. Donor microbiota from both cohorts were transplanted into antibiotic-pretreated recipients via oral gavage for seven days prior to ARDS induction. Comprehensive assessments included: histopathological evaluation of lung injury using H&E staining and semi-quantitative scoring quantification of alveolar-capillary leakage



via bronchoalveolar lavage fluid (BALF) protein levels and pulmonary edema measurement (lung wet weight/whole body weight); cytokine profiling of TNF-α, IL-1β, and IL-6 in BALF using ELISA. Additionally, metagenomic and metabolomic analyses were conducted on fecal samples from the survival and non-survival groups to explore differences in microbial composition and metabolite profiles between the two groups.

Results: Recipients of survival-group FMT demonstrated substantially attenuated lung injury compared to non-survival FMT recipients, with histological evidence of preserved alveolar architecture. Barrier function metrics showed significant improvements, including decreased BALF protein concentration and lower pulmonary edema indices. Pro-inflammatory cytokine levels were markedly suppressed in both lung tissue and BALF samples. Metagenomic analysis revealed distinct dysbiosis patterns, with non-survival microbiota dominated by Enterobacteriaceae species, particularly Escherichia coli. In contrast, survival-associated microbiota exhibited greater phylogenetic diversity with enrichment of Duncaniella family. Metabolic pathway analysis identified enhanced butyrate synthesis capacity in survival-group microbiota, corroborated by metabolomic detection of elevated fecal butyrate levels.

In contrast, survival-associated microbiota exhibited greater phylogenetic diversity with enrichment of Duncaniella family. Metabolic pathway analysis identified enhanced butyrate synthesis capacity in survival-group microbiota, corroborated by metabolomic detection of elevated fecal butyrate levels.

Conclusions: This study establishes proof-of-concept that gut microbiota significantly impacts ARDS outcomes, potentially mediated through butyrate-driven immunoregulation. The findings implicate Escherichia coli overgrowth as a risk factor for barrier disruption. These results advance our understanding of gut–lung interactions in ARDS and support further investigation of microbiome-targeted therapies, including probiotic formulations and SCFA-based interventions, for critical care applications.

Conclusions: This study establishes proof-of-concept that gut microbiota significantly impacts ARDS outcomes, potentially mediated through butyrate-driven immunoregulation. The findings implicate Escherichia coli overgrowth as a risk factor for barrier disruption. These results advance our understanding of gut-lung interactions in ARDS and support further investigation of microbiome-targeted therapies, including probiotic formulations and SCFA-based interventions, for critical care applications.

The role of gut microbiota in the progression of acute respiratory distress syndrome. A. Schematic diagram illustrating the experimental procedure for fecal microbiota transplantation (FMT). B. Kaplan–Meier survival curves comparing survival proportions among all experimental groups. Statistical significance was determined using the Gehan–Breslow–Wilcoxon test, with p-values as follows: SF vs. DF, $p = 0.0876$; HF (healthy fecal transplant) vs. DF, $p = 0.0128$; NF (normal fecal transplant) vs. DF, $p = 0.0155$. C. mRNA expression levels of pro-inflammatory cytokines (TNF-α, IL-1β, and IL-6) in lung tissue, quantified by quantitative real-time PCR (qRT-PCR). D. Total protein content in bronchoalveolar lavage fluid (BALF) and lung wet/dry weight ratio. E. Representative images of hematoxylin and eosin (HE)-stained lung tissue sections and corresponding lung injury scores, assessed based on alveolar wall thickness, hemorrhage, and inflammatory cell infiltration. F. Metagenomic analysis depicting the relative abundance of differentially enriched bacterial species between the surviving fecal transplant group (SF) and the deceased fecal transplant group (DF).

***Intensive care Medicine Experimental 2025* 13(1):*000313*.**

Introduction: Aneurysmal subarachnoid haemorrhage (SAH) is a condition that predominantly affects women between forty and sixty. Its incidence is low compared to other types of strokes, but due to the characteristics of the patients it affects, its socio-health burden is high, and the loss of working life years is similar to that of other stroke types. Hospital mortality is around 25–50%, mainly due to the direct effects of the initial bleeding and secondary complications, both neurological and systemic. Systemic complications have a similar attributable mortality rate to neurological complications or the haemorrhage itself. Among these, cardiopulmonary complications are numerous and may present with a wide range of signs and symptoms.
Objectives: To assess the presence of cardiopulmonary complications in patients with SAH at the time of admission, track their evolution during ICU stay, and determine their impact on morbidity and mortality. We also aim to evaluate risk factors for these complications.
Methods: A prospective cohort study was conducted, including all patients with SAH who were admitted to the ICU at the General University Hospital of Castellón from March 2017 to August 2020. Data were collected at five time points: upon admission, 24 h, 48–72 h, 5 days, and 7 days. Demographic, clinical, ultrasound, and outcome variables were recorded. Statistical analysis was performed using STATA 14.0. Quantitative variables are presented as means and standard deviations and compared using Student's t-test, while categorical variables are described with percentages and compared using Chi-square tests.
Results: A total of 57 patients were included, 73.7% of whom were women, with a median age of 58 years (50–63). 77.2% presented with ultrasound complications upon ICU admission, and 43.2% of these resolved by discharge. No significant differences were found between groups of patients with and without complications. However, patients with complications were older (59 ± 12 vs. 53 ± 13, $p = 0.10$) and had higher severity scores (Hunt–Hess 3 (IQR 2–5) vs. 2 (IQR 2–3), $p = 0.20$), though these differences were not statistically significant. Among the groups that did and did not resolve from these complications, those who recovered were less likely to present with low levels of consciousness at onset (21% vs. 56%, $p = 0.02$).
Systolic function abnormalities appeared in 10.5% of patients, diastolic function in 28%, contractility changes in 12.3%, cardiac output abnormalities in 56.1%, and pulmonary oedema in 1.75% upon ICU admission. Systolic dysfunction and pulmonary oedema were fully recovered, 71% of contractility changes, 50% of diastolic dysfunction, and 40% of cardiac output issues also resolved. Patients with complications had more abnormalities in their ECG ($p = 0.06$) and elevated CPK ($p = 0.04$) and troponin levels ($p = 0.13$). The incidence of stress cardiomyopathy was 12.3%.
The mortality was 30% in the complication group and 15.4% in the non-complication group ($p = 0.48$). ICU stay was longer in the complication group (8 vs. 4 days, $p = 0.27$), but hospital stay did not differ. 3-month prognosis was better for the non-complication group by RSm scale 62% vs. 73%, but no difference was found at 6 months.
Mortality was 21% in the group that resolved and 36% in the group that did not resolve these complications ($p = 0.28$). ICU stay was longer in the group that resolved the complications (9 vs. 5 days, $p = 0.07$) and hospital stay was also longer (22 vs. 12 days, $p = 0.02$). The prognosis at 3 months was similar, but at 6 months, the group that did not recover had a better prognosis by RSm scale 69% vs. 86%, $p = 0.30$.
Diastolic abnormalities and low cardiac output were associated with mortality, alongside elevated troponin levels. Patients who did not resolve abnormalities in e' values and low cardiac output had higher mortality and worse prognosis.
The risk factors for complications were primarily higher scores on severity scales and initial systolic blood pressure. In the case of non-recovery of complications, severity grading and low levels of consciousness at the onset of symptoms were also significant factors.
Conclusions: The incidence of cardiac complications is high, though a significant percentage recover by discharge from the ICU. Patients with complications have higher mortality, longer ICU stays, and worse prognosis at three months. Detecting these abnormalities should alert us to possible associated clinical complications that could worsen the short-term prognosis.

Associations between blood alcohol concentration, risky riding behaviors, and fatal injuries in motorcyclists: a nationwide study (2011–2023)

CC. Chao[1]
[1]Emergency Department, Taipei Medical University Hospital, Taipei, Taiwan
Correspondence: C.C. Chao
Intensive care Medicine Experimental 2025* 13(1):*000314.

Introduction: Motorcycle crashes are a major public health concern worldwide, especially in low- and middle-income countries. Behaviors such as riding without a helmet, operating a motorcycle without a valid license, or driving under the influence of alcohol significantly increase the risk of severe or fatal injuries. Among these, alcohol consumption plays a important role by impairing cognitions and increasing the chance of engaging in risky behavior. Despite existing traffic laws, binge drinking remains widespread and has been linked to higher crash severity.
Objectives: This study explored how different levels of alcohol consumption relate to risky riding behaviors and fatal injuries among motorcyclists in Taiwan over a 13-year period.
Methods: This study analyzed police-reported traffic accident data from Taiwan's A1A2 dataset, spanning 2011 to 2023. Only motorcycle crashes that resulted in injuries or fatalities (classified as A1 and A2) were included in the analysis, while other types of road users and property-damage-only cases (A3) were excluded. Blood alcohol concentration (BAC) of the motorcyclist was divided into four groups: none (BAC = 0), low (BAC 0 ~ 0.03%), moderate (0.03% ~ 0.08%), and binge drinking (BAC > 0.08%). The study aimed to examine how BAC relates to behaviors such as helmet use, license status, crash type, and whether the crash involved a head-on crash or a run-off-road scenario. To assess the relationships between BAC levels and different variables, descriptive statistics and Chi-square tests were conducted across defined BAC categories.
Results: Riders with positive for blood alcohol concentration (BAC) were significantly more likely to engage in risky behaviors and suffer fatal injuries. Those with a BAC above 0.08% had a fatality rate of 1.8%, compared to just 0.2% among riders with no alcohol detected. Alcohol-impaired motorcyclists were more likely to ride un-helmeted (6.6% vs. 2.7%), without a valid license (35.9% vs. 9.1%), and to be involved in single-vehicle crashes (38.3% vs. 6.7%), head-on collisions (2.9% vs. 1.1%), and run-off-road incidents (3.2% vs. 0.2%).
Fatal injury risk rose sharply with age among binge drinkers, from 1.7% in riders under 18 to 3.5% in those aged 65 and older, compared to just 0.7% in sober riders of the same age. Young to middle-aged adults (18–40) accounted for the highest number of alcohol-related crashes, with 1.6% resulting in death.
Temporal and environmental factors further influenced outcomes. Elderly riders in rural areas with speed limits ≥ 51 km/h experienced fatality rates as high as 5.2%. While protective gear significantly reduced fatal outcomes, the highest fatality rate—18.4%—was seen in older male binge drinkers who were unhelmeted and crashed in high-speed rural areas.
Conclusions: The findings highlight that elevated BAC levels—particularly when combined with older age, rural environments, and the absence of protective gear—significantly increase the risk of fatal injuries in motorcycle crashes. Targeted safety interventions are essential to mitigate these risks and improve outcomes for motorcyclists.

Table 1 (abstract 000314) Distribution of fatal and non-fatal outcomes across key variables

Variable	Not Drunk		Not Binge		Binge	
	Non-Fatal	Fatal	Non-Fatal	Fatal	Non-Fatal	Fatal
Age category						
Age Category <18	99.8% (59086)	0.2% (109)	97.6% (741)	2.4% (18)	98.3% (343)	1.7% (6)

Identifying facilitators and barriers for palliative and end-of-life care in ICU: a sub-study of the "Enhancing palliative care in ICU" (EPIC) study

HI. Jensen[1]; V. Metaxa[2]; C. Hartog[3]; S. Mentzelopoulos[4]
[1]Departments of Anesthesiology and Intensive Care, Lillebaelt Hospital, University Hospital of Southern Denmark, Vejle, Kolding, Denmark; [2]Intensive Care Medicine, King's College Hospital, London, United Kingdom; [3]Klinik für Anästhesie und operative Intensivmedizin, Charité – Universitätsmedizin Berlin, Berlin, Germany; [4]Department of Intensive Care Medicine, National and Kapodistrian University of Athens, Πανεπιστημίου, *A*θήνα, *E*λλάδα, *AΘHNA*, Greece.
Correspondence: H.I. Jensen.
Intensive care Medicine Experimental 2025* 13(1)*:000315.

Introduction: In order to improve palliative and end-of-life care in the ICU, knowledge about facilitators and barriers is needed. A number of studies have previously identified facilitators or barriers (1), but the studies are mostly mono-national.

Objectives: The objective of the study was to explore facilitators and barriers to palliative and end-of-life care in the ICU among multinational ICU healthcare professionals.
Methods: As part of a "European Survey on Palliative Care and Law Perceptions" for ICU physicians and nurses, four questions about facilitators and barriers were included (one Likert Scale and three free text). The survey was distributed via an open, anonymous link at conferences, ICU networks, etc., from April 2024 to January 2025.
Results: A total of 586 ICU healthcare professionals (510 European, 55 from outside Europe, 21 unknown), representing 58 countries (40 European), responded to the question: "Do you believe that there is adequate focus on palliative care needs in your ICU?" Of these, 38% found this to be the case to a high or very high degree, while 16% responded, "No, not at all."
Of the 586, 164 (28%) had added free text comments. Main identified facilitators and barriers for palliative and end-of-life care in ICU were:

Facilitators (1)		**Barriers (1)**	
Education and training	16%	Resource limitation/wrong use of resources	26%
Staff recognition of the need for palliative care	15%	Absence/lack of knowledge of clear legislation	20%
Legislation/Guidelines	11%	Personal staff differences	15%
Interprofessional teamwork	8%	Lack of training	10%
Ethics and timely discussions/decision-making	7%	Unrealistic expectations of family/non-ICU staff	9%
Family inclusion	5%	Lack of palliative care specialists and guidelines	6%
Palliative care integration	5%	Fear of misconduct/legal repercussion	4%
Environment (e.g. time prioritized, open visitation, enough staff)	4%	Disagreements within the team	4%
Knowledge about patients' wishes	4%	Misconceptions about palliative care	4%
Poor prospect for patient	4%	Cultural and religious influence	4%

1. Percentages of the 164, who had added free text comments

Conclusions: The survey results show that the focus on palliative care in the ICU varies greatly. Likewise, the results reveal a complex interplay of factors that promote and hinder effective palliative and end-of-life care in the ICU. The identified facilitators and barriers can help provide a roadmap for improving palliative and end-of-life care in ICU settings.

ICU nurses' perception of communication barriers with patient's families and end-of-life care practices

WS. Jung[1]; SH. Tak[2]
[1]Nursing Department, Seoul National University Hospital, Seoul, Republic of Korea; [2]Research Institute of Nursing Science, College of Nursing, Seoul National University, Seoul, Republic of Korea

Intensive care Medicine Experimental 2025* 13(1)*:000318.

Introduction: Although end-of-life (EoL) care is important in intensive care units due to the high severity of illness and mortality rates, it is often overlooked for various reasons. EoL care includes both treatment of dying patients and support provided to patients' families. A patient-family-centered approach is strongly recommended to ensure high-quality EoL care in intensive care. A key element of this approach is sharing information with family members, which requires open communication between them and the nurses. Therefore, in providing EoL care in the intensive care unit, it is important to recognize the patient's family members as recipients of care and to identify any communication barriers with them.
Objectives: The aim of this study was to identify the communication difficulties with patient's families recognized by intensive care unit nurses. In addition, the importance and performance of EoL care for the family members as recipients of care were explored.
Methods: This study was conducted from March 4 to March 31, 2022, with intensive care unit nurses at a university hospital in Seoul. The survey accessed communication barriers with the patient's families, as well as the importance and performance of end-of-life care practices among 124 ICU nurses.
Results: 1) The mean score of communication barriers with patient's families perceived by intensive care nurses was 3.60 ± 0.49 out of 5. The highest score of communication barriers was 'Family' (mean 3.73, S.D. = 0.52).

Table 1 (abstract 000318) Self-perceived communication barriers with patient's families

Variables	M ± SD
Communication barrier	3.60 ± 0.49
Nurses	3.62 ± 0.54
Family	3.73 ± 0.52
Environment	3.34 ± 0.63
Patient condition	3.51 ± 0.74

2)The importance of EoL care practices recognized by intensive care nurses was 4.06 ± 0.40 and the performance of EoL care practices was 3.50 ± 0.48 out of 5. The highest score of the importance of EoL care practices was 'Explaining and providing information' (mean = 4.37, S.D. = 0.48). The highest score of performance of EoL care practices was 'Symptom management and comfort care'(mean = 4.21, S.D. = 0.52).

Table 2 (abstract 000318) The importance and performance of EoL care practices

Variables	Importance M ± SD	Performance M ± SD
End-of-life care practices	4.06 ± 0.40	3.50 ± 0.48
Patient and family centered decision-making scale	4.24 ± 0.50	3.22 ± 0.84
Explaining and providing information	4.37 ± 0.48	4.05 ± 0.55
Continuity of care	4.26 ± 0.58	3.57 ± 0.72
Emotional and practical support for patients and families	3.96 ± 0.54	3.06 ± 0.75
Symptom management and comfort care	4.05 ± 0.48	4.21 ± 0.52
Comfort care-environmental factors	3.97 ± 0.52	3.52 ± 0.63

3) The importance of EoL care practices (t = 2.661, p = 0.009) and the performance (t = 3.114, p = 0.002) were differed significantly by EoL care education.
4) The communication barriers with the patient's families had a significant positive correlation with the importance of care practices(r = 0.38 p < 0.001) and the performance(r = 0.21 and p = 0.017). The importance of EoL care practices had a significant positive correlation with the performance of EoL care practices(r = 0.45, p < 0.001).
Conclusions: It is necessary to develop various intervention to address communication barriers with patient's families in intensive care units. Furthermore, end-of-life care education programs is critical in order to improve awareness of comprehensive end-of-life care and effectively communicate with nurses and patient families.

NCOA4-mediated iron dysregulation and immune dysfunction in macrophage drives sepsis-induced intestinal injury

Y. Le[1]; Q. Liu[2]; Y. Yang[1]; J. Wu[1]
[1]Jiangsu Provincial Key Laboratory of Critical Care Medicine, Department of Critical Care Medicine, Southeast University, Nanjing, China;
[2]Department of General Surgery, Southeast University, Nanjing, China

Intensive care Medicine Experimental 2025* 13(1)*:000319.

Introduction: The gut is commonly affected in sepsis, and patients with intestinal injury have a poor prognosis[1]. Recent research and our prior work have indicated that dysregulation of iron metabolism within macrophages may exacerbate organ injury by modulating immune responses[2,3]. Nuclear receptor coactivator 4 (NCOA4) plays a critical role in both regulating iron homeostasis and immune homeostasis. However, the function and precise regulation of NCOA4 in sepsis-induced intestinal injury remains to be elucidated clearly.
Objectives: To investigate the role and molecular mechanisms of NCOA4 in sepsis-induced intestinal injury, providing novel insights and potential therapeutic targets for sepsis prevention and treatment.
Methods: To explore the role of NCOA4 in macrophages, we generated the conditional ablation of *Ncoa4* in macrophages (*Ncoa4*LyzM-/-) in mice by using Cre/loxP technology, and a mouse model of severe sepsis was established by cecal ligation and puncture (CLP). The 7-day mortality of *Ncoa4*LyzM-/- and wild-type mice were compared. Intestinal histopathological damage, epithelial barrier function, and immune barrier function were further examined. Intestinal iron and lipid peroxidation levels were measured, and transcriptomic analysis combined with NCOA4 expression and distribution changes in macrophages were used to explore the underlying molecular mechanisms.
Results: We found that the *Ncoa4*LyzM-/- septic mice exhibited significantly lower 7-day mortality, reduced intestinal barrier injury, decreased inflammatory cytokine levels, and alleviated iron dysregulation and lipid peroxidation compared to wild-type mice. Thoroughly, it showed that the immune response and regulation are among the top 5 pathways enriched in peripheral blood mononuclear cells (PBMCs) of *Ncoa4*LyzM-/- CLP mice. Consistently, NCOA4 may influence adhesion and cytokine-receptor interactions of macrophage, based on GSVA analysis of all the differentially expressed genes in bone marrow-derived macrophage (BMDM) of *Ncoa4*LyzM-/- mice with the Kyoto Encyclopedia of Genes and Genomes (KEGG). Mechanistically, during early stage of sepsis, NCOA4 distribution in macrophages was disrupted, with cytoplasmic accumulation and a significant reduction in nuclear, indicating hyperactivation of its iron regulatory and pro-inflammatory (cytoplasmic) functions and suppression of its anti-inflammatory and antioxidant (nuclear) functions.
Conclusions: NCOA4 within macrophages acts as a pathogenic driver, accelerating intestinal injury during sepsis. Mechanistically, aberrant cytoplasmic-nuclear distribution of NCOA4 in macrophages may lead to iron dysregulation and immune dysfunction. Therapeutic strategies targeting NCOA4 trafficking may mitigate sepsis-induced intestinal injury.

NCOA4 deficiency in macrophage alleviate sepsis-induced intestinal barrier injury. (A) Survival analysis of WT and Ncoa4LyzM-/- mice is shown. (B) Representative histopathological section images, immunohistochemical or fluorescent images in the intestinal tissues of indicated mice. (C) qPCR analysis of il-1b, tnf-a and il-6 mRNA in intestinal tissues from mice with sepsis. (D) qPCR analysis of occludin, muc2 and claudin-1 mRNA in intestinal tissues from mice with sepsis. (E) Differential pathways enriched in WT and Ncoa4LyzM-/- mice after CLP model by GSVA. (F) Differential pathways enriched in BMDM with LPS at 4 h (1 μg/ mL) from WT and Ncoa4LyzM-/- mice by GSVA. (G) Immunoblot analysis of the indicated proteins in BMDMs treated with 1 μg/ mL LPS for 2 and 4 h.

A machine learning approach to prediction of postoperative morbidity and mortality in elective surgical patients using pre and intraoperative data

J. Hunter[1]; S. Harris[2]
[1]Institute of Health Informatics, University College London, London, United Kingdom; [2]Critical care department, University College Hospital, Euston Road, London, United Kingdom
Correspondence: J. Hunter
Intensive care Medicine Experimental 2025* 13(1)*:000320.

Introduction: ICU beds are a scarce resource, and elective surgical admissions account for a significant and rising proportion of demand (1). Currently, cases are selected for ICU admission preoperatively using clinical judgement and statistical risk scores such as the SORT score (2), and intraoperative data are not used in risk prediction. Using both pre- and intraoperative data could improve postoperative morbidity and mortality (POMM) risk prediction models, enabling better prioritisation of patients for ICU admission following elective surgery.

Objective:

Compare the performance models using only preoperative data, and pre- and intraoperative data, to predict POMM relevant to need for ICU care.

Evaluate importance of intraoperative features.

Methods: The dataset included adult elective surgical cases at a large UK NHS Trust planned for inpatient surgery under general anaesthesia lasting over 30 min between 1st May 2019 and 31st December 2024.

Features included patient and surgery characteristics, preoperative laboratory test results, physiological observations and echocardiograms, and intraoperative physiological observations and ventilation parameters.

POMM outcomes definitions were based on a review of literature on perioperative outcome definitions, electronic health record data availability, and relevance to ICU care needs.

Data were split into 80% for training and 20% for testing. Machine learning models were trained to predict each outcome using preoperative data only, or pre- and intraoperative data. Accuracy, average precision and area under receiver operator curve (AUROC) were calculated in the test set. DeLong's test was used to compare AUROCs of preoperative and pre- and intraoperative models (3). Feature importances were evaluated using SHapley Additive exPlanation values (4).

Results: The dataset included 31,332 cases, with 20.3% admitted to ICU postoperatively (Table 1). Models using combined pre- and intraoperative data showed significantly better performance in predicting respiratory and cardiovascular morbidity, postoperative infection, prolonged ICU stay, and composite POMM outcomes (Table 2). There was no significant difference in the AUROCs of the preoperative and pre- and intraoperative models predicting hospital mortality. Both performed significantly better than the SORT score (AUROC 0.847), with the caveat that the SORT score predicts 30-day mortality rather than hospital mortality.

Intraoperative features are important in prediction models. For cardiovascular and respiratory morbidity models, 10 and 6 of the top 20 features described cardiovascular and respiratory physiology, respectively (Fig. 1).

Conclusions: Updating estimates of risk using intraoperative data could significantly improve discriminative performance of morbidity prediction models, and better inform decisions around postoperative ICU admission. Postoperative risk predictions could help anaesthesia and outreach services reviewing surgical cases postoperatively to more appropriately prioritise patients.

Table 2 (abstarct 000320) Performance of models using preoperative data only and pre + intraoperative data to predict each outcome measure. P values for Delong's test comparing AUROCs for preoperative and pre + intraoperative data models for each outcome are shown

Intensive care Medicine Experimental 2025* 13(1):*000323.

Introduction: We performed this study to investigate the effect of intraoperative brainstem auditory evoked potential (IBAEP) changes on the development of postoperative nausea and vomiting (PONV) after microvascular decompression (MVD) for neurovascular cross compression.
Methods: A total of 373 consecutive cases were treated with MVD. The use of rescue antiemetics after surgery was used as an objective indicator of PONV. IBAEP monitoring was routinely performed in all.
Results: The use of rescue antiemetics was significantly associated with female sex (OR = 3.427; 95% CI, 2.077–5.654; p < 0.001), PCA use (OR = 3.333; 95% CI, 1.861–5.104; p < 0.001), and operation time (OR = 1.017; 95% CI, 1.008–1.026; p < 0.001). A Wave V peak delay of more than 1.0 ms showed a significant relation with the use of rescue antiemetics (OR = 1.787; 95% CI, 1.114–2.867; p = 0.016) and a strong significant relation with the use of rescue antiemetics more than five times (OR = 2.426; 95% CI, 1.372–4.290; p = 0.002).
Conclusions: A wave V peak delay of more than 1.0 ms, might have value as a predictor of PONV after MVD. More detailed neurophysiological studies will identify the exact pathophysiology underlying PONV after MVD.

Identification and validation of clinical phenotypes in non-intubated patients with acute respiratory failure: a multi-cohort study

N. Shi[1]; R. Zheng[2]; X. Chen[3]; H. Qiu[1]; H. Chen[1]
[1]Critical Care Unit, Zhongda Hospital, Nanjing, China; [2]Critical Care Unit, Northern Jiangsu People's Hospital, Yangzhou, China; [3]Emergency Department, Nanjing Medical University First Affiliated Hospital and Jiangsu Province Hospital, Nanjing, China

Intensive care Medicine Experimental 2025* 13(1):*000325.

Introduction: Acute respiratory failure (ARF) is a heterogeneous disease caused by multiple etiologies, including infection, shock, and trauma [1]. Researches have focused predominantly on patients receiving IMV and precision therapies [2–4], with limited attention given to those receiving non-invasive respiratory strategies.
Objectives: We aimed to explore the heterogeneity among non-intubated ARF patients and the interactions between phenotypes and treatment strategies.
Methods: In this retrospective study, both severe COVID-19 and non-COVID-19 patients were recruited (training cohort, n = 609; validation cohort A, n = 409; validation cohort B, n = 706). Unsupervised algorithms were employed to derive phenotypes. We used the Cox regression model to explore the associations between phenotypes and 28-day mortality. The heterogeneity of the treatment effect (HTE) was investigated. Finally, we developed a parsimonious model for phenotype classification.
Results: In the severe COVID-19 training cohort, a two-class model was identified and had the optimal fit. Phenotype 1 (hypoinflammatory phenotype) presented slight oxygenation impairment and nearly normal inflammation, whereas Phenotype 2 (hyperinflammatory phenotype) presented poorer oxygenation and a hyperinflammatory state. Patients with Phenotype 2 had worse outcomes, with higher intubation and mortality rates. Similar phenotypes were identified in two dependent validation cohorts. HTE revealed that patients with Phenotype 1 could benefit more from prolonged awake prone positioning than from standard care in the validation cohort A. Moreover, three or four variables had accurate performance for the assignment of phenotypes.
Conclusions: We identified and validated two distinct phenotypes in non-intubated ARF patients, with both prognostic and predictive enrichment. The phenotypes could be accurately identified with simple classifier models.

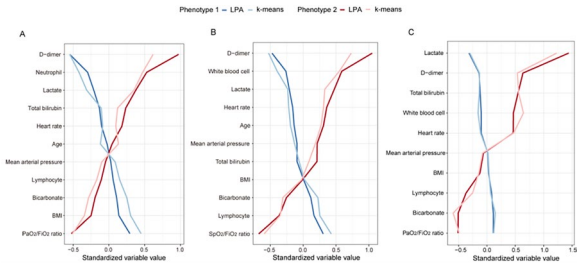

Fig. 1 (abstract 000325) Comparison of variables that contribute to clinical phenotypes in three cohorts. A: the training cohort, B: the validation cohort A, C: the validation cohort B

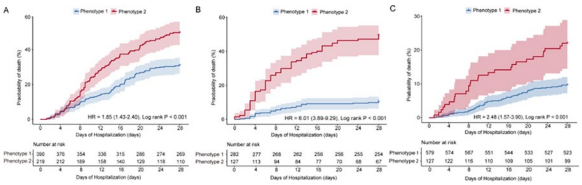

Fig. 2 (abstract 000325) Probability of death by phenotypes. A: the training cohort, B: the validation cohort A, C: the validation cohort B. Hazard ratio was calculated by Cox proportional-hazards model. The log-rank test demonstrated a significant between-group difference

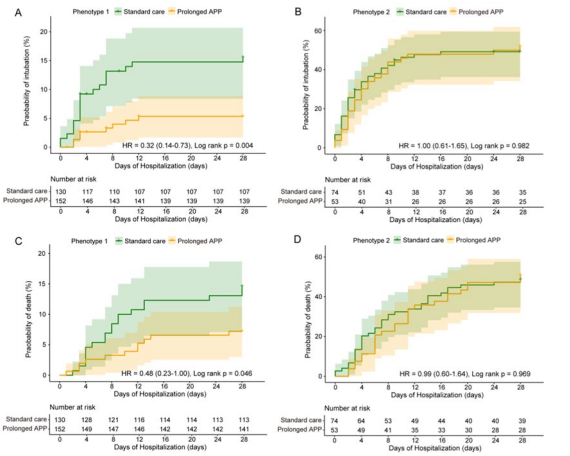

Fig. 3 (abstract 000325) Probability of endotracheal intubation and death by awake prone positioning in the validation cohort A. A&C: Phenotype 1, B&D: Phenotype 2. Hazard ratio was calculated by Cox proportional-hazards model. The log-rank test demonstrated a significant between-group difference. Prolonged APP: prolonged awake prone positioning, a minimum of 12 h daily with several breaks if needed for up to 7 days. Standard care: whether to be prone or not according to patients' wishes, however, they were not encouraged to remain in the prone position for a prolonged period of time (> 12 h/day)

Introduction: Outcomes reported in airway management studies are heterogeneous, hampering evidence synthesis [1,2]. Furthermore, there is a paucity of published literature on patient views of outcomes relevant to airway management research. The Airway Terminology and Outcome Measures (ATOM) project set out to invite views from clinicians, researchers and patients to identify a range of core outcomes to be used in all future airway management studies. Here, we report preliminary findings of the first phase of a modified Delphi process.
Methods: We conducted a Delphi study using a sample of outcomes from airway studies published between January 2006 and November 2023. The first two rounds were surveys distributed internationally to clinicians of any specialty involved in airway management, researchers and patients with previous experience of airway management, in both elective and emergency settings. Outcomes were divided into five domains: procedural effectiveness; physiology; adverse events; patient-reported outcomes and other outcomes. To aid comprehension, lay explanations were provided for each outcome and animated videos co-created with a lay representative. All participants were asked to score the perceived importance of each proposed outcome on a nine-point scale. Prespecified thresholds for outcome inclusion and exclusion were used [3]. Decisions were analysed according to stakeholder group and outcome domain, with Fisher's exact test used to compare clinician and patient decisions, and odds ratios (OR) and 95% confidence intervals (CI) calculated using logistic regression.
Results: In the first round, we presented 68 outcomes to 453 respondents, of which 328 (72%) were clinicians, 67 (15%) patients, and 58

(13%) researchers or others. Participants were predominantly from Europe (51%), with additional representation from Oceania (21%), North America (13%), Asia (9.5%), South America (3.5%) and Africa (2.4%). Ten outcomes were included and seven excluded at this stage, with decisions for each outcome presented in Fig. 1. Patients were significantly more likely to exclude outcomes compared with clinicians (OR 12.2, 95% CI 4.5–36.7, p < 0.001), with exclusion rates of 68% versus 15% across domains, respectively (Table 1). Decisions on outcome inclusion were most congruent for 'Adverse events' (p = 0.699), but highly discordant for 'Procedural effectiveness' (p < 0.001), with patients more likely to exclude outcomes that clinicians included.

Table 1 (abstract 000327) Comparison of stakeholder decisions according to outcome domain

Domain	Outcomes, n	Stakeholder group	Inclusion, n (%)	Exclusion, n (%)	Indeterminate, n (%)
Procedural effectiveness	28	Clinicians	22 (79%)	0 (0%)	6 (21%)
		Patients	0 (0%)	16 (57%)	12 (43%)
Adverse events	15	Clinicians	11 (73%)	0 (0%)	4 (27%)
		Patients	9 (60%)	0 (0%)	6 (40%)
Physiology	11	Clinicians	5 (45%)	1 (9%)	5 (45%)
		Patients	1 (9%)	3 (27%)	7 (64%)
Patient-reported outcomes	7	Clinicians	1 (13%)	4 (50%)	3 (38%)
		Patients	3 (38%)	5 (63%)	0 (0%)
Other outcomes	6	Clinicians	2 (33%)	2 (33%)	2 (33%)
		Patients	0 (0%)	3 (50%)	3 (50%)

Conclusions: In the first survey round of the ATOM Delphi study, there was substantial agreement on the inclusion of adverse event outcomes between patients, clinicians and other stakeholders. Procedural outcomes were favoured by clinicians, but not by patients, presenting a challenge for finding consensus in upcoming stages of the project. This work represents a novel glimpse into patient views on outcomes relevant to airway management research. Insights from subsequent Delphi rounds will inform future airway management research.

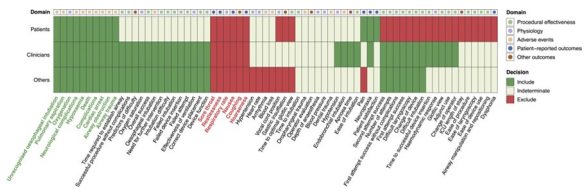

Fig. 1 (abstract 000327) Heatmap of decisions on outcomes according to stakeholder group and outcome domain following the first stage of the ATOM Delphi process. Outcomes are displayed on the x-axis and highlighted in green (Include) and red (Exclude) where all three stakeholder groups reached the same decision

Single-cell transcriptome profiling of sepsis identifies the hypermetabolic, biosynthetically active phenotype of CD11c + HLA + + monocytes: a novel sepsis biomarker

L. Jia[1]; Y. Tang[1]; Y. Wang[1]; P. Wang[1]; S. Liu[1]; R. Huo[1]; J. Xie[1]

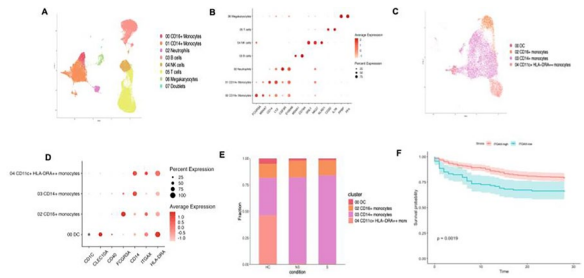
Intensive care Medicine Experimental 2025* 13(1):*000328.



Introduction: Sepsis results from a dysregulated host immune response to infection. However, studies on the immune traits of sepsis remain limited, restricting their potential as biomarkers for prognosis prediction.
Objectives: This study aims to investigate the relationship between CD11c + HLA + + monocytes and sepsis, as well as their prognostic value, and to explore its potential biological functions during sepsis.
Methods: The study analyzed 731 peripheral blood immune cell traits [1] from the UK Biobank database, combined with GWAS data of sepsis and sepsis mortality at 28 days, using two-sample bidirectional MR. Publicly available scRNA-seq datasets (GSE67363) were analyzed to validate the selected immune subsets, successfully clustering the CD11c + HLA-DR + + monocyte subset. Based on the hub genes of the CD11c + HLA-DR + + monocyte subset, differentially expressed gene (DEG) analysis and enrichment analysis were performed.
Results: This study systematically evaluated the causal relationship between peripheral blood immune cell phenotypes and both sepsis susceptibility and 28-day mortality by two-sample bidirectional MR analysis. We identified multiple immune cell subsets, including CD11c + HLA-DR + + monocytes, CD40 + CD14 + CD16- monocytes, CD40 + CD14-CD16 + monocytes, CCR2 + monocytes and granulocytes, CD24 + CD27 + B cells, CD127−CD8 + T cells, CD28 + CD45RA + CD8dim T cells, CD28 + CD45RA + CD8 + T cells, CD28 + CD45RA-CD8 + T cells, CD28-CD127-CD25 + + CD8 + T cells, and CD25 + CD39 + CD4 + regulatory T cells, were significantly associated with sepsis and 28-day mortality risk of sepsis. However, validation using multiple scRNA-seq PBMC datasets revealed that only the $CD11c^{+}HLA\text{-}DR^{++}$ monocyte subset could be reliably annotated.
The higher percentage of CD11c + HLA-DR + + monocytes was associated with a lower risk of sepsis (OR = 1.07, 95% CI: 1.01–1.12, P = 0.0145) and lower 28-day mortality in sepsis patients (OR = 1.07, 95% CI: 1.00–1.13, P = 0.0378). The immune subset of CD11c + HLA-DRA + + monocytes is identified in scRNA-seq data of the PBMC of septic patients. In healthy controls, CD11c + HLA-DRA + + monocytes constituted approximately 47.5% of total monocytes, but their proportion significantly decreased in septic patients. In septic survivors, the proportion of CD11c + HLA-DRA + + monocytes is 2.6% and 1.5% in sepsis non-survivors. Survival analysis based on the AmsterdamUMCdb database (GSE65682) showed that sepsis patients with high ITGAX(CD11c) expression in monocytes had significantly better outcomes compared to those with relatively low ITGAX expression, with a significant difference (P = 0.0019).

Enrichment analysis of upregulated differentially expressed genes specific to CD11c + HLA-DRA + + monocytes revealed significant enrichment in ATP synthesis coupled electron transport, with cellular components primarily localized to the ribosomal subunit and ficolin-1-rich granule lumen. This suggests that ribosome biogenesis and mitochondrial functions in CD11c + HLA-DRA + + monocytes may undergo significant changes in sepsis, which requires further validation.

Conclusions: This study identified CD11c + HLA + + monocytes as a novel immune biomarker negatively associated with sepsis. Their depletion in sepsis, potentially driven by enhanced mitochondrial activity, ribosome function and autophagy triggered by ficolin-rich granules, may contribute to immune suppression and poor prognosis. Future studies will validate their depletion, assess prognostic relevance, and investigate underlying molecular mechanisms.

Scatter plot of the MR analysis showing the relationships of eosinophil levels with risks of sepsis (A) and sepsis-related mortality (B). MR, Mendelian randomization; SNP, single-nucleotide polymorphism.

scRNA-seq analysis validates the CD11c + HLA + + monocytes in PBMCs of sepsis patients and healthy controls. CD11c + HLA + + monocytes are significantly reduced in septic patients. (A) UMAP plots of PBMCs, with identified cell clusters. (B) Marker gene identification for each cluster, with dot size representing the proportion of cells expressing the gene and color indicating average expression. (C) Frequency of each cell type. (D) UMAP projection of monocytes, clustered into CD16 + , CD14 + , and CD11c + HLA-DRA + + monocytes. (E) Dotplot showing marker genes for monocyte and dendritic cell clusters. (F) Survival analysis curve using deconvolution method shows that patients with high ITGAX (CD11c) expression have better prognosis than those with low expression.

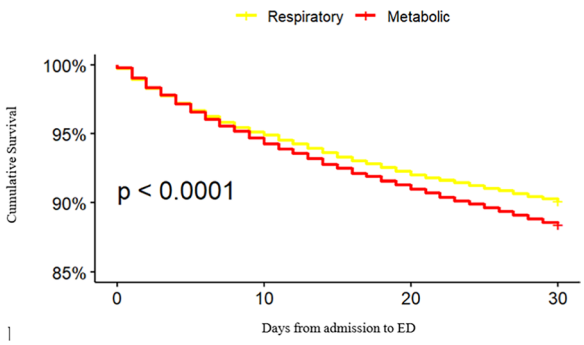
Intensive care Medicine Experimental 2025* 13(1)*:000331.



Introduction: Acid base disturbances are frequently found in patients presenting to the emergency department (ED). Recently, we found that in patients presenting to the ED with significant alkalemia, the mechanism of alkalemia, i.e., primarily metabolic versus primarily respiratory, rather than the absolute degree of alkalemia, is associated with increased mortality (1).

Objectives: To evaluate the prognostic significance of alkalemia (significant or mild) upon emergency department admission.

Methods: We retrospectively reviewed the records of all patients aged 18 years or older evaluated in the ED of a tertiary referral center during 1999–2024 with the first measurement of pH > 7.45. Alkalemia was defined as primarily metabolic (PM) if PCO2 was ≥ 35 mmHg and primarily respiratory (PR) if bicarbonate ≤ 24 mEq/L. The primary outcome was survival 30 days from ED presentation.

Results: Patients with PM had a 10.02 times higher hazard of death at 30 days from ED presentation (95% CI: 2.55–39.36, p < 0.001) compared to patients with either PR or combined alkalemia. (figure) Higher serum pH (HR = 1.8 95% CI: 1.3–2.2, p = 0.006) and older age (HR = 4.72, 95% CI: 1.42–15.68, p = 0.011) were independently associated with an increased 30 day mortality, with the effects of higher pH more pronounced in older age (interaction HR = 0.81, 95% CI: 0.69–0.95, p = 0.011). While hyperkalemia was only marginally associated with increased 30 days mortality in the cohort as a whole (HR = 1.33, 95% CI: 0.96–1.84, p = 0.082), this association was much more pronounced in the PM group (HR = 0.60, 95% CI: 0.42–0.86, p = 0.005), suggesting an interaction.

Conclusions: In patients presenting to the ED with alkalemia, the mechanism of alkalemia (PM versus other), age, and pH levels are important predictors of 30 day mortality.

Comulative survival rate according to the origin of alkalosis.

Out-of-hospital versus in-hospital cardiac arrest: neuro-prognostication practice adherence in a tertiary NHS hospital

L. Rodrigues Mendes[1]; S. Vlachos[1]; P. Zolfaghari[2]
[1]Critical Care, King's College Hospital, London, United Kingdom;
[2]Intensive care unit, Barts Health NHS Trust, London, United Kingdom
Correspondence: L. Rodrigues Mendes
Intensive care Medicine Experimental 2025* 13(1):*000332.

Introduction: Out-of-hospital (OHCA) and in-hospital cardiac arrest (IHCA) can lead to a variety of neurological deficits. Almost 80% of patients admitted to intensive care (ICU) post return of spontaneous circulation (ROSC) are comatose and with uncertain prognosis [1]. For these, under certain criteria, a multimodal neuro-prognostication approach consisting of various validated tests, is advised, to help steer treatment decisions, that ultimately can lead to withdrawal of life-sustaining therapy (WLST) [2;3].
Objectives: This audit aimed to compare local prognostication guidelines adherence, based on current international neuro-prognostication practice, between OHCA and IHCA patients staying comatose after 72 h post-ROSC, in an NHS hospital.
Methods: Audit approved by Kings College NHS Hospital (KCH) Critical Care Board in October 2023, as service evaluation project. Included adult patients (≥ 18 years) admitted to KCH 6 ICUs post cardiac arrest (CA) (OHCA or IHCA) in the preceding 24 h, from July 1st, 2021, to June 30th, 2023. Data were collected on patient demographics, CA location, and neuro-prognostication adherence concerning clinical neurological examination (pupillary reactivity; motor score; cough/gag reflex; seizures/status myoclonus) and timing of tests performed: CT/MRI head, two EEGs; SSEP; NSE.
Results: 368 post-CA patients were admitted to KCH ICUs during this period, of whom 114 remained comatose 72 h post-ROSC, mostly OHCA patients (n = 84), male (n = 69) and 59 years median age. Post-OHCA patients had poorer clinical neurological findings (fixed dilated pupils ($p = 0.018$), lower motor scores ($p = 0.003$), absent cough/gag reflex ($p = 0.035$)). CT Head at 48 h occurred in 98.2% of patients, being repeated in 78.1% of patients, with no differences between groups. MRI Head was done in 13.2% patients (n = 15) mainly post-IHCA ($p = 0.016$). No group differences were seen on timings of EEG (performed in 80.7% of patients, repeated in 47.4%), SSEP (done in 31.6% of patients) and NSE (taken in 15.8% of patients) (Table 1).
Conclusions: For post-CA comatose patients, KCH ICU adherence to multimodal neuro-prognostication approach was similar between groups, though more MRI head were performed post IHCA. A NSE underutilisation as prognostication tool was noted, aspect highlighting need for awareness and future improvement.

Table 1 (abstract 000332) Neuro-prognostication adherence before considering WLST

		IHCA (N=30)	OHCA (N=84)	TOTAL (N=114)	p-value

Out-of-hospital versus in-hospital cardiac arrest: a 2-year overview of comatose patients' characteristics and outcomes in a tertiary NHS hospital ICU

L. Rodrigues Mendes[1]; S. Vlachos[1]; P. Zolfaghari[2]
[1]Critical Care, King's College Hospital, London, United Kingdom;
[2]Intensive care unit, Barts Health NHS Trust, London, United Kingdom

Intensive care Medicine Experimental 2025* 13(1):*000333.

Introduction: After cardiac arrest (CA) circulation ceases, triggering systemic metabolic failure, with shock from ischaemia–reperfusion patterns present in 50–70% of patients after return of spontaneous circulation (ROSC) [1,2]. Albeit a temporary complication, it can lead to systemic inflammation and multi-organ failure, with 20–55% in-hospital mortality, hence post cardiac arrest (CA) patients may need intensive care (ICU) admission, for specialised treatment management and optimised recovery [3].
Objectives: This audit aimed to compare treatment management and outcomes between out-of-hospital (OHCA) or in-hospital cardiac arrest (IHCA) patients, in a subgroup of patients remaining comatose after 72 h post-ROSC, in a tertiary NHS Hospital.
Methods: Audit approved by Kings College NHS Hospital (KCH) Critical Care Board in October 2023, as service evaluation project. Included adult patients (≥ 18 years) admitted to KCH 6 ICUs, after receiving cardiopulmonary resuscitation for OHCA or IHCA in the preceding 24 h, that remained comatose after 72 h post-ROSC, from July 1st, 2021, to June 30th, 2023. Data were collected on patient demographics, CA location, ICU-days of organ systems supported (respiratory, cardiac, neurological, and renal), ICU length of stay (LOS), ICU/Hospital mortality and withdrawal of life-sustaining therapy timing (WLST).
Results: Of the 368 post-CA patients admitted to KCH ICUs in this period, 114 remained comatose 72 h post-ROSC, mostly OHCA patients (n = 84), male (n = 69) and 59 years median age. No differences were seen concerning gender or age, between groups (p = 0.388 and p = 0.347, respectively). It was observed that post IHCA patients had more ICU median days of respiratory (p = 0.027), cardiac (p = 0.048) and renal support (p = 0.002) compared to post OHCA patients. The opposite was noted for ICU median days of neurological monitoring (p = 0.021) in the post OHCA group. Post IHCA median ICU LOS was longer (p = 0.015), however no differences existed in ICU or hospital mortality between groups (p = 0.453 and p = 0.838, respectively). There were no differences between groups in WLST (p = 0.829), though WLST occurred sooner for post OHCA patients (p = 0.033) (Table 1).
Conclusions: In post-CA comatose patients, no group differences existed as for gender, age ICU or hospital mortality and WLST. Post IHCA patients had more ICU median days of respiratory, cardiac, and renal support, while post-OHCA patients had more ICU median days of neurological monitoring. ICU LOS was longer in post IHCA patients and WLST occurred sooner post OHCA.

Table 1 (abstract 000333) Characteristics of a subgroup of patients remaining comatose after 72 h post-ROSC in a tertiary NHS Hospital

		IHCA (N=30)	OHCA (N=84)	TOTAL (N=114)	p-value

Intensive care Medicine Experimental 2025 **13(1)**:***000334***.

Introduction: Aneurysmal subarachnoid hemorrhage (SAH) is a global health burden with serious consequences, including permanent disability. To reduce this burden, it is important to understand the risk factors for disability and identify those that can be prevented.

Objectives: To evaluate risk factors for disability at discharge from a tertiary hospital neurotrauma ICU in patients with SAH.

Methods: Prospective study of patients with SAH admitted from October 2013 to December 2024, in a 10-bed neurotraumatic ICU. We analyzed: main diagnosis at admission; demographic data, neurological data (clinical exam and pupillary size, and Glasgow Coma Score (GCS); location and size of the aneurysm; presence and size of the aneurysm; presence of intracranial hematoma (ICH); presence of intraventricular intraventricular hemorrhage; days to develop vasospasm; development of delayed cerebral ischemia (DCI) Fisher scale, modified Fisher scale, Hunt and Hess scale, Hunt and Hess scale, Hess and scale, Hunt and Hess scale, Word Federation of Neurosurgeons (WFNS) scale; presence of vasospasm on Doppler and/or arteriography; delay in ICU admission; aneurysm treatment; complications, including aneurysm; complications, including infections; Glasgow Outcome Scale (GOS) in the ICU; at discharge and 6 months after discharge from the ICU and other factors; a univariate study and multivariate logistic regression analysis of disability at ICU discharge. To determine the discriminatory capacity of the score, an analysis of the recipient's receiver operating characteristic (ROC) analysis was performed. The diagnostic ability of the score was assessed using the area under the ROC curve, which was estimated using a 95% confidence interval. Sensitivity, specificity, positive predictive value (PPV) and negative predictive value (NPV) were calculated for the chosen cutoff point.Statistical significance was set at < 0.05. Data were analyzed using the R package, version 4.2.1 (R Development Core Team, 2022).

Results: Of the 291 admitted SAH patients had 107 (36.76%) severe disability at discharge with a GOS ≤ 3. Demographics and associated factors of disability at ICU discharge, in univariate analysis, are described in Table 1. Those who developed acute cerebral ischemia (ACI) (15.9%) and those who required decompressive craniectomy (12.2%) had significantly greater disability. Independent factors associated with disability were: (Table 2) and mechanical ventilation (MV) greater than 7 days 6.469 (2.993; 13.981), ACI:4.842 (1.342; 17.465); Hunt and Hess scale OR:1.475 (1.139; 1.911), and APACHE II on admission OR: 1.181 (1.108; 1.258).A prediction score was obtained:$0.166 \times$ APACHE II score $+ 1.867 \times$ MV > 7 days $+ 1.557 \times$ AH F $+ 0.389 \times$ Hunt and Hess scale score.MV > 7 days: 1/0 depending on whether V M > 7 days or not (Fig. 1).The area under the curve was 0.924 CI 0.892; 0.954 (Fig. 2). Cut-off point: 3.848; specificity 84.3 [78.1; 89.3]; sensitivity: 88.9 [81.2; 94.1] NPV: 92.6 [87.7; 96.1]; PPV: 77.2 [68.8; 84.3] (Table 3).

Conclusions: The 36.76% of patients with SAH were severely impaired at the time of discharge from the ICU. Independent factors associated with disability were: APACHE II on admission, Hunt and Hess scale, AHF and MV > 7 days. A score was obtained to predict disability at ICU discharge.

Intensive care Medicine Experimental 2025* 13(1)*:000336.

Introduction: Delayed cerebral ischemia (DCI) is recognized as a relevant cause of morbidity and mortality attributed to vasospasm in individuals with subarachnoid hemorrhage (SAH). Balloon angioplasty is indicated as the therapy of choice in case of vasospasm of proximal arteries. However, some vessels are not accessible to instrumentation due to the presence of carotid tortuosity or the distal location of perforating arteries. Some studies have reported that nimodipine appears to be a safe and effective alternative for the treatment of secondary vasospasm in individuals with SAH, either in the context of angioplasty or as pharmacological monotherapy depending on angiographic and anatomic parameters. We have some experience with intra-arterial cerebral treatments.

Objectives: To describe the results of intra-arterial treatment in patients with SAH who develop DCI in a neurotraumatic ICU.

Methods: Retrospective study of SAH patients with DCI requiring intra-arterial cerebral treatment, admitted to a 10-bed neurotrauma ICU from July 2018 to June 2024. We analyzed: demographic and neurological data; aneurysm location; degree of vasospasm before and after endovascular treatment; dose and type of vasodilator; Glasgow Outcome Scale (GOS); modified Rankin (MR) at ICU discharge, at hospital discharge, and at 1 year; and other variables. Categorical variables are expressed as frequencies and percentages, and continuous variables are expressed as means and standard deviations or medians and interquartile ranges. Univariate analysis was performed. Statistical significance was set at $p < 0.05$.

Results: The characteristics of the 26 patients with DCI are shown in Table 1. They required 40 sessions of cerebral intra-arterial endovascular treatment, which are described in Table 2a and Table 2b. Of the 40 procedures performed in these 26 patients, 25 (62.5%) had severe vasospasm. The angiographic result was good in 33 (82.5%) treatments The right and left anterior cerebral arteries were most frequently treated with 29 (72.5%), followed by the right middle cerebral artery with 24 (60%). Recovery of partial hemiparesis was achieved in 14 intravascular treatments (35%), recovery of total hemiparesis in 4 (10%) cases, and recovery of aphasia in 4 cases (10%). Of the 26 patients who underwent cerebral endovascular treatment, 3 required stent, 2 of whom had previous angioplasty in both middle cerebral arteries. All 3 had stent placement in the left middle cerebral artery. They also had regular angiographic results in 2 cases. The remaining 23 patients received intra-arterial vasodilator treatment. Only 4 of them received verapamil and the other 19 received nimodipine. Of the 40 arteriographies performed, 32 used nimodipine (80%). Seven patients required more than one intra-arterial treatment (two procedures each); the median number of days between these intra-arterial treatments was 2.3 (0.5; 3).Nine patients had severe disability with a GOS $\leq$ 3 (34.6%) at ICU discharge. These patients presented significant variables: a lower percentage of permeable cisterns, lower alert patients, as well as a lower GCS at ICU admission, but with a higher SOFA, Fisher scale, modified Fisher, as well as more patients with more than 7 days of mechanical ventilation. Three patients (11.5%) died in the ICU and 2 (7.7%) at hospital discharge. At ICU discharge modified Rankin was 4 (2; 5), at hospital discharge 3 (1; 5) and at 12 months improved to 2 (0; 5).

Conclusions: Preliminary results of cerebral intra-arterial treatment in our ICU are positive in SAH patients with DCI. The angiographic result was good in 82.5% of the procedures. There was recovery of partial hemiparesis in 35% and recovery in total hemiparesis in 10%.In 88.45% of the patients intrarterial vasodilators were used, 84.6% of them with nimodipine. At ICU discharge the modified Rankin was 4, while at hospital discharge it was 3 and 2 at 12 months. At ICU discharge severe disability was 34, 6% of patients and mortality 11.5%.

Equipment fingerprint encodes surgical case identity

J. Porter[1]
[1]Anesthesia, Critical Care, and Pain Medicine, Massachusetts General Hospital, Boston, United States of America
Correspondence: J. Porter
Intensive care Medicine Experimental 2025* 13(1)*:000337.

Introduction: Case type is crucial for perioperative planning, yet traditional case descriptions rely on procedure names that are frequently ambiguous or inconsistent. State-of-the-art computational methods for handling case identity are complex machine learning approaches with significant technical overhead. I propose "equipment fingerprinting" as an intuitive alternative that conceptualizes surgical cases not by their names, but by their required equipment.
Objectives: To demonstrate how the pattern of surgical equipment used—the equipment fingerprint—can serve as an alternative method for characterizing surgical cases and understanding perioperative parameters.
Methods: We analyzed 1,568 surgical cases from Massachusetts General Hospital performed between January and September 2023. We calculated each case's equipment fingerprint, a binary vector representing the presence/absence of 121 equipment types for each case. Using simple analytical models, we tested how well these fingerprints could identify case types and predict important clinical outcomes.
Results: Equipment fingerprints revealed natural clustering of similar procedures. In a reduced-dimension space, visually distinct regions emerged for distinct case types. Within each region, similar procedures clustered together. Furthermore, by simply averaging similarly fingerprinted cases, we were able to accurately predict important case properties including EBL, duration, and ICU admission.
Conclusions: The equipment fingerprint offers a novel way to conceptualize surgical cases—not by what we call them, but by what tools they require. This approach has several practical advantages: it bypasses the ambiguities of text descriptions, provides an intuitive representation of case similarity, and could adapt in real-time as equipment needs change during surgery. For ICU teams preparing for post-surgical patients, equipment fingerprinting presents a complementary lens through which to understand incoming cases—one based on the concrete choices made by the OR team rather than potentially misleading case bookings.

Intensive care Medicine Experimental 2025* 13(1)*:000338.

Introduction: The objective of this study is to analyse ICU, hospital, and at 6-month survivals, as well as functional prognosis at 6 months of patients with ischemic stroke undergoing mechanical thrombectomy (MT) and admitted to the ICU according to the initial NIHSS score.
Methods: Retrospective cohort study (January 2015–May 2024) including patients admitted to the ICU after MT. Patients were categorized into three cohorts based on NIHSS score at admission (Group A: NIHSS < 5; Group B: NIHSS 5–25; Group C: NIHSS > 25). The following variables were compared: age, gender, comorbidities, anticoagulation, antiplatelet therapy, Rankin score at admission, IV fibrinolysis, time from symptom onset to hospital arrival (excluding wake-up strokes), hospital and ICU length of stay, ICU, hospital and six-months survivals as well as the 6-month Rankin score.
Statistical analysis: Quantitative variables are presented as mean ± SD or median (IQR25–IQR75), and categorical variables as absolute values (%). The Kruskal–Wallis test was used for quantitative variables, while Fisher's exact test or the chi-square test was applied to categorical variables, according to sample size (n < 30; n > 30).
Results: 395 patients were included: 22 in Group A, 360 in Group B, and 13 in Group C. General characteristics are summarized in Table 1.
The differences between variables are shown at Table 2.
Conclusions: MT performed in patients with NIHSS > 25 is associated with higher mortality and functional dependency, suggesting that its indication in these cases may be detrimental to the patient. A NIHSS

score < 5 is associated with better functional outcomes, lower mortality, and shorter hospital stays.

Table 1 (abstract 000338) .

Variables	Group A (n=22)	Group B (n=360)	Group C (n=13)	p
Age	65,3±15,8	71,7±12,8	71,5±14,4	n. s

Introduction: Tuberculosis (TB) remains a major public health issue worldwide, particularly in low- and middle-income countries. In 2021, an estimated 10.6 million people developed TB, with nearly 1.6 million deaths globally. Pulmonary tuberculosis with acute respiratory failure (TB-ARF) is associated with high mortality, particularly in patients requiring mechanical ventilation. Mortality rates among TB-ARF patients admitted to the ICU can reach 50–80%. Identifying risk factors associated with poor outcomes is essential for developing effective management strategies to improve survival.
Objectives: To evaluate the clinical characteristics, risk factors, and outcomes of patients with confirmed TB-ARF and identify prognostic factors associated with mortality.
Methods: This retrospective, cross-sectional study was conducted at Songkhla Provincial Hospital, a 508-bed hospital in Southern Thailand. All patients aged ≥ 15 years with a confirmed diagnosis of pulmonary tuberculosis and acute respiratory failure requiring mechanical ventilation and ICU admission between 2020 and 2024 were included. Data collected included baseline characteristics, clinical presentations, radiographic findings, laboratory results, and clinical outcomes.
Results: A total of 123 patients were included. The mean age was 55.85 ± 17.53 years, with 100 (81.3%) being male, and 52 (42.3%) aged over 60. Comorbidities were present in 70 (56.9%) patients, including diabetes (19.5%), HIV (13%), COPD (11.4%), old cerebrovascular disease with sequelae (9.8%), and heart disease (8.9%). The most common clinical presentation was dyspnea with acute respiratory failure (58.5%), followed by unconsciousness (12.2%). Over 80% of patients experienced symptoms for less than one week before admission.
Chest radiographs revealed consolidation in 27.6%, reticulonodular infiltrates in 26.8%, miliary patterns in 5.7%, and at least one radiographic finding in 38.2%. Cavitary lesions were observed in 32.5%, and pleural effusions in 27.6%. The overall hospital mortality rate was 48.0% (59 patients). The median length of hospital stay was 9 days (IQR: 4–16), and the median duration of mechanical ventilation was 5 days (IQR: 3–10).
Multivariate analysis identified low serum albumin levels (adjusted OR: 0.14; 95% CI: 0.03–0.56; p = 0.006) and higher SOFA scores at presentation (adjusted OR: 1.36; 95% CI: 1.09–1.69; p = 0.007) as significant predictors of mortality.
Table: Multivariate logistic regression for predictors of in-hospital mortality in TB-ARF patients.

Variable	Adjusted OR	95% CI	p-value
Serum Albumin (gm/dL)	0.14	0.03–0.56	0.006
SOFA score	1.36	1.09–1.69	0.007
Age	1.31	0.27–6.27	0.735
HIV	0.50	0.08–3.28	0.471
Old cerebrovascular disease with sequelae	0.70	0.04–11.27	0.805
AFB 3 +	3.75	0.67–20.97	0.132

Conclusions: Low serum albumin and high SOFA scores on admission are significant prognostic indicators of mortality in TB-ARF patients requiring ICU care. Early identification of these risk factors may guide clinical decision-making and improve patient outcomes.

Table 1 (abstract 000339) Legal picture

Table: Multivariate Logistic Regression for Predictors of In-Hospital Mortality in TB-ARF Patients

Variable	Adjusted OR	95% CI	p-value
Serum albumin	0.14	0.03–0.56	0.006
SOFA score	1.36	1.09–1.69	0.007
Age	1.31	0.27–6.27	0.735
HIV	0.50	0.08–3.28	0.471
Old cerebrovascular disease with sequelae	0.70	0.04–11.27	0.805
AFB 3+	3.75	0.67–20.97	0.132

Introduction: Endotoxin (lipopolysaccharide, LPS) is recognized as a key factor in the development of sepsis and septic shock. Clinical studies have confirmed that elevated levels of endotoxin are associated with poor clinical outcomes. Therefore, timely clearance of endotoxin is crucial to prevent excessive inflammation, cell death, and organ damage. Traditional antibiotics do not neutralize endotoxin and may even lead to increased levels of circulating endotoxin and inflammatory mediators. HD5-myr, a C-terminally myristoylated version of human α-defensin 5 (HD5), is a redesigned antimicrobial peptide (AMP). In this study, we found that HD5-myr can neutralize endotoxin and mitigate LPS-induced inflammatory cytokine release and organ injury.
Objectives: This study aims to investigate the critical role of HD5-myr in alleviating organ damage and inflammation in an LPS-induced sepsis mouse model, and to explore its underlying mechanisms.
Methods: First, qPCR, HE staining, and other methods were used to validate the anti-inflammatory effects of HD5-myr at both cellular and animal levels. Surface plasmon resonance (SPR) and immunofluorescence techniques were then employed to explore the mechanism by which HD5-myr targets and binds LPS and affects its cellular entry. Finally, we investigated the intracellular degradation pathway of the HD5-myr/LPS complex in macrophages.
Results: In vitro experiments showed that HD5-myr effectively inhibited the pro-inflammatory effects of LPS. In vivo, HD5-myr improved survival rates and reduced lung injury in LPS-induced septic mice. SPR analysis demonstrated a strong binding affinity between HD5-myr and LPS. Immunofluorescence studies revealed that HD5-myr binds to LPS, forming HD5-myr/LPS complexes, which are more readily engulfed by macrophages through F-actin-dependent phagocytosis. When the disulfide bonds in HD5-myr were disrupted, its cellular uptake capacity was significantly diminished. Furthermore, immunofluorescence and Western blot analyses showed that HD5-myr/LPS complexes promoted the expression of acyloxyacyl hydrolase (AOAH) in macrophages, facilitating the intracellular degradation of LPS.
Conclusions: This study demonstrates that HD5-myr binds to LPS, forming HD5-myr/LPS complexes that are rapidly captured and phagocytosed by macrophages via an F-actin-dependent pathway, activating AOAH expression and promoting intracellular degradation of LPS. The disulfide bonds in HD5-myr play a critical role in this process. These findings highlight the potential of HD5-myr as a novel nanobiotic that not only exhibits antimicrobial activity, but also facilitates endotoxin clearance.

Intensive care Medicine Experimental 2025 **13(1)**:*000341*.

Introduction: Volatile sedatives are increasingly used for sedation in critically ill patients undergoing invasive mechanical ventilation. Although various randomized controlled trials (RCTs) and observational studies have been conducted to compare volatile to intravenous sedation, its safety and efficacy remain controversial.
Objectives: This meta-analysis aimed to evaluate the safety and efficacy of volatile sedatives compared to intravenous agents in critically ill patients receiving mechanical ventilation.
Methods: A systematic search was conducted across PubMed, EMBASE, Cochrane Central Register of Controlled Trials, and Web of Science databases for studies published up to March 2025. RCTs, prospective studies, and observational studies that compared volatile sedation (isoflurane, sevoflurane, or desflurane) with intravenous sedation (propofol or midazolam) in patients admitted to intensive care unit (ICU) for mechanical ventilation were included for the analysis. Eligible studies included adults aged ≥ 18 years, invasive mechanical ventilation, volatile or intravenous sedative use, and at least one outcome for interest: incidence of delirium, mortality, ICU length of stay, and the duration of mechanical ventilation.
Results: Out of 3,181 identified publications, fourteen studies (n = 2,436; 8 RCTs, 1 prospective cohort study, and 5 observational studies including 3 propensity-matched) were included in the analysis (Fig. 1). Compared to intravenous sedation, volatile sedation was associated with a significantly lower incidence of delirium (risk ratio [RR] 0.68; 95% confidence interval [CI] 0.53 to 0.88), reduced ICU length of stay (mean difference -0.86 days; 95% CI -1.45 to -0.26), and shorter duration of mechanical ventilation (mean difference -29.26 h; 95% CI -37.66 to -20.86) (Fig. 2). No significant difference was observed in mortality between the two groups (RR 0.99; 95% CI 0.89 to 1.10).
Conclusions: Volatile sedation in critically ill patients was associated with a lower incidence of delirium and reductions in both ICU length of stay and the duration of mechanical ventilation compared to intravenous sedation. Further large-scale, high-quality randomized trials are warranted to confirm these benefits and define optimal patient selection for volatile sedation in critical care settings. (PROSPERO registry number: CRD420251024298).

Intensive care Medicine Experimental 2025* 13(1)*:000343.

Introduction: Accurately assessing depth of sedation in mechanically ventilated critically ill patients in ICU remains challenging. Current methods, such as the Richmond Agitation-Sedation Scale (RASS) and processed electroencephalography (EEG, e.g., BIS), have limitations in reliability and applicability [1]. Ocular microtremor (OMT), a nanoscale, involuntary eye movement driven by brainstem activity, specifically the reticular activating system (RAS), has been proposed as a potential biomarker of sedation depth [2]. Current acquisition techniques are invasive and thus unsuitable for routine clinical use [2]. We investigated whether non-invasive electrooculography (EOG), using electrodes located around the eyes, can be used to acquire OMT. Induction of general anaesthesia was used as an intervention model for RAS activation.
Objectives: To ascertain whether OMT can be acquired using EOG using elective surgical patients undergoing general anaesthesia as a model.
Methods: We conducted a prospective observational study in a University Hospital. After achieving consent, patients receiving general anaesthesia for elective surgery were included. Electrooculography (EOG) electrodes were placed peri-ocularly before undergoing anaesthesia. Anaesthetic depth was recorded concurrently using calculated effect site concentration of propofol. OMT frequency and amplitude were extracted using signal processing techniques, and correlations with sedation depth analysed.
Results: Figure 1 demonstrates the signal processing technique and results from a patient undergoing anaesthesia. Results were reproducible across other patients. Preliminary data suggest good correlation between depth of anaesthesia and signal processing results including power-spectral density and subsequent ocular microtremor.
Conclusions: OMT can be acquired using EOG with strong correlates to depth of anaesthesia. Future work is aimed at assessing EOG in critically ill ventilated patients to ascertain the technique's performance characteristics.

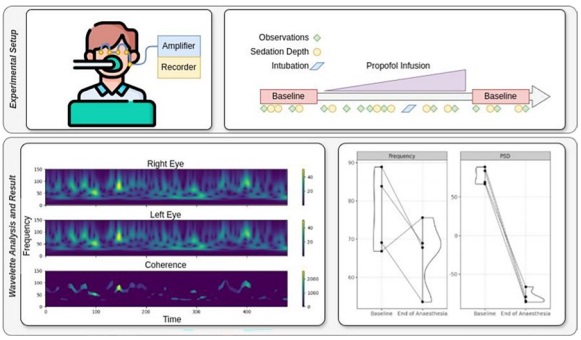

Illustration showing the apparatus, signal processing, and proof of concept results for the use of electro-oculography for the detection of ocular microtremor. Two-channel bipolar EOG is measured continuously during propofol anaesthesia. Signal processing techniques include wavelet coherence analysis with a 480 Hz window resolution. Averaged frequency and power spectral density are computed per window and plotted over time resulting in a decrement of frequency and power spectral density during induction.

Multi-channel vital waveform 1D transformer-based alarm classification model for ventricular tachycardia in the ICU

J. Kwon[1]; S. Na[2]; K. Jeong Min[2]

Intensive care Medicine Experimental 2025* 13(1):*000346.

Introduction: False alarms triggered by electrocardiographic (ECG) monitoring systems remain a significant challenge in intensive care units (ICUs). Although ECG signals serve as a critical modality for real-time cardiac monitoring of ICU patients, current bedside monitors frequently raise alarms in response to deviations from normal ECG patterns. A substantial proportion of these alarms, however, are false positives, contributing to alarm fatigue and creating a distracting, and potentially unsafe, clinical environment[1]. Among the various arrhythmias, ventricular tachycardia (VT) is particularly difficult to detect accurately due to the challenge of simultaneously achieving high sensitivity and positive predictive value[2,3].

Objectives: In this study, we propose a 1D Transformer-based deep learning model that classifies true and false VT alarms using multi-channel vital waveform data from the 10 s preceding each alarm event. By leveraging the self-attention mechanism, the model not only improves alarm precision, but also provides interpretability by highlighting which segments of the input signals contributed most to the classification decision. This approach enhances both the accuracy and transparency of alarm validation.
Methods: A total of 1,748 cases were extracted from PhysioNet's VTaC (ventricular tachycardia alarms from ICU monitors) dataset[4], which provides electrocardiographic (ECG) Lead II, photoplethysmogram (PPG), and arterial blood pressure (ABP) waveforms. Each case includes six minutes of data—five minutes preceding the alarm and one minute following it—but only the 10-s segment immediately prior to the alarm was utilized in this study (Fig. 1A). To preserve essential signal features while minimizing computational complexity, this 10-s segment was downsampled to 125 Hz. The proposed lightweight one-dimensional (1D) Transformer model comprises four Transformer encoder layers. Each waveform was divided into overlapping two-second patches at one-second strides. The model was trained to determine whether a VT alarm was true or false (Fig. 1B). Performance was tested using individual waveforms (Lead II, PPG, ABP) as well as pairs and triplets of these waveforms (Lead II + PPG, Lead II + ABP, PPG + ABP, Lead II + PPG + ABP).
Results: In the results, a clear trend emerged wherein incorporating additional waveforms led to improvements in accuracy, precision, recall, and F1-score. Notably, the highest performance was achieved when all three waveforms were used simultaneously, yielding an accuracy of 85.6% and an F1-score exceeding 0.90 (Table 1.). Furthermore, examination of the attention maps revealed distinct behaviors between single-waveform and multi-waveform models (Fig. 1C). Whereas the single-waveform approach relies solely on one signal to differentiate true from false alarms, the multi-waveform model leverages complementary information across two or more signals. This integration of cross-sensor data helps refine the decision process and provides a clearer basis for discriminating between alarm types, as the attention mechanism collectively focuses on salient features from each waveform (Fig. 1D).

Table 1 (abstract 000346) Performance metrics

Models	Accuracy	Precision	Recall	F1-Score
Lead II	0.767	0.861	0.813	0.836
PPG	0.742	0.846	0.784	0.814
ABP	0.781	0.866	0.816	0.841
Lead II, PPG	0.794	0.877	0.823	0.848
Lead II, ABP	0.837	0.892	0.867	0.871
PPG, ABP	0.811	0.883	0.860	0.871
Lead II, ABP, PPG	0.856	0.914	0.889	0.901

Conclusions: This finding underscores the value of complementary information across sensors in more effectively filtering out false alarms. Furthermore, visualizing the attention maps revealed that single-waveform models tended to focus narrowly on distortion-dominated regions, whereas the multi-waveform model leveraged information from multiple sensors to distinguish more accurately between sensor malfunctions and genuine changes in waveform. The proposed algorithm has the potential to classify VT alarms in the ICU with attention information of model in waveform, reducing fatigue of medical staff.

***Intensive care Medicine Experimental 2025* 13(1):*000347*.**

Introduction: This study evaluated diaphragm function using ultrasonography in Guillain–Barre syndrome (GBS) patients in the neurointensive care unit (NICU).
Objectives: The primary objective was to measure the diaphragmatic excursion (DE), diaphragmatic thickness fraction (DTF), peak contraction velocity (Vc) of diaphragm by ultrasound in patients with GBS at NICU admission and observe their association with discharge from NICU. Secondary objective was to observe the weekly changes of the diaphragmatic parameters until the patient was discharged or up to a maximum of 8 weeks.
Methods: After the ethical approval, all patients aged 18 to 70 years fulfilling the National Institute of Neurological Disorders and Stroke criteria for GBS and Brighton level of certainty of diagnosis of one or two and requiring NICU admission were included. Written consent was obtained from the patient's next of kin. Patients with refusal of consent, cardiac, renal or liver failure, preexisting uni- or bilateral diaphragmatic paralysis, and severe sepsis were excluded. All admitted patients were managed as per the standard guidelines. We recorded the DE, DTF and peak Vc of diaphragm by ultrasound on the 1st day of NICU admission and weekly once until the patients were discharged or for a maximum of 8 weeks, whichever was earlier. In patients requiring mechanical ventilation (MV), all assessments were done in the semi-recumbent position, in pressure support ventilation with a pressure support of 8–10 cm H2O and positive end-expiratory pressure of 0–5 cm H2O. The patients not requiring MV were monitored for diaphragmatic parameters at the predefined times. We defined early discharge as discharge within 3 weeks of NICU admission.
Results: We included 30 patients (17 male and 13 female) with a median (interquartile range) age of 44.5 (32.25–58.75) years and Erasmus GBS Respiratory Insufficiency Score of 4 (3–5). Out of the 30 patients, 6 did not need MV. The median duration of MV (n = 24) was 13 (10.25–26.50) days. Eleven out of the 30 patients (36.6%) had early discharge, while 18 (60%), had delayed discharge from NICU. Younger patients (32.5 vs 48 years; p = 0.04) and a higher proportion of females [8 (66.6%) vs 5 (29.4%); p = 0.018] were discharged earlier. In the early discharge group, the baseline peak Vc (cm/s) was significantly higher [4.04 (3.26–5.02) vs 3.03 (2.8–3.2); p = 0.024], the baseline DTF (%) was higher [36.67(15.44–51.39) vs 19.23 (11.1–33.3); p = 0.24] than those who had late discharge. Similarly, the baseline DE (mm) was higher in patients discharged earlier [16.55 (13.93–18.20) vs 12.5 (9–16); p = 0.08]. (Table-1) No differences were found in the weekly trend of the diaphragmatic parameters between the early and late discharge group of patients. (Figs. 1,2).
Conclusions: The peak Vc of the diaphragm at baseline was higher in GBS patients who were discharged early from NICU. Although the DE and DTF were also higher, the difference was not statistically significant.

Table 1 (abstract 000347) Comparison of baseline variables in patients with discharge < 3 weeks and beyond 3 weeks

Parameters	Early discharge (<3 weeks)		P-value
	Yes (12)	No (17)	
Age (years)	**32.5 (27-51.25)**	**48 (37-65)**	**0.013**
Female	**8 (66.6%)**	**5 (29.4%)**	**0.047**
EGRIS (High grade)	5 (41.6%)	7 (41.7%)	0.883
Baseline Excursion (mm)	16.55 (13.93-18.20)	12.5 (9-16)	0.08
Baseline DTF (%)	36.67(15.44-51.39)	19.23 (11.1-33.3)	0.24

Nonagenarians in the ICU: defying expectations

R. Fumis[1]; F. Ramos,[1]; M. Santos,[1]; G. Teixeira,[1]; E. Queiroz,[1]; L. Pastore Junior[2]; ELV. Costa.[3]
[1]Intensive Care Unit, Hospital Sirio Libanes, São Paulo, Brazil; [2]Icu, Hospital Sirio Libanes, São Paulo, Brazil; [3]Research and education institute, Hospital Sirio Libanes, São Paulo, Brazil.

***Intensive care Medicine Experimental 2025* 13(1):*000350*.**

Introduction: With increasing life expectancy, the admission of very elderly patients (≥ 90 years) to intensive care units (ICUs) is becoming more frequent. However, despite their growing numbers, data on the outcomes and complications of nonagenarians and centenarians in the ICU remain scarce.
Objectives: To describe the clinical characteristics, ICU interventions, and outcomes of nonagenarians (90–99 years) and centenarians (≥ 100 years) admitted to a tertiary ICU.

Methods: This retrospective cohort study included all ICU admissions from January 2022 to December 2024 in a 30-bed tertiary ICU at Hospital Sírio-Libanês, São Paulo, Brazil. We used data from an administrative, electronic database of patients admitted to the ICU (Epimed Solutions®, Rio de Janeiro, Brazil).
Results: After excluding readmissions, a total of 757 unique patients were included in the study. Table 1 provides a detailed overview of patient characteristics at ICU admission. Notably, these patients were frequently bedridden and had a diagnosis of dementia in over 40% of cases. ICU interventions, including mechanical ventilation, vasopressor use, and renal replacement therapy, were frequent. Mortality and the standardized mortality ratio (SMR) were relatively low (Table 2). This could imply that higher mortality rates found in other studies in this age group could be the result of self-fulling prophecies. While functional dependence (being bedridden) was associated with lower survival (Fig. 1), dementia was not (Fig. 2).

Table 1 (abstract 000350) Baseline characteristics

Age catsegory (years)	90–99 (n = 727)	≥ 100 (n = 30)	P value
Age (mean (SD))	93.1(2.5)	102.0(1.9)	-
SAPS3 (median [IQR])	56[50,61]	57 [52,64]	0.221
Bedridden	210(29)	10(33)	0.257
Charlson Score (median [IQR])	2[1,3]	2[1,2]	0.496
Female Sex, n (%)	439(60)	19(63)	0.894
Medical admission (%)	617(85)	27(90)	0.542
Dementia, n (%)	298(41)	17(57)	0.129

Table 2 (abstract 000350) Outcomes

Age category (years)	90–99 (n = 727)	≥ 100 (n = 30)	P value
ICU mortality, n (%)	44(6.1)	3(10.0)	0.623
Hospital mortality, n (%)	123(17.0)	7(23.3)	0.515
SMR	0.6[0.5,0.7]	0.7[0.4,1.4]	0.605
ICU LOS	2[1–4]	2 [1–3]	0.274
Hospital length of stay	12[8–21]	10[6–19]	0.219
Mechanical ventilation (%)	58(8)	5(17)	0.177
Mechanical ventilation duration	3[1–6]	6 [5–7]	0.273
Vasopressors (%)	187(26)	9(30)	0.755
Renal replacement therapy (%)	17(2.3)	0 (0)	0.827
Decision to limit treatment	164(23)	15(50)	0.003

Conclusions: Our findings suggest that nonagenarians and centenarians can achieve relatively low ICU and hospital mortality rates, which challenge the notion that extreme age alone should guide ICU admission and treatment decisions. However, optimizing the decision to admit these patients to the ICU requires considerations beyond hospital survival. Long-term data on functional independence and quality of life remain crucial to fully assess the benefits and implications of ICU care in this population.

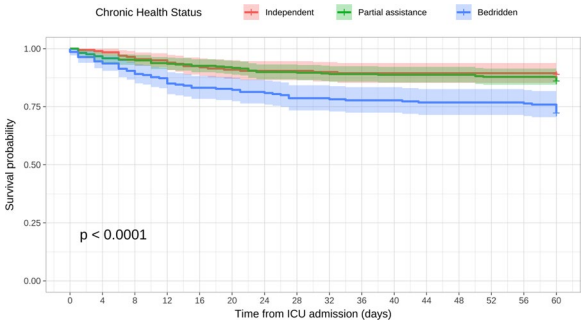

Fig. 1 (abstract 000350) Kaplan–Meier estimates of all-cause survival rate up to 60 days. Overall survival was significantly different in previously bedridden patients (blue) as compared to patients who were independent (red) or who required partial assistance (green) (logrank p < 0.0001)

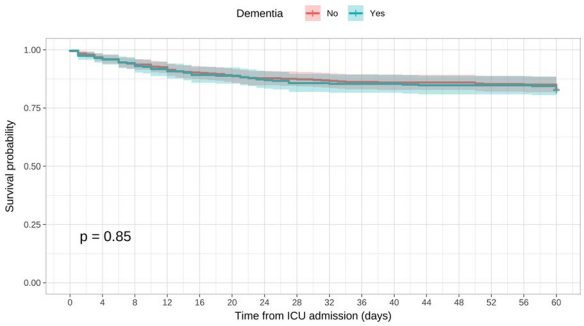

Fig. 2 (abstract 000350) Kaplan–Meier estimates of all-cause survival rate up to 60 days. Overall survival was not significantly different in patients previously diagnosed with dementia (blue) as compared to patients without dementia (red) (logrank p < 0.085)

Septic shock and IL-6: looking for a new mortality biomarker

P. Nicolás-Morales[1]; L. Chiscano[1]; RS. Adolf[1]; I. Bajana[1]; J. Bastidas[1]; N. Larrosa[2]; M. Hernandez-Gonzalez[3]; R. Ferrer[1]; JC. Ruiz-Rodríguez[1]

Intensive care Medicine Experimental 2025* 13(1):*000352.

Introduction: Interleukin-6 (IL-6) plays a key pro-inflammatory role in sepsis and has been consistently linked to patient outcomes. However, data on the phenotypic characterization of patients with extremely high hypercytokinemia, particularly those with refractory septic shock, remain scarce. Moreover, the plasma IL-6 concentration threshold associated with mortality has not been clearly established, limiting its potential role in guiding decision-making for cytokine hemoadsorption therapies.

Objectives: Analyze the relationship between IL-6 levels and mortality in patients with septic shock and severe sepsis, identifying plasma concentration thresholds above which the incidence of mortality becomes clinically relevant.
Methods: Single-center, observational, retrospective study. Inclusion criteria comprised patients diagnosed with septic shock or severe sepsis, in whom the Sepsis Code was activated at Vall d'Hebron University Hospital between July 2018 and December 2024. The diagnosis of sepsis was based on Sepsis-2 criteria.
Interleukin-6 (IL-6) levels were prospectively measured within the first 12 h after the onset of shock, using a peripheral blood sample and the ELLA platform (ProteinSimple, California, USA).
Statistical analysis included the chi-square test to assess the independence between categorical variables and the Shapiro–Wilk test to evaluate the normality of continuous variables. To estimate mortality probability, cumulative conditional relative frequencies were analyzed across increasing IL-6 levels. A reference threshold was identified at the IL-6 concentration above which the cumulative mortality frequency exceeded 50%. Mortality probability was defined based on the observed frequency percentage at each IL-6 interval.
A receiver operating characteristic (ROC) curve analysis was conducted to assess the sensitivity and specificity of the identified IL-6 cutoff. Additionally, the odds ratio (OR) was calculated to estimate the relative risk of mortality between groups stratified by this threshold.
All statistical analyses were conducted using R software (version 4.1.0). The study was approved by the Clinical Research Ethics Committee of our institution (PR(AG)336/2016).
Results: Included 1669 patients (Table 1) [SOFA 6 (6), APACHE II 20 (14), septic cardiomyopathy 193 (11.7%) mechanical ventilation 493 (29.5%)], of whom 1150 (69%) survived and 519 (31%) died. In living patients, the mean IL6 was 16,266 (53,219) pg/ml. In deceased patients, it was 75,978 (237,531) pg/ml. IL-6 analysis shows that a value of 14,930 (95% CI: 8640–22289) pg/ml is the cutoff point at which the probability of mortality exceeds that of survival in patients [E = 0.85, S = 0.35, OR 2.87 (95% CI: 2.15, 3.55)] (Fig. 1). For values above 74,238 (70,059–83708) pg/ml, the probability of mortality exceeds 60%. For valuesabove 178,693 (168,705–182355) pg/ml, the probability of mortality reaches 70%. From an IL-6 level ≥ 500,000 pg/ml, 100% of the patients studied were observed to die. When analyzing the 15,000 pg/mL quantiles, the greatest change in clinical outcomes was found when comparing patients with IL-6 levels < 15,000 pg/mL versus those with levels ≥ 15,000 pg/mL. Further stratification using 1,000 pg/mL intervals within the first 30 quantiles revealed the greatest change in the likelihood of mortality for IL-6 levels between 0.1 and 15,000 pg/mL (Fig. 2). Multivariate analysis shows that SOFA score (OR: 3.00, 95% CI: 2.28–4.04, sd: 0.146), baseline lactate (OR: 1.67, 95% CI: 1.32–2.14, sd: 0.123), presence of acute kidney injury (AKI) (OR: 3.89, 95% CI: 1.92–8.35) are factors related with mortality.
Conclusions: Patients with septic shock and multiorgan dysfunction, extremely high levels of IL-6 are associated with very high mortality. In our cohort of patients with septic shock and severe sepsis, a plasma IL-6 concentration of 14,930 pg/mL represents a critical cutoff point beyond which the probability of mortality exceeds that of survival.

Intensive care Medicine Experimental 2025* 13(1)*:000354.

Introduction: Participant identification and enrolment in time-sensitive clinical trials in critical care can be challenging due to various factors, with potentially eligible participants missing out on the opportunity to participate in research. Previous studies have described criteria-based technologies to improve recruitment rates and time-to-identification [1–3]. We designed an easy-to-deploy software solution embedded in a widely used electronic patient record (EPR) with the aim of improving participant identification for time-sensitive interventions.
Methods: As part of a prospective observational cohort study, we developed an automated research notification (ARN) system embedded into the EPR (Epic Systems Corporation), which generates a real-time mobile alert for the research team when triggered by an event [4]. Patients were eligible if they were started on one of two antimicrobials and admitted to the intensive care unit with a severe respiratory infection. For each potentially eligible participant recorded on the screening log, we noted the time elapsed from ARN notification generation (time of antimicrobial prescription) to eligibility assessment by the principal investigator. We compared this strategy ('automated research notifications') with a simulated usual strategy using twice-daily static reports at 9.00 and 14.00 from Monday to Friday ('intermittent screening'), assessing the proportion of participants that could be recruited within one hour (i.e. time of first dose of antimicrobial). We calculated median times with interquartile ranges (IQR). Time-to-event analysis using Cox proportional hazards was undertaken to compare the two strategies. A Kaplan–Meier plot was generated, inverting the Y-axis to correlate with the direction of outcome. The clinical study received a favourable opinion from the Yorkshire & The Humber—Leeds East Research Ethics Committee and the Health Research Authority (23/YH/0203). Study registration: NCT05971979.
Results: Between 12 December 2023 and 21 June 2024, we identified 276 notifications, of which 166 were during regular working hours. Thirty-two notifications translated to study enrolment, resulting in an 11.6% enrolment rate. The most common reason for ineligibility was lack of laboratory capacity at time of assessment and a non-respiratory infection in 174 (69%) and 47 (19%) non-enrolled individuals, respectively. The median (IQR) time to eligibility assessment was 19 (9–48) min for enrolled participants (n = 32), and 32 (13–71) min for non-enrolled individuals (n = 244), with 199 (72%) assessed for eligibility within 1 h of antimicrobial prescription. Among the 166 regular working hour notifications used in the simulated comparison, median (IQR) times for assessment were 0.5 (0.2–1.2) hours and 4.6 (3.1–14.9) hours for 'ARN' and 'Intermittent screening', respectively (Fig. 1). Time-to-event analysis using the Cox proportional hazards model demonstrated a significant difference between ARN screening and simulated intermittent screening ($p < 0.001$). Time of day distributions of ARNs are presented in Fig. 2.
Conclusions: Automated research notifications lead to rapid identification of potentially eligible trial participants where eligibility criteria are tied to EPR events. ARN implementation is a simple, low-cost intervention. The high sensitivity requires continued input from the research team. Expansion of ARNs to studies with narrow eligibility windows may improve recruitment and present cost savings in investigator and research nurse time. Future research should investigate the real-world effectiveness of automated research notifications.

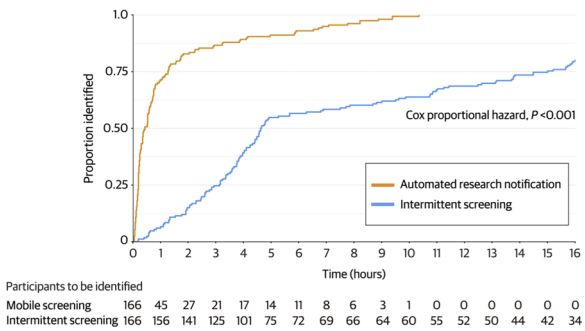

Fig. 1 (abstract 000354) Kaplan–Meier plot of time from antimicrobial prescription to screening (n = 166), comparing automated research notifications as assessed and recorded by the principal investigator (yellow line) and a simulated time assuming twice daily report generation used for screening (blue line). Time recorded is time from research notification to eligibility assessment. For the simulated comparison, the time from research notification generation to the next available report time (Monday to Friday 09:00 or 14:00) is calculated. Notifications generated between Friday 16:00 and the following Monday 08:00 were excluded from analysis

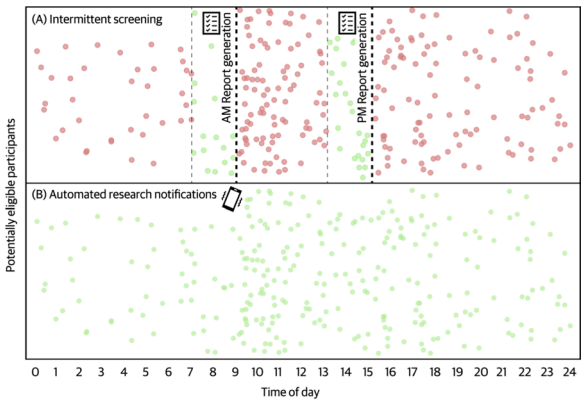

Fig. 2 (abstract 000354) Event-based participant discovery for time-sensitive trials. A comparison between the two workflows is demonstrated. A trial with a two-hour eligibility window (e.g. the participant needs to be enrolled within two hours of a given event that triggers a notification) is used as an example. Workflow A demonstrates intermittent screening, where reports are generated twice a day, listing all potentially eligible patients cross-sectionally at a given point in time. Workflow B represents automated research notifications (ARNs). Green dots represent participants identified within the 2-h window. Red dots represent identified participants who are outside of the 2-h eligibility window at the time of identification. Datapoints are participants identified as potentially eligible for recruitment in the study (n = 276) during the 6-month recruitment period using an automated research notification designed to alert at the time of prescription of piperacillin/tazobactam or meropenem for patients admitted to the intensive care unit. Notably, a large proportion of potentially eligible participants (n = 95, 34%) are missed between the two reporting times during normal working hours (9:00 to 13:00) in workflow A only. Other factors (e.g. time of day, staffing, availability of specialist equipment) will affect the real-world recruitment potential of a given potential participant

Intensive care Medicine Experimental 2025* 13(1):*000355.

Introduction: Consistently, females have shown worse outcomes and survival following cardiac arrest compared with age-matched males.1,2 Following cardiac arrest, many patients experience hypoxic ischemic brain injury (HIBI), a result of the global ischemia and reperfusion from arrest and resuscitation. Despite this knowledge, little is known about how biological sex influences the underlying pathophysiology that contributes to HIBI and the ensuing treatment, recovery, and survival.
Objectives: The aim of this study was to investigate how biological sex interacts with the cerebrovascular pathophysiology of HIBI.
Methods: We conducted a post hoc analysis of a prospective observational study in 43 HIBI patients with invasive neuromonitoring following cardiac arrest. Invasive multimodal neuromonitoring consisted of brain tissue oxygen tension (PbtO2), intracranial pressure (ICP), cerebral perfusion pressure (CPP), and jugular venous bulb oxygen saturation (SjvO2). Data were recorded in real time at 300 Hz into ICM + monitoring software (Cambridge University Enterprises) over 24 h following return of spontaneous circulation (ROSC). Demographics were compared with Mann–Whitney tests and physiological outcomes were explored with linear mixed models and adjusted for age and time to ROSC.
Results: There were no differences in age ($p = 0.433$) and time to ROSC ($p = 0.473$) between males and females (31 M/12F). ICP and CPP over the first 24 h following ROSC were not influenced by sex (ICP, $p = 0.891$; CPP, $p = 0.670$). PbtO2 was not associated with sex ($p = 0.517$). However, PbtO2 was related to survival ($p = 0.007$) and Cerebral Performance Category scores ($p = 0.004$). When stratified by sex, PbtO2 was related to survival in males ($p = 0.004$), but not females ($p = 0.389$). Similarly, PbtO2 and Cerebral Performance Category scores were associated in males ($p = 0.010$) but not females ($p = 0.269$). Finally, SjvO2 was not related to sex ($p = 0.675$; Fig. 3), but was related to age ($p = 0.004$) and time to ROSC ($p = 0.026$). When dichotomized by sex, these relationships only existed in females, but not males.
Conclusions: There are important interactions between sex, age, and outcomes with the underlying cerebrovascular physiology in HIBI patients. These findings suggest PbtO2 is related to survival and Cerebral Performance Category scores in males but not females. Thus, worsened outcomes in females appear to be related to mechanisms other than tissue oxygenation. These findings have important implications for bettering treatment of HIBI and improving outcomes.

Intensive care Medicine Experimental 2025* 13(1):*000356.

Introduction: Extracorporeal membrane oxygenation (ECMO) is used in trauma cases with severe cardiopulmonary failure, showing survival rates of 66–70% (1–2). ECMO application in blast-related trauma, common in warfare and terrorist incidents, is scarcely documented. Such injuries, often from explosions and toxic inhalations, can rapidly lead to severe lung damage (3), with primary blast lung injury (PBLI)

occurring in up to 80% of fatalities in enclosed-space explosions (4). Limited medical resources in combat zones make early ECMO use challenging, with its deployment generally restricted to managing later-stage respiratory complications (5).

Objectives: This study assesses ECMO's role in combat-induced severe lung injuries.

Methods: A retrospective analysis was conducted on all combat trauma patients requiring ECMO support for respiratory failure from October 2023 to October 2024 across four trauma-level hospitals.

Results: Twenty-five patients (median age 20; IQR 20–24) were included, with injuries classified as blast injuries (n = 5), smoke/toxic inhalation (n = 9), other causes (n = 5), and multi-trauma-related ARDS (n = 6). No significant differences were observed among groups in age, evacuation method (airlifted vs. ground), or initial respiratory support (p = 0.29, p = 0.63, p = 0.42). The median Injury Severity Score (ISS) was 29 (IQR 25–50), highest in the blast injury group (50) and lowest in the inhalation injury group (25). The median Sequential Organ Failure Assessment (SOFA) score at admission was 6 (IQR 4–10).

All patients received veno-venous extracorporeal membrane oxygenation (VV-ECMO). Anticoagulation was administered to 13 patients (52%), including all inhalation injury patients, while only one patient (20%) in the blast injury group received anticoagulation due to a high prevalence of pulmonary hemorrhage. ECMO was initiated at a median of four days (IQR 3–5) in the multi-trauma group, whereas the blast and inhalation injury groups had a median initiation time of one day (IQR 0–4), often requiring ECMO within hours. The median ECMO duration was 13 days (IQR 6–15), with an overall survival rate of 85% (n = 20). Notably, all patients in the blast and inhalation injury groups survived.

Conclusions: ECMO support for combat trauma respiratory failure cases has survival rate that resembles non-combat related. Blast and smoke-related lung injury may necessitate a very early intervention, sometimes within hours post-injury, but when available is associated with high survival rates.

Table 1 (abstract 000356) Patient characteristics in combat-related lung injuries requiring ECMO

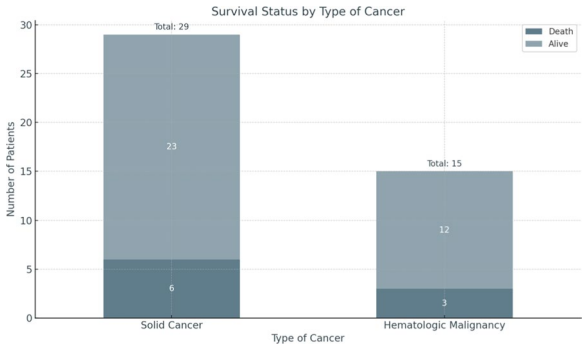
Intensive care Medicine Experimental 2025* 13(1)*:000357.

Introduction: Critically ill patients with underlying malignancies are at high risk of early mortality due to complex pathophysiological processes, including anemia and systemic inflammation. Hemoglobin (Hb) and C-reactive protein (CRP) are routinely available biomarkers that may serve prognostic purposes.

Objectives: This study aimed to evaluate the association of Hb and CRP levels with 28-day mortality in cancer patients admitted to a medical intensive care unit (ICU).



Methods: A prospective study was conducted in a single-center ICU between November 2023 and March 2024. Adult patients with active cancer requiring ICU admission were enrolled. Demographic characteristics, clinical diagnoses, laboratory parameters, and illness severity scores (APACHE II) were collected at admission. The primary outcome was 28-day all-cause mortality. Based on pre-study power analysis (α = 0.05, 80% power), 42 participants were required to detect a clinically significant difference in mortality between CRP-stratified groups. Univariate and multivariate logistic regression analyses were performed to identify independent predictors of mortality.

Results: A total of 44 critically ill cancer patients were enrolled, with a mean age of 60.1 ± 13.0 years, a mean APACHE II score of 25.98 ± 7.64, and an average ICU length of stay of 4.64 ± 3.97 days. Of these, 29 patients (65.9%) had solid tumors, while 15 patients (34.1%) had hematologic malignancies. The most frequent clinical conditions were neutropenic fever (63.6%), pneumonia (31.8%), and systemic inflammatory response syndrome (SIRS) (6.8%). The 28-day all-cause mortality rate was 20.45%.

Compared to survivors, non-survivors had lower mean hemoglobin levels (7.8 vs. 8.9 g/dL), higher APACHE II scores (28 vs. 24), and higher platelet counts (800,000 vs. 246,000 cells/μL); however, these differences did not reach statistical significance.

Multivariate logistic regression identified severe anemia (Hb < 7 g/dL) as an independent predictor of 28-day mortality (OR: 49.84; 95% CI: 1.63–1527.24; p = 0.025). Neither elevated C-reactive protein levels (> 75 mg/L) (OR: 0.28; p = 0.355) nor hemoglobin increase per 2 g/dL (OR: 1.64; p = 0.352) were significantly associated with mortality.

Conclusions: Severe anemia at ICU admission is significantly associated with increased 28-day mortality in critically ill cancer patients. This finding highlights the prognostic utility of Hb and the potential value of early correction of anemia. Although CRP did not emerge as a significant predictor in this cohort, further research is warranted to assess the broader role of inflammatory markers in this population. Larger multicenter studies are needed to validate these findings and guide targeted interventions.

Comparison of survival status among patients with solid cancer and hematologic malignancy.

Utility of the nucleated red blood cell count (NRBC) in predicting inpatient cardiac arrest

R. Sullivan[1]; A. Green[1]
[1]Critical Care Medicine, Cooper University Hospital, Camden, United States of America
Correspondence: R. Sullivan
Intensive care Medicine Experimental 2025* 13(1)*:000358.

Introduction: In-hospital cardiac arrest (IHCA) carries a significant morbidity and mortality burden. Despite efforts such as rapid response teams and early warning systems, IHCA incidence continues to rise [1][2]. Identifying at-risk patients on general medical/surgical wards remains a challenge.
The nucleated red blood cell (NRBC) count, which measures circulating RBCs with nuclei [3] is considered abnormal when exceeding 1% and has been studied as a biomarker in critically ill patients [4], ARDS [5], and cardiac surgery [6]. However, its role in predicting IHCA and the timing of its elevation prior to IHCA have not been previously investigated.
Objectives: This study aimed to determine whether NRBCs could serve as a biomarker for predicting IHCA in adult general ward patients. A secondary objective was to assess the lead time between NRBC positivity and cardiac arrest to evaluate its potential as an early warning tool.
Methods: A five-year retrospective study (2019–2024) at a tertiary academic medical center reviewed all IHCA cases on general wards. Patients were identified via "Code Summary" notes and excluded if the IHCA occurred in ICUs, the OR, or the ED. IHCA was defined as time zero. NRBC values were assessed retrospectively across the hospitalization for time of first positive value (> 1%) and maximum level. Data collected included demographics, admission diagnosis, return of spontaneous circulation (ROSC), survival, and NRBC trends. A comparison group was made by data abstraction, analyzing all patients who were admitted to a non-critical care unit and did not have IHCA over the same time period; their charts were evaluated for NRBC presence.
Results: Among 231 general ward IHCA patients, 77 (33.3%) had a positive NRBC before arrest. In contrast, 1,461 of 44,403 non-IHCA patients (3.3%) had a positive NRBC. Sensitivity and specificity of NRBC for predicting IHCA were 33.3% and 96.7%, respectively. positive predictive value (PPV) was 5.0% and negative predictive value (NPV) was 99.6%. The positive likelihood ratio (LR +) was 10.0, indicating a ten-fold increased IHCA risk with a positive NRBC.
Among IHCA patients with positive NRBCs, the average maximum pre-arrest NRBC count was 7.6% (range: 1–63.7%). The median time from first NRBC positivity to IHCA was 20 h.
Conclusions: Among hospitalized patients who have a cardiac arrest, 33% have a positive NRBC count prior to their arrest. NRBC count is highly specific but insensitive for IHCA prediction. A negative NRBC does not rule out risk, however the presence of a positive NRBC warrants a close evaluation of the patient and consideration for escalation of care. With a median 20-h lead time, NRBC monitoring may help identify patients in decline who do not yet meet other ICU criteria. Further research is needed to explore relationships between NRBC trends, ROSC, survival, and patient subgroups most susceptible to NRBC elevation.

Table 1 (abstract 000358) Characteristics of patients with a positive NRBC count prior to cardiac arrest on the general wards

Variable	% (n)
Male	55.8% (43)
Female	44.1% (34)
Mean age	63 [26-93]
HTN	59% (46)
CAD	33% (26)
DM	28% (22)
COPD	13% (10)
ESRD	12% (9)
Malignancy	20% (16)

Table 2 (abstract 000358) Frequency of positive NRBC count and IHCA among patients admitted to the general wards

	Cardiac Arrest	No Cardiac Arrest	Total Patients
Positive NRBC	77 (TP)	1461 (FP)	1538
Negative NRBC	154 (FN)	42942 (TN)	43,096
Total patients	231	44,403	

Table 3 (abstract 000358) Test characteristics of the NRBC count in predicting IHCA among adult patients admitted to general wards

Sensitivity	33.3%
Specificity	96.7%
Positive Predictive Value	5.0%
Negative Predictive Value	99.6%
LR+	10.0
LR-	.68

Table 4 (abstract 000358) Features of NRBC results for patients who had a IHCA and positive NRBC

Mean NRBC % prior to cardiac arrest	7.6% [1-63.7%]
Median time of NRBC positivity prior to cardiac arrest	20 hours [1- >120 hours]

Intensive Care Medicine Experimental**, **2025;** **13(1)**: **000359

Introduction: Critically ill patients are at risk of malnutrition, leading to muscle loss and prolonged weaning [1]. Various scores (e.g., NUTRIC-score) and biomarkers (e.g., prealbumin) are used to assess malnutrition, but their accuracy is limited. Serum cholinesterase (s-CHE) has recently been reconsidered as a malnutrition marker [2].
This retrospective study examines the correlation between NUTRIC-score and biomarkers with weaning and mortality in an ICU cohort.

Methods: Between 2020 and 2022, all medical records of patients admitted for acute respiratory failure (ARF), undergoing mechanical ventilation in the ICU of Città della Salute e della Scienza Hospital, Torino-Italy, were analyzed. Patients were divided into 3 groups: *Early-Weaning* (EW, weaning < 7 days, n = 12), *Prolonged-Weaning* (PW, weaning > 7 days, n = 75), and *Deceased* patients (D, n = 12) within the first 7 days of ICU admission. NUTRIC-score was computed at ICU admission, while albumin, prealbumin, and s-CHE levels were measured during the ICU stay. For the analysis, the first available biomarkers after admission were selected to assess their correlation with mortality and weaning.

Results: Albumin, prealbumin, s-CHE levels were higher in EW, respectively, 28, 0.19, 5969, compared to PW 26, 0.18, 3788 (Fig. 1). Group D has the lowest levels (24, 0.11, 3586). Only s-CHE reaches statistical significance in EW vs PW and EW vs D ($p < 0.05$). NUTRIC-score ranges from 4 to 5 across all groups, without any significant statistical difference.
We then analyzed mortality: non-survivors had lower levels of albumin, prealbumin ($p < 0.05$), s-CHE ($p < 0.001$), while NUTRIC-score was not significant.

Conclusions: In this population, s-CHE showed the strongest correlation with PW and mortality. This may be due to its short half-life compared to other plasma proteins, allowing a better correlation with patients' clinical course. These results suggest that more reliable markers for assessing malnutrition, and its complications are needed.

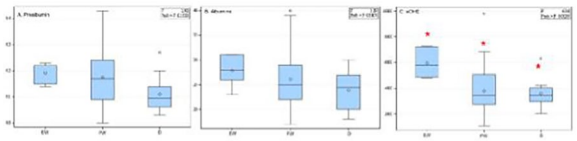

Fig. 1 (abstract 000359) Biomarker values for the study groups. Values are expressed as means and standard deviations (SD).*Panel A: prealbumin values (gr/dl) for each group EW 0.19(± 0.02), PW 0.18 (± 0.1), D11(± 0.1) **Panel B:** Albumin values [gr/dl] for each group EW 28(± 3), PW 26 (± 6), D 24(± 4) **Panel C:** s_CHE (serum cholinesterase) (U/l) for each group EW 5969(± 1084), PW 3788(± 1532), D 3586(± 3687) ***:** s-CHE reaches statistical significance in EW vs PW and EW vs D ($p < 0.05$). Intensive Care Medicine Experimental*, *2025;*13(1)**: ***000360

Introduction: Trauma remains a major cause of morbidity and mortality worldwide. Early identification of severely injured patients is crucial to guide optimal resource allocation, including ICU admission.
Objectives: To describe and compare potentially severe polytrauma patients treated in a tertiary care centre, differentiating between those requiring ICU admission and those who did not.
Methods: Descriptive analysis (January 2023 – April 2024), including patients identified as potentially severe trauma cases during the initial assessment, based on the American College of Surgeons criteria (physiological, anatomical, mechanism of injury, and comorbidities). Clinical and demographic data were collected. Quantitative variables were reported as medians (IQR), and categorical variables as absolute frequencies (%). Statistical comparisons using Student's T-test for continuous variables and odds ratios (ORs) with 95% confidence intervals for categorical variables.
Results: 200 patients were included; 100 required ICU admission, while 100 did not following initial assessment. No significant differences were observed in age [43.9 (39.6–48.2) vs. 45.2 (41.3–49.1) years] or male sex (66% vs. 60%). ICU-admitted patients had higher Injury Severity Scores [19 (17–20.9) vs. 7.4 (6–8.9); p < 0.001] and lower Revised Trauma Scores [7 (6.8–7.3) vs. 7.8 (7.7–7.9); p < 0.001]. Among mechanisms of injury, only falls from height were significantly associated with ICU admission (25% vs. 10%; OR 3.0, 95%CI: 1.4–6.6; p = 0.007). Falls from standing height showed a trend without statistical significance (19% vs. 10%; OR 2.1, 95%CI: 0.9–4.8; p = 0.075). Traffic accidents were not associated with increased ICU admission, with car accidents acting as a protective factor: motorcycle accidents (13% vs. 17%; OR 0.7, 95%CI: 0.3–1.6; p = 0.423) and car accidents (14% vs. 37%; OR 0.3, 95% CI 0.1–0.6; p < 0.001). ICU-admitted patients had longer hospital stays [17.5 (14.3–20.7) vs. 6.7 (0–14.1) days; p = 0.009] and higher in-hospital mortality (13% vs. 0%; p = 0.018).
Conclusions: Prognostic scoring systems proved useful in identifying severely injured trauma patients. Falls from height and from standing were associated with greater injury severity compared to traffic accidents. Overall, the assessment criteria employed allowed for accurate identification of patients who would benefit from ICU admission.

Intensive Care Medicine Experimental*, *2025*;13(1)**: ***000361

Introduction: The mortality rate of sepsis remains unacceptably high [1], and the heterogeneity of the disease is closely related to the slow progress of research on treatments for this condition [2-4]. Studies have demonstrated that the multicomponent proprietary Chinese medicine Xuebijing injection effectively reduces the 28-day mortality rate in sepsis patients while ensuring clinical safety [5].
Objectives: We aimed to investigate the dynamic biological phenotypes of sepsis and the heterogeneity of the therapeutic effect of Xuebijing injection in patients with sepsis.
Methods: In this secondary analysis, we used a variety of clinical, organ function, blood, and biomarker variables from 193 patients with sepsis who were enrolled in the EXIT-SEP trial and explored longitudinal changes in biomarkers. The phenotype was established through latent profile analysis, and the heterogeneity of the therapeutic effect of Xuebijing injection was investigated. The ΔSOFA score [6], which was defined as the change in organ failure, served as the primary outcome (ΔSOFA score = [SOFA-D7] – [SOFA-D1]).
Results: Among 193 patients from the EXIT-SEP trial, the average participant age was 61 years, and the 28-day mortality rate was 10.9%. The ΔSOFA score in the Xuebijing group was greater than that in the control group (-3.6 [3.7] versus -2.0 [4.4]; $P < 0.01$). In the Xuebijing treatment group, there was a notable decrease in the serum VEGF level on Days 1, 4, and 7. A positive correlation was observed between the ΔSOFA score and the ΔVEGF level in sepsis patients ($P = 0.02$)(Fig. 1). Two phenotypes were identified. Phenotype 2 (n = 147, 76.2%) was characterized by low levels of inflammation, mild endothelial injury, and coagulation disorders, with mild organ damage (Fig. 2). For patients with phenotype 2, the ΔSOFA score in the Xuebijing group was significantly greater than that in the control group (-3.5 [3.6] versus -1.6 [4.5]; $P < 0.01$) (Fig. 3).
Conclusions: Evidence of hyper- and non-hyperinflammatory sepsis subphenotypes with significantly different degrees of organ dysfunction was identified. Patients with lower levels of inflammatory biomarkers and mild organ damage may benefit more from Xuebijing injection.

Intensive Care Medicine Experimental*, *2025*; 13(1)**: ***000362

Introduction: The Acute Physiology and Chronic Health Evaluation (APACHE) II scoring system is widely used for mortality prediction in intensive care units. Although it generally performs well for all patients, its performance in extreme age groups, specifically those over 80 years old, remains inadequately explored.
Objectives: To evaluate APACHE II score in patients aged ≥ 80 years, and to analyze its predictive value across genders and clinical context.
Methods: We conducted a retrospective analysis of all patients aged ≥ 80 years admitted to our ICU (01/2022-03/2025). Data collected included demographics, APACHE II scores, predicted mortality,

Charlson comorbidity index, and observed mortality. Performance was assessed using standardized mortality ratios (SMR), receiver operating characteristic (ROC) curves, Hosmer–Lemeshow goodness-of-fit tests, and logistic regression.
Results: We included 182 patients (54% male, 46% female; median age 84 years [IQR 81.75-86]) admitted as medical (27%), elective surgical (35%), and emergency surgical (38%) cases. Overall mortality was 34.6%, with no significant difference between gender. Median APACHE score was 16[IQR 12-21.25], with median predicted mortality of 23.5%[IQR 15-42.4%]. Median Charlson comorbidity index was 7[IQR 6-8]. The overall SMR was 1.053, indicating higher observed than predicted mortality. When stratified by gender, similar SMR values were observed. However, differences were revealed in medical (SMR = 1.30), emergency surgical (SMR = 1.34), and elective surgical (SMR = 0.21) cases. ROC analysis demonstrated optimal overall performance at a threshold of 17.8%, yielding high sensitivity (93.7%) but low specificity (52.9%). Gender-specific ROC analyses showed similar optimal thresholds. The Hosmer–Lemeshow test revealed poor calibration overall ($p = 0.037$), with significant gender differences (males: $p = 0.037$; females: $p = 0.007$). Calibration appeared acceptable in all case types. In gender-stratified analyses, predicted mortality was strongly predictive for males (OR = 1.051, $p < 0.001$) but marginally not significant for females (OR = 1.017, $p = 0.065$). APACHE showed strong predictive ability in emergency surgical cases (OR = 1.078, $p < 0.001$) but no significant value in medical or elective surgical cases. Multivariable logistic regression confirmed predicted mortality as an independent predictor of mortality (OR = 1.046, 95% CI: 1.017-1.076, $p = 0.002$) even after adjusting for gender and Charlson comorbidity index, neither of which showed significant associations. Case type was strongly associated with mortality ($p < 0.001$), with differences between elective surgical (4.7%), emergency surgical (40.6%), and medical cases (65.3%).
Conclusions: APACHE shows acceptable overall performance in the very elderly but with important gender differences and dramatic variations by clinical context, underpredicting mortality in medical and emergency surgical patients while overpredicting in elective surgical elderly patients.

Intensive Care Medicine Experimental*, *2025;*13(1)**: ***000363

Introduction: Acute brain injury increases the risk of developing ventilator-associated pneumonia (VAP). It has been proposed that administering prophylactic antibiotic in patients with low level of consciousness at admission could reduce the incidence of early VAP.
Objectives: To evaluate the impact of antibiotic therapy within the first 24 h of admission on the development of early VAP in patients admitted to the ICU with a low level of consciousness, as well as the risk factors for early VAP in this population.
Methods: A retrospective observational study was conducted using real-life data automatically obtained from electronic medical records. All patients admitted between January 1, 2014, and December 1, 2024 with decreased level of consciousness or head injury (TBI) with/without other associated trauma, with a Glasgow Coma Score (GCS) of ≤ 8 and who required mechanical ventilation (MV) upon admission to the ICU for more than 48 h were included. Demographic variables, severity scores, clinical and laboratory variables, administration of antibiotic upon admission for other reasons than VAP prophylaxis, and incidence of early VAP were collected. Differences between groups were assessed using the Chi-square test or t-test, as appropriate. We used a propensity score matching analysis to reduce confounding factors. Cox proportional hazards were performed to assess the daily proportional risk of developing VAP. Factors associated with the development of early VAP were determined using a multiple logistic regression model. A p-value of < 0.05 was considered significant.
Results: We included 449 patients, 67.4% were men with a median age of 57.2 years. A total of 242 patients (53.8%) received antibiotic treatment at admission. There were no differences in the incidence of early VAP between patients with and without antibiotic treatment (8.2% vs 8.7%, $p = 0.99$). Table 1 shows the differences between these two populations. After propensity score matching, antibiotic treatment (HR 0.38, CI 95% 0.17-0.83) and procalcitonin (HR 0.89 CI 95% 0.80-0.98) were the only variables associated with early VAP in the Cox regression (Fig. 1). Antibiotic treatment showed a tendency to decrease the incidence of early VAP in multiple logistic regression, although these differences did not reach statistical significance (OR 0.45, CI 95% 0.18–1.1, $P = 0.08$).
Conclusions: Our real-life data suggest that receiving prophylactic antibiotic at admission could reduce the incidence of VAP. Studies with larger numbers of patients are needed to evaluate the impact of prophylactic antibiotic treatment in patients with a low level of consciousness

Table 1 Characteristics of the 449 patients included according to the receipt of antibiotics. IQR: interquartile range; GCS: Glasgow Coma Scale; VAP: ventilator-associated pneumonia; MV: mechanical ventilation; ICU: intensive care unit; LOS: length of stay; APACHE: acute physiology and chronic health evaluation; SAPS: simplified acute physiology score

Variables	Antibiotic no	Antibiotic yes	p-value
Age, median (IQR 25-75)	61.0 (52.0-72.0)	57.0 (45.0-68.8)	0.006
Male gender, n (%)	126 (60.9)	177 (73)	0.008
Head trauma, n (%)	39 (18.8)	125 (51.7)	<0.001
GCS at admission, median (IQR 25-75)	5 (3-7)	5 (3-7)	0.493
VAP, n (%)	17 (8.2)	21 (8.7)	0.995
Days of MV, median (IQR 25-75	7.9 (4-1-15.9)	11.3 (5.1-20.9)	0.004
ICU LOS, median (IQR 25-75)	10.7 (6.1-20.6)	15.0 (7.7 – 28.7)	0.002
APACHE II, median (IQR 25-75)	24 (17-30)	23 (17-27)	0.05
SAPS 2, median (CI 95%)	55 (45-66)	52 (42-66)	0.207
Leucocytes 10*6/µl, median (IQR 25-75)	12.7 (19.4 – 15.6)	14.0 (11.1 – 18.5)	<0.001
C-reactive protein mg/dl, median (IQR 25-75)	4.2 (2 – 6.9)	6.6 (3.6 – 10.1)	<0.001
Procalcitonine ng/ml, median (IQR 25-75)	3.8 (1.9 – 6.4)	4.1 (2.4 – 7.7)	0.203

Introduction: Atrial fibrillation (AF) is a common complication following cardiothoracic surgery, occurring in approximately 30-40% of patients. Several risk factors for post-operative AF have been identified, but the preventive effect of pre-operative beta-blocker administration remains controversial.
Objectives: This study aimed to determine whether pre-operative beta-blocker administration reduces the incidence of new-onset atrial fibrillation following elective thoracic aortic surgery and to identify potential predisposing factors for post-operative AF occurrence.
Methods: We conducted a retrospective analysis of 250 patients who underwent elective thoracic aortic surgery at our institution from June 2012 to December 2022 Patients with pre-existing chronic atrial fibrillation were excluded. The primary outcome was new-onset post-operative atrial fibrillation. Potential predictors included pre-operative beta-blocker use, age, gender, EuroSCORE II, diabetes mellitus, dyslipidemia, hypertension, baseline ejection fraction (EF), cardiopulmonary bypass (CPB) time, and Bentall procedure. Secondary analysis examined mortality as an outcome. Univariate analyses (Mann–Whitney U tests for continuous variables and Chi-square tests for categorical variables) and multivariable logistic regression were performed to identify associations between clinical variables and outcomes.
Results: Of the 250 patients, 185 (74%) were male. Median age of all patients was 66 years [IQR: 55.75-72]. Pre-operative beta-blockers were administered to 137 patients (55%). Post-operative AF occurred in 79 (32%), and overall mortality was 4% (11 patients). In univariate analysis, none of the categorical variables showed significant association with post-operative AF. Among continuous variables, CPB time approached but did not reach statistical significance ($p = 0.062$). In multivariable logistic regression analysis, pre-operative beta-blocker administration was not significantly associated with post-operative AF (OR 0.685, 95% CI 0.383-1.228, $p = 0.204$). Similarly, age ($p = 0.498$), gender ($p = 0.812$), diabetes ($p = 0.343$), dyslipidemia ($p = 0.448$), hypertension ($p = 0.652$), EuroSCORE II ($p = 0.896$), baseline ejection fraction ($p = 0.234$), CPB time ($p = 0.238$), and Bentall procedure ($p = 0.605$) showed no significant association with post-operative AF. In the secondary analysis examining mortality, extended CPB time was the only significant predictor (OR 1.024, 95% CI 1.012-1.037, $p < 0.001$). Post-operative AF was not associated with increased mortality ($p = 0.700$).
Conclusions: Pre-operative beta-blocker administration did not significantly reduce the incidence of new-onset post-operative atrial fibrillation. Extended cardiopulmonary bypass time was the only independent predictor of mortality, with each additional minute of CPB increasing mortality risk by 2.4%. These findings suggest that the pathophysiology of post-operative AF is complex and likely multifactorial.

Learning the language of echocardiography: how does image interpretation and clinical decision-making change over time since Basic Critical Care Echo accreditation?

S. Fuller[1]; A. Gowland,[2]; J. Powell-Tuck[1]
[1]Intensive care, St Thomas' Hospital, London, United Kingdom; [2]Echocardiography, St Thomas' Hospital, London, United Kingdom
Correspondence: S. Fuller
Intensive Care Medicine Experimental*, *2025;*13(1)**: ***000365

Introduction: Basic Critical Care Echo (CCE) has become increasingly recognised as a core competency for Intensivists (Cheng & Arntfield, 2024) and is essential for management of patients' haemodynamics (Flower et al., 2024; Vieillard-Baron et al., 2019). Basic CCE accreditations, such as Focused Ultrasound in Intensive Care (FUSIC) Heart, in the U.K. have gained significant popularity due to their comparative accessibility, however there is no established re-accreditation process. If basic CCE is relied upon for clinical management, how can we ensure competence is maintained and what factors influence this?
Objectives:-Validate a structured set of basic CCE cases as a tool to assess ongoing echo interpretation competence in accredited clinicians.
- Identify factors affecting competence following initial basic CCE accreditation.
- Explore the necessity for formal or informal revalidation processes for basic echo accreditation.
Methods: Five basic CCE cases were developed with a standard FUSIC Heart reporting form. Objective marks were assigned based upon recognition of key clinical findings and an overall pass or fail grade was separately allocated based on whether the primary key pathology was identified. The cases were validated by two different control groups; An "expert" group of advanced accredited echocardiographers to validate the image interpretation and second control group of critical care resident doctors without basic CCE accreditation. This was a proof of principle study in a single centre.
Results: 16 responders with basic CCE accreditations compared with 13 unaccredited controls. The average score per case was 7.25/10 (unaccredited control group 4.1/10) This can be seen in Fig. 1 plotting average scores for and Fig. 2 showing the Pass/Fail recognition of key clinical information for FUSIC, physiologist and control groups cohorts. There were 3 outliers who missed key information 3/5 times. They were all within 1 year of their FUSIC accreditation, reported 0 h of echo continued professional development (CPD) and had done between 10 and 50 scans in the last year. Selecting only those with greater than 2 years since accreditation (7 of 16), showed an improvement to 7.8/10 score and they recognised the key clinical information 98% of the time (4.9/5). This was replicated by selecting for those who reported completing echo CPD (7.6/10 score and 4.6/5 key clinical information from 11 of 16 responders).
Conclusions: A small single-centre study suggestive of a valid test of Basic CCE level competence, given the difference between the basic CCE accredited responses and the unaccredited control group. The data also suggest that although there is no formal accreditation process similar to advanced CCE, basic CCE skills improve with time and experience. Revalidation may not be needed formally if there is ongoing evidence of engagement with echo CPD and using basic CCE as part of their clinical practice. Is accreditation an introduction that is built upon in clinical practice? This area requires a larger study.

The role of cenobamate in refractory status epilepticus in ICU patients: Are we witnessing a shift in management?

S. Martin-Sastre[1]; D. Campos-Fernandez[2]; L. Abraira[2]; E. Santamarina[2]; M. Sueiras Gil[3]; V. Thonon[3]; RM. Gràcia[1]; R. Ferrer[1]; A. Sánchez Corral[1]
[1]Intensive care department, Vall d'Hebron University Hospital, Barcelona, Spain; [2]Neurology department, Vall d'Hebron University Hospital, Barcelona, Spain; [3]Neurophysiology Department, Vall d'Hebron Barcelona Hospital Campus, Barcelona, Spain

Intensive Care Medicine Experimental, 2025;*13(1)**: ***000366

Introduction: Cenobamate (CNB) is a novel antiseizure medication (ASM) initially approved for focal-onset seizures in adults. It has a dual mechanism of action, contributing to its unique pharmacological profile, which has led to improved seizure control. On the other hand, refractory status epilepticus (RSE) presents a significant therapeutic challenge, often requiring alternative strategies due to its high morbidity and mortality. The use of ASMs, such as CNB is increasingly being considered as a potential option in selected cases. CNB is administered exclusively oral, being given to these patients via a nasogastric tube.

Objectives: This study aims to evaluate the potential role of CNB in the management of RSE and super refractory status epilepticus (SRSE) by reviewing patients admitted to the intensive care unit (ICU) of a tertiary centre. We seek to describe the characteristics of RSE and SRSE patients who have been treated with CNB.

Methods: A retrospective review was conducted on patients diagnosed with, RSE or SRSE and admitted to the ICU of Vall d'Hebron Hospital between January 2022 and February 2025. Clinical records were analyzed to determine treatment strategies, focusing on patients who received CNB. Patients who were previously on CNB treatment were excluded from the analysis. Demographic data, treatment response, and outcomes were collected.

Results: A total of 95 patients were admitted in the ICU with a diagnosis of SE, RSE or SRSE. Among them, 2 patients in 2022, 1 patient in 2023, 8 patients in 2024, and 2 patients in the first two months of 2025 received CNB. All of those thirteen with a diagnosis of RSE or SRSE.

The cohort consisted of 13 patients. The mean age is 47.3 years (± SE 22.4). Eight were male and five were female. During their ICU stay, 8 out of 13 patients required invasive mechanical ventilation. The mean ICU stay was 26 days, (± SE 19), while the mean hospital stay was 52 days (± SE 53)

Two patients died during their ICU stay (one of the causes was limitation of therapeutic effort due to the neurological condition, and the other was disease progression in a patient with diffuse large B-cell lymphoma with central nervous system involvement). After six months of follow-up five additional patients had passed away, resulting in a six-month mortality rate of 53.8%. At the time of this publication, six patients remain under follow-up.

All patients received CNB as part of combination therapy, with it being at least the third drug used.

Conclusions: Cenobamate is not among the first-line anticonvulsant drugs for the treatment of SE but is used as part of combination therapy. Our preliminary findings suggest that it could play a role in the management of refractory status epilepticus (RSE) achieving improvements. However, further studies are necessary to confirm its efficacy and safety in this context

Effects of nasal continuous positive airway pressure Compared with high-flow nasal cannula on the coordination between swallowing and breathing in post-extubation patients, a randomized crossover study

S. Cowawintaweewat[1]; N. Kongpolprom[1]
[1]Department of Medicine, Faculty of Medicine, Chulalongkorn University, King Chulalongkorn Memorial Hospital, Bangkok, Thailand
Correspondence: S. Cowawintaweewat
Intensive Care Medicine Experimental*, *2025;*13(1)**: ***000367

Introduction: Effective coordination between swallowing and breathing is essential for preventing aspiration, with swallowing during expiration and resuming respiration with expiration being the most common and protective pattern [1,2]. High-flow nasal cannula (HFNC) and continuous positive airway pressure (CPAP) may influence swallowing-breathing patterns [3-6], but the difference in their effects on post-extubation patients remains unknown.
Objectives: The primary objective was to compare the effects of nasal CPAP and HFNC on swallowing-breathing coordination patterns in post-extubation patients. The secondary objective was to identify factors influencing the coordination between swallowing and breathing in this population.
Methods: This was a randomized, controlled, crossover trial involving post-extubation patients aged 18–80 years who were admitted to a medical intensive care unit or inpatient department, had received invasive mechanical ventilation for at least 48 h, and had been extubated within 48 h prior to enrollment. At the time of enrollment, patients underwent a modified water swallowing test and were excluded if they scored below 4, indicating dysphagia. Eligible patients were randomly assigned to one of two groups: Group A (nasal CPAP followed by HFNC) or Group B (HFNC followed by nasal CPAP). Each intervention was applied for 5 min, followed by three continuous water swallowing tests. The swallowing and respiratory phases were recorded using surface electromyography (EMG) and ECG-derived respiration. A 5-min washout period with low-flow nasal oxygen (1–5 L/min) was provided before the second intervention and swallowing assessments (Fig. 1). The coordination between swallowing and breathing was classified into four patterns: (1) E-E swallow: exhale-swallow-exhale, (2) I-E swallow: inhale-swallow-exhale, (3) E-I swallow: exhale-swallow-inhale, and (4) I-I swallow: inhale-swallow-inhale. The primary outcome was the percentage of E-E swallows. Secondary outcomes included the percentages of other swallowing-breathing coordination patterns, swallowing frequency, expiratory time within 1 min, and respiratory rate. All outcomes were averaged across three swallowing tests per device and analyzed using linear mixed-effects models to assess differences between treatments.
Results: Fourteen patients were enrolled. The primary outcome, the percentage of E-E swallows, was significantly higher with HFNC than with nasal CPAP, with estimated marginal means (EMMs) of 73.19% (95% CI: 68.79, 77.59) for HFNC and 65.58% (95% CI: 61.18, 69.99) for nasal CPAP, resulting in a mean difference of -7.61% (95% CI: -11.72, -3.50, p = 0.002) (Fig. 2). Among the secondary outcomes, HFNC resulted in significantly greater exhalation before swallowing (E-E + E-I swallows), with a mean difference of -5.40% (95% CI: -9.81, -1.00, $p = 0.020$) (Fig. 3). Other swallowing–respiration coordination patterns, swallowing frequency and respiratory rate did not differ significantly between treatments. Expiratory time was significantly longer with HFNC (mean difference: -2.45 s, 95% CI: -3.86, -1.05, $p = 0.002$). Carryover and period effects were evaluated and found to be non-significant for all outcomes. Sensitivity analyses indicated that a longer duration of mechanical ventilation was significantly associated with a lower proportion of E-E swallows (β = -0.717; p = 0.042), while age, APACHE II score, and BMI had no significant effect.
Conclusions: HFNC significantly increased the percentage of E-E swallows compared to nasal CPAP in post-extubation patients, along with a higher proportion of exhalation before swallowing and a longer expiratory time. These findings suggest that HFNC may be more effective than nasal CPAP in enhancing swallowing-breathing coordination.

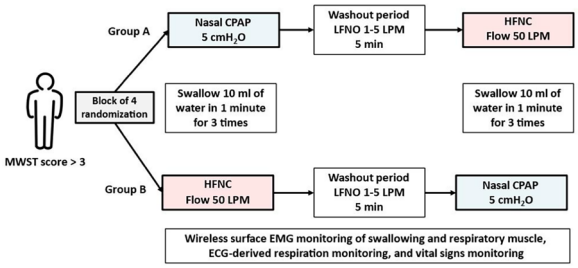

Fig 1 (abstract 000367) The study protocol. MWST, modified water swallowing test; EMG, electromyography; CPAP, continuous positive airway pressure; HFNC, high-flow nasal cannula; LFNO, low-flow nasal oxygen; ml, milliliters; min, minute; LPM, liters per minute

Low-dose recombinant haemoglobin treatment of ischaemia–reperfusion injury induces a marked diuresis and natriuresis

Introduction: We developed a recombinant human haemoglobin variant (pF48) from *E coli bacteria*, incorporating targeted mutations to modulate nitric oxide metabolism. We previously found that pF48 was safe in healthy rats [1] and, at low dose, reduced oxidative stress and improved haemodynamics and survival in a rat model of haemorrhage–reperfusion injury [2]. An unexpected observation was marked polyuria with pF48, with an average fivefold increase in urine output compared to controls.
Objectives: To explore the hypothesis that the pronounced diuresis observed following pF48 administration in the rat haemorrhage-reperfusion model relates to inhibition of renal Na^+/K^+-ATPase activity.
Methods: Anaesthetised Wistar rats (10 per group, weight 280–360 g) underwent vascular cannulation and bladder catheterisation. Urine was collected over 60 min (baseline). Following 90 min of ischaemia (withdrawal of 35% of circulating blood volume) animals were randomised to receive equal volume resuscitation of pF48 (8.33 mL/Kg) or placebo (Hartmann's solution). Urine and blood samples were collected at 60 and 240 min post-treatment for subsequent measurement of plasma urea and creatinine, and urinary electrolyte concentrations (Na^+, K^+, Cl–). Electrolyte content excreted was calculated as the product of urine volume and electrolyte concentration at each timepoint. Data were analysed using two-way RM-ANOVA with Sidak's post hoc test, log-rank and Mann–Whitney tests.
Results: The marked diuresis in the pF48-treated animals compared to IRI controls (Fig. 1A) resulted in a lower plasma urea level at 60 min (Fig. 1B) though haematocrit was unchanged (data not shown). pF48 treatment resulted in a higher urinary sodium concentration, lower potassium concentration, and unchanged chloride concentration (Fig. 1 D-F). In view of the large diuresis, total urinary excretion of sodium, potassium, and chloride were all significantly elevated ($p < 0.05$) in pF48-treated animals compared to controls for all (Fig. 1 G-I).
Conclusions: pF48-treated animals exhibited a significant diuresis with natriuresis, kaliuresis, and chloruresis. The reduction in renal tubular electrolyte reabsorption is likely mediated by inhibition of Na^+K^+-ATPase and/or the $Na^+K^+2Cl^-$ cotransporter systems.

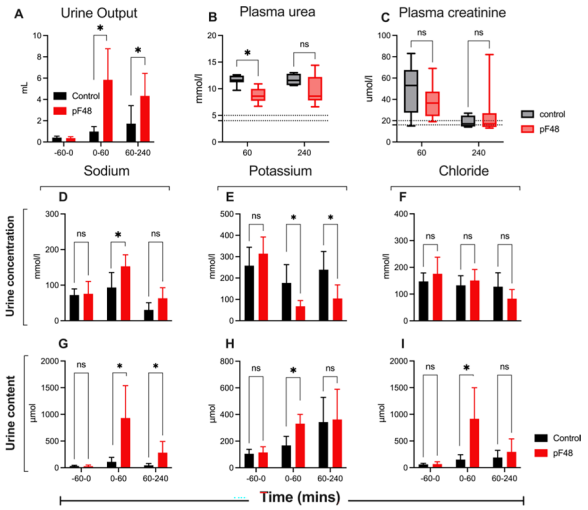

Fig. 1 (abstract 000369) Effects of pF48 on urine output, renal function, and urinary electrolytes in the haemorrhage–reperfusion model. **(A)** pF48 treatment resulted in a five-fold increase in urine output vs. placebo. **(B–C)** Plasma urea was significantly reduced at 60 min in the pF48 group; dotted lines represent normal ranges from sham animals. **(D–F)** Urinary Na + concentration was higher and K + lower at 60 min in the pF48 group while urinary chloride was unchanged. **(G–I)** Total urinary excretion of sodium, potassium, and chloride was elevated with pF48 ($p < 0.05$). Data are presented as mean ± SD.

Introduction: Regular training in high-risk low-volume (HRLV) critical care procedures is challenging to achieve solely through clinical practice. The elevated complexity of these procedures, their performance under stress, and the lack of proficiency among clinicians contribute to increased morbidity and mortality rates (1). Cadaver-based training offers advantages such as recurrent practice and a high-fidelity experience. Therefore, a cadaver-based procedural training was repeated one year after an initial course (2) to assess self-perceived skill proficiency, retention, and the speed of improvement.
Objectives: This study aims to identify the impact of sequential HRLV Critical Care procedural training on ICU personnel perceived proficiency, retention and learning speed.

Methods: A 5-h cadaver-based HRLV procedural training course was developed after conducting a procedural needs assessment with attending physicians and advanced care practitioners (APPs) in the Intensive Care Unit (ICU). The course included procedures such as chest tube insertion, cricothyrotomy, difficult airway management (DAM), lung isolation, Minnesota tube insertion, pericardiocentesis, and temporary transvenous pacemaker insertion, utilizing a modified Peyton four-step approach. Identical pre- and post-course surveys were completed using a four-point Likert scale: 1. Novice, 2. Competent, 3. Proficient, 4. Expert. Data were analyzed and compared with the previous year's surveys using paired t-tests. Participants who considered themselves as experts before and after the course were excluded.
Results: Of the 39 course participants, 51.3% completed both pre- and post-course surveys. All procedures showed a statistically significant increase in self-perceived skill level (Table 1). Chest tube insertion, Minnesota tube insertion, and DAM exhibited the highest improvement (Fig. 1). Retention decayed 12 months after the first course for chest tube insertion and lung isolation, but skill level did not return to initial baseline (Fig. 2). Data for the speed of improvement after reiterative training were not statistically significant ($p > 0.05$).

Table 1. Course procedure results

Procedure	Delta mean	CI 95%	Participants reporting increased proficiency	p value
Chest tube insertion	0.83	0.55,1.12	70.50%	< 0.05
Cricothyrotomy	0.35	0.16,0.54	35%	< 0.05
Difficult airway management	0.50	0.22,0.78	56.25%	< 0.05
Lung isolation	0.39	0.14,0.64	30%	< 0.05
Minnesota tube insertion	0.58	0.34,0.82	57.89%	< 0.05
Pericardiocentesis	0.30	0.02,0.58	25%	< 0.05
Temporary transvenous pacemaker insertion	0.42	0.07,0.76	44.44%	< 0.05

Conclusions: Cadaver-based training in critical care HRLV procedures enhances self-perceived skill levels and provides an alternative for achieving regular proficiency. Periodic training more frequently than annually may minimize skill decay.

Introduction: The second-line treatment of intracranial hypertension (ICH) proposed by the European Brain Trauma Foundation includes barbiturates, moderate hypothermia, and decompressive craniectomy (DC), but results are controversial. Our purpose was to evaluate factors associated with disability and mortality after ICU discharge in patients undergoing DC.
Objectives: To assess factors associated with disability and mortality after discharge from a neurotrauma ICU in patients in patients with DC.
Methods: Prospective study. Patients admitted from 1 January 2013 to 1 December 2024 who required DC, admitted to a 10-bed neurotrauma ICU of a tertiary hospital. DC was performed for intracranial hypertension (ICH) refractory to medical treatment. Variables analyzed: main diagnosis on admission; demographic data; neurological data; hypotension episodes; type of craniectomy and complications; GCS and motor response, Rankin scale and Glasgow outcome scale (GOS); preoperative serum lactate levels and number of hours with elevated intracranial pressure before DC; hypo- and hyperglycaemia; application of hyperosmolar treatment; leucocytes and platelets before DC and other related factors. Categorical variables are expressed as frequencies and percentages and continuous variables as mean and standard deviation (SD) when the data followed a normal distribution, or as median and interquartile range (IQR = 25th-75th

percentile) when the distribution deviated from normality. Percentages were compared, as appropriate, by the Chi-square test (χ^2) or Fisher's exact test, means by the t-test and medians by the Wilcoxon test for independent data. Univariate analysis of mortality and disability at ICU discharge and 6 months after ICU discharge was performed. Statistical significance was set at P < 0.05. Data were analysed using the R package version 4.2.1 (R Development Core Team, 2022).

Results: Sixty-six patients with DC were analyzed. The majority were TBI: 29 (43.9%) and SAH (spontaneous and traumatic) were also 29 (43.9%). Cerebral vascular accidents with malignant cerebral artery requiring DC were 13 (19.7%). The most common complications were hydrocephalus in 25 patients (38.5%) and need for reoperation in 17 patients (27.4%). 18 patients (27.7%) died in the ICU, and a total of 26 patients died within 6 months of discharge. Seven patients with spontaneous SAH died at ICU discharge. Of the 29 patients with TBI, 13 died 6 months after ICU discharge, including 8 (ICU mortality 27.58%) in ICU. Median Rankin at ICU discharge was 5 (4; 5.8) and GOS was 3 (1.2; 3). At 6 months after ICU discharge, Rankin was 5.0 (4; 6) and GOS was 3 (1; 4) (Table 1). In the analysis of disability after ICU discharge and at 6 months after discharge, no statistically associated factors were found. However, in the analysis of mortality at 6 months after ICU discharge in patients with DC, both reactive pupils were statistically significant (lower mortality) (Table 2).

Conclusions: Rankin and GOS reflect moderate disability in our DC patients at ICU discharge and 6 months later. The ICU mortality of patients with DC was 27.7%. However, TBI patients with DC had an ICU mortality of 27.58%. Mortality at 6 months after ICU discharge in DC patients was significantly associated with both reactive pupils.

Intensive Care Medicine Experimental*, *2025;*13(1)**: ***000372

Introduction: Intra-abdominal infections (IAI) involve a complex mix of pathogens. Intraperitoneal specimens for microbiological evaluation from the site of infection are always recommended in hospital or community acquired IAI in patients at risk for resistant pathogens, particularly in critically ill patients to guide antimicrobial therapy1,2.

Objectives: This study aims to analyze the utility of microbiologic samples in guiding antimicrobial treatment in critically ill patients with IAI.

Methods: Retrospective cohort study including all patients with IAI, under empiric antibiotic therapy, admitted to an ICU of a secondary care hospital between April 1, 2021, and December 31, 2023.

Results: There were 128 patients enrolled in the study. Patients with microbiological documentation had a higher rate of antibiotic modification when compared with those without, 45% (n = 33) vs. 21% (n = 9), p < 0.001. Similar results were observed if we consider only identification in local products, 48% (n = 23) vs. 24% (n = 19), p = 0.004. There was a low prevalence of MDR pathogens.

Table 1 (abstract 000372) Characteristics of the patients included

Variable		Location of intra-abdominal infection

ICU mortality, n (%)		21 (16)	9 (13)	8 (28)	4 (12)
Hospital mortality, n (%)		31 (24)	11 (16)	9 (31)	11 (33)

IQR—inter-quartile range; SD—standard deviation; BC—blood cultures; LOS—length of stay

Conclusions: Our study shows a high usefulness of blood cultures and local products collection for microbiology analyzes in IAI, measured by a significant proportion of patients in whom it was necessary to adjust antimicrobial therapy according to the results obtained, in this population with low prevalence of MDR pathogens.

Intensive Care Medicine Experimental*, *2025;*13(1)**: ***000373

Introduction: Neuromuscular blocking agents (NMBAs) are commonly used in critically ill patients requiring invasive mechanical ventilation (MV) to facilitate lung-protective MV and improve oxygenation (1). Randomized controlled trials provided equivocal results regarding their effects on mortality (2-3). It is yet unclear whether responses in key determinants of lung-protective MV, most importantly driving pressure (ΔP) (4), following NMBA administration predict NMBA-associated risk of mortality (5).

Objectives: To investigate whether ΔP changes in response to NMBA administration were associated with differential risks of mortality.

Methods: 1,168 critically ill patients undergoing invasive MV in an intensive care unit (ICU) at Beth Israel Deaconess Medical Center, Boston, MA and receiving NMBAs for indications other than intubation between 2010 and 2023 were included in this retrospective cohort. The primary exposure was the change in ΔP within six hours before and after NMBA administration. First, 28-day mortality was analyzed depending on the change in ΔP after NMBA administration. Then, to determine NMBA-associated mortality, a separate cohort was created using 1:1 matching of 996 mechanically ventilated, non-CMO, non-surgical ICU patients with baseline S/F ratios ≤ 300 with and without NMBA initiation in the first 48 h of invasive MV. Multivariable logistic regression, adjusted for patient demographics, comorbidities, and ICU-specific markers of baseline case severity was applied.

Results: Across 1,420 NMBA administrations, an increase in ΔP followed 695 (48.9%) NMBA administrations, and 582 (41.0%) NMBA administrations were followed by a decrease in ΔP (**Table 1** and Fig. 1). An increase in ΔP after NMBA administration was associated with a higher risk of 28-day mortality (ORadj 1.32 per 5 cmH2O increase in ΔP, 95%CI 1.08-1.62, p = 0.007) and more likely pronounced when baseline ΔP was low (ORadj per every -1 cmH2O baseline ΔP 1.24, 95%CI 1.18-1.30, p < 0.001; 58.8% (n = 514/874) among a subset of patients with baseline ΔP ≤ 13). In the matched cohort, 41.6% (n = 207/498) of patients who received NMBAs died within 28 days, compared to 36.1% (n = 180/498) of patients who did not receive NMBAs. Across all patients, NMBA administration was associated with a higher risk of mortality (ORadj 1.64, 95%CI 1.19-2.26, p = 0.003), while this association was not observed in patients with a high baseline ΔP (> 13 cmH2O, n = 234, ORadj 0.87, 95%CI 0.45-1.71, p = 0.70, p-for-interaction = 0.017) nor in patients with a baseline S/F ratio ≤ 100 (n = 190, ORadj 0.51, 95%CI 0.22-1.16, p = 0.11, p-for-interaction = 0.003; **Fig. 2)**.
Conclusions: An increase in ΔP following NMBA administration is associated with a pronounced risk of 28-day mortality. Patients with low ΔP prior to NMBA administration are more likely to respond with an increase, and are at higher risk of NMBA-associated mortality. These findings support incorporating patients baseline ΔP and oxygenation into decisions on administration of NMBA in critically ill patients.

Association between admission high-sensitivity cardiac troponin T and major adverse cardiovascular events in burn patients

A. Joseph[1]; N. Moreno Brahimi[2]; B. Deniau[1]; F. Depret[1]; Z. Bellas[1]; T. Walter[1]
[1]Anesthesiology and Critical Care, Saint-Louis Hospital, Paris, France; [2]Biochemistry and Molecular Biology, Saint-Louis Hospital, Paris, France

Intensive Care Medicine Experimental*, *2025;*13(1)**: ***000374

Introduction: Initial value of high-sensitivity cardiac troponin T (hs-cTnT) is increased in myocardial injury and is associated with adverse outcomes in critically ill patients. Its prognostic value for major adverse cardiovascular events (MACE) in burn patients, however, remains unknown.
Objectives: To investigate the association between hs-cTnT levels measured within 24 h after burn injury and MACE.
Methods: This retrospective observational monocentric study was approved by an ethics committee (IRB 00010254—2024 – 030). Burn patients admitted between January 2012 and December 2022 were included if they underwent at least one hs-cTnT measurement on the day of the burn injury. Primary outcome was MACE defined as the occurrence of acute coronary syndrome, stroke, acute heart failure, and/or all-cause death during an ICU stay.
Logistic regression models assessed associations between hs-cTnT levels and outcomes. Sub-group analyses were also conducted while receiver operating characteristic (ROC) curves evaluated predictive performance.
Results: Among 495 burned patients admitted, 43% (n = 212) exhibited elevated hs-cTnT levels (> 14 ng/L). Most of the patients were males (n = 342, 69%). The median age was 50 years (IQR 33–65). A total of 60 patients (12%) had a history of cardiovascular disease (CV history).
MACE occurred in 23% of patients (n = 115) and those who experienced MACE had significantly higher initial hs-cTnT levels (median 27 ng/L [0, 74]) compared to those who did not (median 0 ng/L [0, 19]). We found a significant association between MACE and initial hs-cTnT levels (OR 1.07 per 10 ng/L, 95% CI 1.03–1.11; p < 0.001). This association persisted across various subgroup analyses (Fig. 1).
A multivariable analysis including Simplified Acute Physiology Score II, body mass index, Charlson comorbidity index, initial lactatemia, sex, thermal nature of burns, smoke inhalation and initial hs-cTnT value only retained hs-cTnT (OR 1.01 per 10 ng/L, p = 0.035) and smoke inhalation (OR 4.69, p < 0.001) as independent predictors of MACE.
ROC analysis for hs-cTnT identified an optimal cutoff value of 14.5 ng/L for predicting MACE during the ICU stay, with a sensitivity of 0.72, specificity of 0.68, and an AUC of 0.73 (95% CI 0.68–0.78). Combining hs-cTnT with initial lactatemia values enhanced predictive performance, achieving an AUC of 0.80 (95% CI 0.75-0.84). However, the DeLong test (p = 0.063) indicated that this improvement was not statistically significant. Both were compared with the Abbreviated Burn Severity Index (ABSI), which demonstrated an AUC of 0.84 (95% CI 0.80–0.88) (Fig. 2).
Conclusions: Elevated hs-cTnT levels are associated with MACE in burn patients regardless of burn severity or CV history and exhibit moderate predictive accuracy. Combining hs-cTnT with lactatemia enhances predictive performance. This association aligns with the already established links between burns and cardiac dysfunction, although the underlying mechanisms remain incompletely understood.

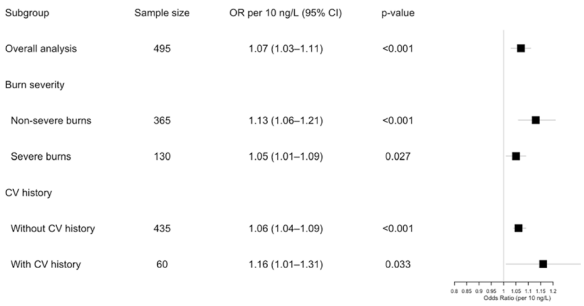

Fig. 1 (abstract 000374) Forest plot: univariate regression analysis of the association between hs-cTnT increase per 10 ng/L and MACE in the overall cohort and specific subgroups

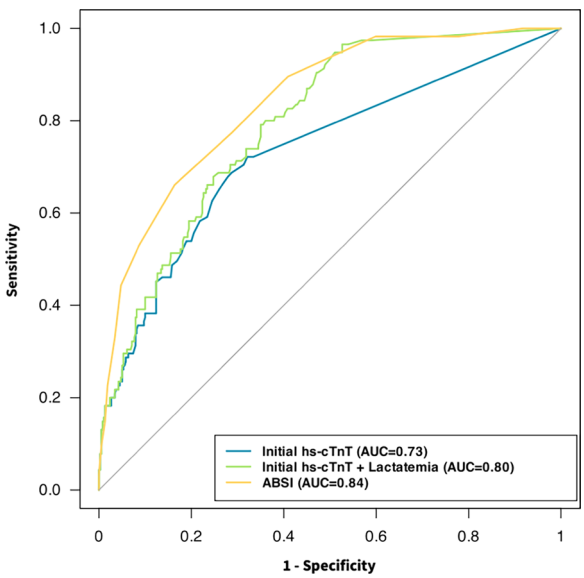

Fig. 2 (abstract 000374) ROC: prediction of MACE using initial hs-cTnT, initial hs-cTnT + lactatemia and ABSI

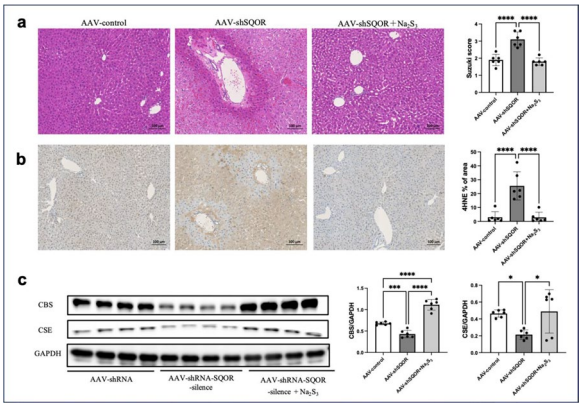
Intensive Care Medicine Experimental, 2***025;13*(1)**: ***000375***



Introduction: Previous studies have indicated a relationship between hydrogen sulfide (H_2S) and ischemia-induced organ injury (1). In the H_2S metabolic pathway, sulfide-quinone oxidoreductase (SQOR)—located in the inner mitochondrial membrane-functions as the primary enzyme in the rate-limiting step (2). In this study, we assessed the role of SQOR in hepatic ischemia–reperfusion injury (IRI).
Methods: All procedures were approved by the Kyushu University Animal Ethics Committee (A24-396-0; July 23, 2024). We inhibited SQOR expression using a short hairpin (sh) RNA targeting mouse SQOR (shSQOR). We compared biochemical analysis, histopathological assessment, 4-hydroxy-2-nonenal (4HNE: as an assessment of oxidative stress and antioxidant capacity), and alterations in metabolic enzymes after IRI between mice injected with adeno-associated virus vector shSQOR (AAV-shSQOR group, n = 6) and controls (AAV-control group, n = 6). Additionally, sodium trisulfide (Na_2S_3) (H2S metabolite donor) was administered daily for seven days before IRI in shSQOR-knockdown mice to assess the effects of H_2S metabolites (AAV-shSQOR + Na2S3 group, n = 6). Hepatic IRI was induced 30 min after the onset of ischemia.
Results: SQOR knockdown exacerbated liver injury in hepatic IRI, as indicated by further increases in aspartate aminotransferase (AST) (AAV-control vs. AAV-shSQOR: 1096 ± 774 IU/L vs. 3201 ± 1720 IU/L, $p < 0.01$), alanine aminotransferase(ALT) (1434 ± 1191 IU/L vs. 8874 ± 6881 IU/L, $p < 0.01$), and Suzuki scores for liver injury (1.9 ± 0.33 vs. 3.1 ± 0.43, $p < 0.01$). Quantitative analysis demonstrated a significantly larger positive area for 4HNE in the AAV-shSQOR group than that in the AAV-control group (2.92 ± 4.03% vs. 25.5 ± 10.2%, $p < 0.01$). Na_2S_3 administration in the AAV-shSQOR group mitigated liver damage, restoring AST (840 ± 524 IU/L), ALT (1159 ± 576 IU/L), and 4HNE (2.88 ± 3.71%) levels and Suzuki scores (1.8 ± 0.22) to those in the control group. Cystathionine β-synthase (CBS) and cystathionine γ-lyase (CSE) expression was reduced in the AAV-shSQOR group than that in the AAV-control group (CBS: 0.68 ± 0.03 vs. 0.43 ± 0.09, $p < 0.01$, CSE: 0.46 ± 0.04 vs. 0.21 ± 0.06, $p < 0.01$). Na_2S_3 administration significantly increased the expression levels of CBS and CSE compared to both the AAV-control and AAV-shSQOR groups (CBS: 1.11 ± 0.13 and CSE: 0.49 ± 0.26).
Conclusions: This study demonstrates the crucial role of SQOR in hepatic IRI. The SQOR-mediated maintenance of H_2S metabolite production may protect against ischemia through antioxidant effects. Na_2S_3 administration is a potential treatment for mitochondrial dysfunction.

Intensive Care Medicine Experimental*, *2025;*13(1)**: ***000376

Introduction: Sepsis-induced left ventricular dysfunction participates in cardiovascular compromise and associated organ failure in patients with septic shock. The tested hypothesis is that dobutamine will reduce tissue hypoperfusion and secondary organ dysfunction in increasing oxygen delivery in fluid-filled patients with septic shock and associated symptomatic septic cardiomyopathy with documented low flow state.
Objectives: To assess the effects of adjunctive dobutamine infusion vs. placebo on organ failure during the first three days after randomization in septic shock patients who received adequate fluid resuscitation and have stabilized mean blood pressure under vasopressor support, and with symptomatic septic cardiomyopathy depicted by echocardiography.
Methods: ADAPT is a blinded, two parallel group, add-on, multicenter (23 ICUs in France), randomized 1:1, placebo-controlled trial. Patients will be included if hospitalized in the intensive care unit with septic shock (Sepsis-3 definition) and septic cardiomyopathy identified using echocardiography (left ventricular ejection fraction $\leq$ 40% and left ventricular outflow tract velocity–time integral < 14 $\pm$ 1.5 cm). Non-inclusion criteria will include ventricular rate > 130 bpm, severe ventricular arrhythmia, obstructive cardiomyopathy, severe aortic stenosis, ongoing acute coronary syndrome, and indication for extracorporeal life support. Patients will receive either dobutamine (incremental steps of 2.5 µg/kg/min up to a maximal dose of 10 µg/kg/min) at the discretion of the investigators according to both efficacy and cardiovascular tolerance, or a placebo (5% Dextrose). Primary outcome will be the evolution of a modified SOFA score (excluding the neurologic system) during the initial ICU stay encompassing screening (before randomization), and Day 1 to 3 after randomization. Randomization will be stratified on participating centers and previously documented heart failure (ejection fraction $\leq$ 40%). The use of open-labelled dobutamine as a rescue therapy will be allowed in refractory shock based on strict clinical requirements. The use of alternative inotropes will not be allowed. Considering a 2-point difference in the SOFA score at Day 3 and a standard deviation of 5.0 at baseline (personal data; conservative approach), the required number of patients would be 266 (133 per group; 90% power); taking into account the repeated measurement of SOFA score, the total number of patients is reduced to 118; when considering that 12.5% of patients would die before Day 3, the required number of patients finally reaches 136 (68 per group) instead of 270.
Results: Between September 2020 and April 2025, 136 out of 136 patients were studied. The last patient was included on April 4th, 2025. First results will be shared at the time of LIVES 2025.
Conclusions: Since no evidence-based recommendation yet exists for the therapeutic management of septic cardiomyopathy, this trial promises to address a current gap of knowledge in determining the value of adding dobutamine to standards of care in the subset of patients with septic shock and symptomatic septic cardiomyopathy.

Introduction: Global cerebral ischemia stemming from circulatory arrest underpins the first phase of hypoxic–ischemic brain injury (HIBI) in post-cardiac arrest patients (1). However, this phase remains poorly understood in humans. Recently, blood-based neurologic biomarkers have emerged as a promising tool for prognostication, however, their utility for the diagnosis of HIBI severity and insights into pathophysiology are limited.
Objectives: We aimed to investigate the impact of global cerebral ischemia on tissue injury by quantifying blood-based neurologic biomarkers during the dying process until circulatory arrest after withdrawal of life-sustaining measures (WLSM) in humans.
Methods: We conducted a single-center prospective observational study to investigate the cerebrovascular and cardiovascular physiology of the dying process, with corresponding blood neurologic biomarkers. Serum and plasma samples were obtained from the radial artery and jugular venous bulb immediately prior to WLSM and once systolic blood pressure (SBP) reached < 60 mmHg. Serum glial fibrillary acidic protein (GFAP), neurofilament-light (Nf-L), total tau, and ubiquitin carboxyl hydrolase L-1 (UCH-L1) were quantified using the Neurology-4-Plex-B Advantage Kit on the Quanterix HD-X platform using Simoa technology. Arterial, venous, and cerebral arterio-venous differences were assessed for differences in biomarker concentrations during the dying process.
Results: Plasma and serum biomarkers were collected before WLSM and just prior to death from 29 (91%) study participants. The median time between SBP < 60 mmHg and death determination was 249 [135, 669] seconds, thereby having blood sampling within close proximity to death determination. Arterial, venous, and cerebral arterial–venous gradients for serum GFAP, Nf-L, Tau, and UCH-L1) did not change during the dying process in critically ill patients, save for an increase in arterial Nf-L concentration ($N = 28$, $r = 0.54$, $P = 0.0032$). There was no relationship between hypotensive (area under MAP < 65 mmHg) or hypoxemic burden (area under SpO2 < 90 mmHg) and changes in arterio-venous biomarker concentration during the dying process.
Conclusions: There were no differences in the cerebral arterio-venous gradients of blood-based neurologic biomarkers during the dying process, nor when indexed for severity of hypoperfusion or hypoxemia. Although the ischemic phase is intuitively critical to HIBI pathophysiology, the lack of biomarker release during the dying process suggest that the reperfusion phase may be especially impactful to HIBI pathophysiology.

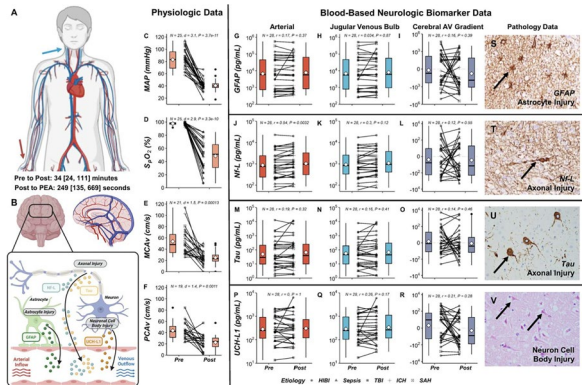

Fig. 1 (abstract 000377) Comparison of blood-based neurologic biomarkers taken prior to withdrawal of life-sustaining measures and during the dying process. Blood-based neurologic biomarkers were taken from the radial artery and internal jugular vein to allow for arteriovenous (i.e., a-v) gradient analysis across the cerebral circulation (A). Biospecimens were collected prior to withdrawal of life-sustaining measures (pre) and from when systolic blood pressure < 60 mmHg (post). Biomarkers were analyzed for common markers of astrocyte, axonal, and neuron cell body injury (B). Physiologic data from the time of biospecimen collection in the critically ill patient cohort was used to contextualize changes in hypotension and hypoxemia elicited by the dying process (C-F). Physiologic data were compared using a two-way paired t-test with Cohen's d for effect size (C-F). The white diamond on top of each boxplot represents each group mean. Arterial, jugular venous, and cerebral a-v gradients (G-R) were pairwise compared using Wilcoxon signed-ranks tests and Wilcoxon effect size (r). These data are presented on a log10 scale (G-R). Only arterial Nf-L was elevated following ischemia of the dying process (J). Subsequent post-mortem analysis of the brain confirmed presence of astrocyte (S), axonal (T, U), and neuron cell body (V) injury. Many brain autopsies had significant amounts of neurons with eosinophilic cytoplasm and shrunken nuclei typical of cases with ischemic brain injury (V).

Introduction: Acute circulatory failure plays a major role in the development of sepsis-related organ dysfunction. Current "bundles" of the *Surviving Sepsis Campaign* (SSC) include the administration of a fluid loading of 30 mL/kg in the presence of hypotension within the first hour of sepsis identification. The impact of hemodynamic assessment using echocardiography at the early phase of management of septic patients in the Emergency Department (ED) on patient-centered outcome is unknown.
Objectives: The main objective of the trial is to determine the impact of early hemodynamic assessment using echocardiography coupled with a predefined therapeutic algorithm on the course of organ dysfunction in patients admitted to the ED with sepsis, when compared to standard of care based on current SSC guidelines.
Methods: GENESIS is a two-parallel arm, randomized trial with blinded assessment comparing early hemodynamic assessment using transthoracic echocardiography aimed at guiding therapeutic management to standard of care according to current SSC recommendations in septic patients during initial management in 13 French EDs. Patients with suspected or documented infection and a qualifying qSOFA score (hemodynamic criterion required: systolic blood pressure ≤ 100 mmHg) were randomized at a 1:1 ratio after 500 mL of fluid loading initiation. In the intervention group, echocardiography allowed identifying the hemodynamic profile at the origin of sepsis-induced circulatory failure and monitoring the efficacy and tolerance of fluid resuscitation, or of any other therapeutic intervention according to a predefined therapeutic algorithm. The control group received conventional 30 mL/kg fluid resuscitation (unless pulmonary venous congestion) according to SSC recommendations. Primary outcome was the course of organ dysfunction assessed by the crude change in the modified SOFA score between baseline and 24 h after randomization. Secondary outcomes were the nature of therapeutic interventions resulting from echocardiography (fluid loading, early initiate vasopressor support or inotrope), the prevalence of the different hemodynamic profiles, the evolution of lactatemia, the safety of the initial therapeutic, the proportion of patients who develop septic shock secondarily, the orientation of patients after ED discharge and both day-7 and in-hospital mortality. We planned to randomize 312 patients.
Results: Between July 2021 and April 2025, 312 out of 312 patients have been enrolled, with the last patient included on April 7th 2025. First results will be shared at the time of the 2025 LIVES.
Conclusions: Overall, this clinical trial promises to optimize therapeutic management of septic patients in the ED using early echocardiography assessment, and ultimately to significantly reduce organ dysfunction at the initial phase of sepsis and associated short-term mortality, when compared to current standard of care.

Systematic review and meta-analysis on the effect of peripheral vasopressor protocols and extravasation rates

J. Wiseman[1]; V. Wiseman,[2]; L. Fei,[2]; JG. Boyd[1]
[1]Critical Care Medicine, Queen's University Kingston, Kingston, Canada; [2]General Surgery, Queen's University, Kingston, Canada
Correspondence: J. Wiseman
Intensive Care Medicine Experimental*, *2025;*13(1)**: ***000379

Introduction: The central venous catheter (CVC) is considered the preferred route of administration for vasopressor infusions based on historical data suggesting the increased risk of extravasation with

peripheral venous catheter (PVC) use [1]. However, there is a growing interest in peripheral vasopressor use for two reasons: 1) to expedite vasopressor initiation in patients with refractory shock and 2) to avoid CVC placement and its potential complications [2]. Several single-center observational studies have suggested that the extravasation rate has decreased with advances in peripheral venous access [3]. Furthermore, the use of peripheral vasopressors resulted in avoidance of CVC placement in almost 50% of patients [4]. While anatomical location and PVC gauge have been the focus of previous systematic reviews, the question of whether implementing standardized peripheral vasopressor protocols reduces extravasations has never been explored.

Objectives: To determine whether a peripheral vasopressor protocol decreases extravasation rates.

Methods: Following PRISMA guidelines [5], a comprehensive search was employed to identify published studies from 2000 to 2025 describing the use of peripheral vasopressors in the Emergency Department and Intensive Care Unit. An extensive search was developed in MEDLINE (Ovid) and adapted for Embase (Ovid), Cochrane Central Register of Controlled Trials (Ovid), and PubMed. A meta-analysis was performed using a random effects model for one-sample binary data for pooled estimates of extravasation rate and CVC conversion (STATA 18 software).

Results: A total of 19 observational studies were selected, which included 5397 patients receiving peripheral vasopressors. The average extravasation rate amongst all studies was 3%. A meta-analysis, which had substantial heterogeneity (I2 = 74.98%), showed no difference between extravasation rates for the presence or absence of the following: peripheral vasopressor protocol (2.6% vs 4.8%, p = 0.27), protocol for peripheral venous catheter (2.6% vs 4.8%, p = 0.27) and extravasation protocol (2.3% vs 4.6%, p = 0.53). The number of patients converted to CVC with the presence or absence of peripheral vasopressor protocol was 31.8% and 40.8%, respectively, which was not statistically significant (p = 0.24).

Conclusions: This systematic review and meta-analysis demonstrated that specific peripheral vasopressor administration protocols did not statistically decrease extravasation rates in patients receiving peripheral vasopressors. The average extravasation rate of peripheral vasopressor use amongst all studies was 3%, which is comparable to the 2.1% extravasation rate of vasopressors through a CVC reported in a recent systematic review [1]. Furthermore, the conversion to CVC placement was the same regardless of a peripheral vasopressor protocol. However, high-quality evidence is needed to evaluate these outcomes further, as all the papers included in this study are observational.

Intensive Care Medicine Experimental*, *2025;*13(1)**: ***000381

Introduction: The diagnostic criteria for ventilator-associated respiratory tract infections (VAP/VAT) are nonspecific and lack accuracy. Therefore, we designed an exploratory study to investigate the utility of myeloperoxidase (MPO) as a diagnostic tool for VAP/VAT.

Methods: Prospective study conducted from March to December 2023. We included patients who had been mechanically ventilated for more than 48 h and collected serial bronchoaspirate samples while they remained intubated. Quantitative cultures and MPO measurements were performed. To analyze the evolution of MPO levels over time, patients with VAP/VAT who had at least four samples collected were matched with control patients who had a similar duration of mechanical ventilation.

Statistical analysis performed using GraphPad Prism v8.0.2. We used T-test/ Mann–Whitney test for differences in MPO levels. Performance for VAP/VAT diagnosis was analysed with a ROC curve and Youden index was used to establish a MPO threshold.

Results: We studied 30 patients: 12 men and 18 women, mean age 68 (± 10.8) years. A total of 117 samples were collected and 64.1% had positive cultures. Seven patients developed VAP/VAT.

Patients with high bacterial load (> 10^5 CFU/mL) had significantly higher MPO levels than those with low bacterial load (< 10^5 CFU/mL), with NPV 95.6% and PPV 29.7% (p0.0133). Among patients with high bacterial load, those who developed VAP/VAT had lower MPO levels than those with bacterial colonization, with a ROC (AUC) of 0.82 (p = 0.0097) and a discrimination threshold for MPO of < 2.12 ng/mL.

In the case–control analysis, baseline MPO levels were significantly higher in the control group than in the VAP/VAT group (p < 0.01). Additionally, in infected patients, MPO levels increased at the onset of the clinical episode in 3 out of 5 VAP cases.

Conclusions: MPO has a high NPV for excluding bacterial growth in respiratory samples and a moderate predictive value for VAP/VAT. Patients who developed VAP/VAT had lower MPO levels, suggesting a form of immune paralysis associated with infection development.

Intensive Care Medicine Experimental*, *2025;*13(1)**: ***000382

Introduction: Climate change and its impact on our healthcare system becomes more and more manifest [1]. Paradoxically, while being impacted by negative effects of climate change, the healthcare sector itself has been identified as a major contributor with up to 4–5% of greenhouse gas emissions (GHG) worldwide [2]. Hospitals in particular are major emitters within this sector, with intensive care units (ICUs) playing a substantial role due to their high resource consumption [2].

Objectives: This study employed a bottom-up life cycle assessment to quantify the carbon footprint of an internal medicine ICU in a tertiary care center in Germany, focusing on emissions from consumable items and electricity consumption.
Methods: The top 15 most frequently purchased products by sales unit and the top 15 most frequently purchased products by expenditure were selected from a list of 321 medical consumable items used over the time-course of one year. Their composition, weight, and transportation from the manufacturing site were assessed (see Fig. 1). For electricity, annual consumption of all electrical machines used on the ward and their carbon dioxide equivalent (CO2eq) were assessed (see Fig. 2).
Results: The results revealed a carbon footprint of 5.9-ton CO2eq per patient in one year of ICU patient care, equivalent to 16.2 kg CO2eq per patient per day. Consumable items were found to be the dominant contributor (57%), followed by electricity (43%). Key contributors to emissions included patient monitors, ventilators, medicine and fluid administrators, special patient monitors (for pulse contour cardiac output (PICCO)) and continuous renal-replacement therapy, disposable blankets, gloves, wet wipes, gowns, syringes of an infusion pump, and waste bins.
Conclusions: These findings underscore the need for a multifaceted approach to reduce the environmental impact of ICUs, encompassing both technological and behavioral changes. As consumable items and CO2-emissions due to their transportation from manufacturing site are the dominant contributors, the selection of the manufacturer and production facility can contribute significantly to the carbon footprint of ICUs. By implementing these strategies, healthcare providers can contribute considerably to a more sustainable healthcare system.

Association between changes in arterial partial pressure of carbon dioxide and physical functional outcomes in severe ARDS patients requiring VV ECMO management: a registry-based retrospective study

Y. Amemiya[1]; M. Nishikimi[2]; K. Yamakawa[1]; A. Takasu[1]
[1]Department of emergency and critical care medicine, Osaka Medical and Pharmaceutical University, Takatsuki, Japan; [2]Department of emergency and critical care medicine, Hiroshima University, Hiroshima, Japan
Correspondence: Y. Amemiya
Intensive Care Medicine Experimental*, *2025;*13(1)**: ***000387

Introduction: Veno-venous extracorporeal membrane oxygenation (VV ECMO) is used for severe acute respiratory distress syndrome (ARDS). Rapid changes in arterial partial pressure of carbon dioxide (PaCO2) during ECMO initiation have been linked to neurological complications, but effects on physical function remain unclear.
Objectives: To investigate the association between PaCO2 changes at ECMO initiation and physical functional outcomes (Barthel Index (BI)) at discharge in severe ARDS patients.
Methods: We analyzed data from the Japan Chest CT of ARDS requiring V-V ECMO registry (2012-2022). Adult ARDS patients on VV ECMO were included. PaCO2 change ratio ((post-ECMO PaCO2 – pre-ECMO PaCO2)/pre-ECMO PaCO2) was categorized into five groups as follows: large decrease (< -30%), mild decrease (-30% to -10%), mild change (−10% to + 10%), mild increase (+ 10% to + 30%), and large increase (> + 30%). Multivariate logistic regression, adjusted for previously described confounders, was performed to evaluate the association between potential predictors and functional outcomes at discharge.
Results: Of 697 eligible patients, 555 were analyzed. Demographics and severity scores were similar across groups. The large decrease group had lower pre-ECMO tidal volumes, with a significant linear relationship with PaCO2 changes. Intracranial bleeding occurred in one patient. Multivariate analysis identified a large PaCO2 decrease as an independent predictor of unfavorable functional outcome (BI less than 75) (OR 0.49 (95% CI: 0.26-0.91)) and higher hospital mortality (OR 0.55, 95% CI: 0.31-0.95). Spline curve analysis revealed a non-linear relationship between PaCO2 changes and functional outcomes. While the maximum odds ratio of 1.44 for achieving a BI 75 or more occurs at a PaCO2 change ratio of 0.244, PaCO2 reductions demonstrated a dose-dependent decline in favorable outcome probability. The Murray lung injury score was not useful for outcome prediction in our cohort.
Conclusions: Large PaCO2 decrease was an independent predictor of unfavorable functional outcome in severe ARDS patients requiring VV ECMO. The non-linear relationship in our analysis indicates both large PaCO2 decreases and increases during ECMO initiation may negatively impact functional recovery, highlighting the importance of careful PaCO2 management during ECMO initiation. Conventional prognostic score was not predictive in our cohort, reflecting the changing patient demographics resulting from widespread adoption of lung-protective ventilation strategies and advancements in ECMO management techniques. This suggests new prognostic tools are needed that account for current ECMO practices and patient selection criteria.

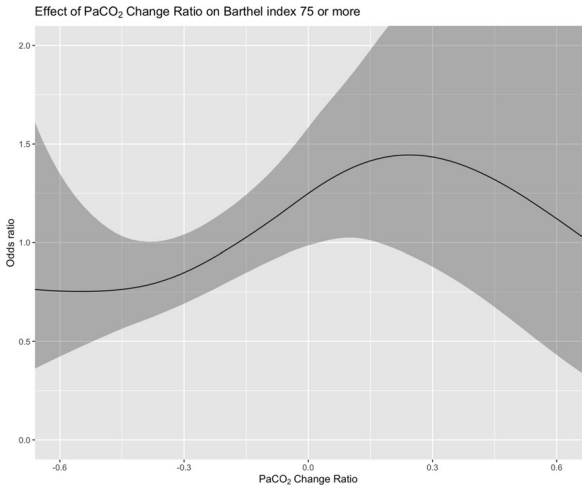

Figure (abstract 000387) Effect of $PaCO_2$ change ratio on Barthel index ≥ 75. The solid line represents the estimated odds ratio for achieving a Barthel index ≥ 75 across different $PaCO_2$ change ratios. The gray-shaded area represents the 95% confidence interval. A non-linear relationship is observed with maximum odds ratio of 1.44 at $PaCO_2$ change ratio of 0.24.

Delirium care-related stress in intensive care unit nurses: focusing on violence experience and self-compassion

S.J. KIM[1]
[1]College of Nursing, Seoul National University(SNU), Seoul, Republic of Korea
Correspondence: S.J. KIM
Intensive Care Medicine Experimental*, *2025;*13(1)**: ***000388

Introduction: ICU nurses often experience heightened anxiety and stress due to the aggression and violence associated with delirium. These emotional challenges can lead to unstable emotions of nurses, such as anger and fear, which may affect their ability to provide high-quality care. Self-compassion, which involves treating oneself with kindness in difficult times, has emerged as a potential protective factor against stress and violence. In this context, the role of self-compassion in reducing stress among ICU nurses caring for delirium patients will be explored.
Objectives: This study aims to identify ICU nurses' experiences of violence from patients with delirium, assess their levels of self-compassion, and examine how these factors influence delirium care-related stress. These findings are intended to contribute to a comprehensive understanding of the delirium care process.
Methods: A descriptive correlational design was used. Surveys were administered to 160 ICU nurses at a tertiary general hospital in Seoul, collecting data on general characteristics, violence experiences, the Strain of Caring for Delirium Index (SCDI), and the Self-Compassion Scale (SCS). Data were analyzed using descriptive statistics, correlation analysis, and hierarchical regression.
Results: The violence experience score of the study participants was 15.669 ± 9.838, with physical threats having the highest score. Participants' SCS score was 3.325 ± 0.564. The subscales of SCS were as follows: self-kindness 2.736 ± 0.725, self-judgment 2.248 ± 0.860, common humanity 3.014 ± 0.717, isolation 2.084 ± 0.873, mindfulness 3.084 ± 0.744, and over-identification 2.533 ± 0.848. The SCDI of the participants was 3.609 ± 0.542. The item "The patient tries to remove invasive devices" had the highest score (mean = 4.694, SD = 0.59). Significant correlations were found between physical threats and increased stress (r = .172, p = .029), and self-compassion and reduced stress (r = -.216, p = .006).

Table 1.(abstract 000388) Summary of significant correlations between violence experience, self-compassion, and strain of caring delirium

Variable	Strain of caring delirium
Physical threats	r = .172, p = .029
Self-Compassion	r = -.216, p = .006
(1) Self-kindness	r = -.228, p = .004
(2) Common humanity	r = -.162, p = .040
(3) Mindfulness	r = = .189, p = .017

Self-compassion explained 3.2% of the variance in delirium care-related stress (F = 5.616, p = .019) (Table 2). Additionally, as shown in Fig. 1, the moderation analysis showed that the stress-reducing effect of self-compassion was weakened in nurses with higher levels of physical threat experience (β = .047, p = .011).

Table 2. (abstract 000388) Influencing factors of strain of delirium care

Variables	B	β	p
Violence experience	.005	.100	.214
Self-compassion	-.180	-.185	.019

*Note: R^2(adjusted R^2) = .159(.119), p < .001. $\triangle R^2$ = .032 (F = 5.616, p = .019). Durbin–Watson statistics = 1.968

Conclusions. This study highlights the potential of self-compassion as a protective factor in reducing delirium care-related stress among ICU nurses, while also underscoring the detrimental impact of physical threat experiences. To ensure high-quality delirium care, it is critical to recognize and manage the stress faced by ICU nurses. Efforts should include the development of targeted interventions, such as training programs and organizational measures, aimed at strengthening self-compassion and minimizing nurses' exposure to violence from delirium patients.

Introduction. Intensive care units (ICU) provide life-saving treatment 24 h a day. Delayed ICU admission is associated with worse prognosis1. Recognition of critical illness and referral to intensive care should not depend on time of day. We reasoned that the mean severity of illness at ICU admission should remain unaffected by admission time, if the time of day does not affect identification of the need for intensive care and admission policies.
Objectives: To investigate if severity of illness and corresponding mortality are associated with time of ICU admission.
Methods: Utilising the national ICU registry, the Finnish Intensive Care Consortium database, we analysed data on admissions to ICUs between 2005 and 2022. We excluded, children, readmissions, elective (non-emergency) admissions, and patients admitted for the purpose of organ donation. We explored the severity of illness, as quantified with the Simplified Acute Physiology Score II (SAPS II) score, and in-hospital mortality according to different admission hours.
Results: The study population consisted of 135,275 ICU patients. The mean (± SD) SAPS II score on admission was 37.9 ± 17.4, and in-hospital mortality was 14.7%. Figure 1 presents the mean SAPS II score and the corresponding mortality for each admission hour. The mean SAPS II score was 39.0 ± 17.9 during morning admissions (6-12 a.m.) and 37.5 ± 17.2 during the rest of the day ($p < 0.001$). The corresponding in-hospital mortalities were 17.5% and 13.9%, respectively. ($p < 0.001$). Higher severity of illness and mortality of patients admitted during morning hours was observed for admissions from the emergency department or ward, but not for admissions from the operating theatre or intermediate-care units.
Conclusions. Patients admitted in the morning hours were more severely ill and experienced higher mortality compared to those admitted during the rest of the day. This phenomenon seems to affect hospital wards and emergency departments.

(abstract 000389) Mean Simplified Acute Physiology Score II (SAPS II) and in-hospital mortality as percentages by admission hours

Introduction: The aim of this project was to evaluate the inclusion of virtual reality (VR) during cycling-based rehabilitation sessions in critically ill patients in an intensive care unit (ICU). The study objectives included assessing patient engagement, safety, acceptability, and feasibility. A diverse cohort of patients was selected, including surgical, medical, mechanically ventilated, and self-ventilating patients.
Methods: This quality improvement project utilised a VR headset from Meta, funded by SPARK Innovation Funding 2023. Approval for evaluation was granted by the St James's Hospital Research Innovation Hub. The software used was VZfit, an interactive game that allows patients to cycle through various cities worldwide. A cadence sensor was integrated into the software, enabling the patient's effort to correspond with their virtual avatar.
Patients were selected by the treating physiotherapist based on predefined inclusion criteria (capacity to actively engage, no visual or auditory dysfunction, no musculoskeletal impairments, and no cognitive impairment). Once deemed eligible, patients provided consent for VR-assisted cycling evaluation.
Pre and post-intervention vital signs were documented, and continuous monitoring was performed throughout the sessions. Feedback was collected using verbal responses or implied gestures (nodding for yes, shaking head for no). Closed-ended questions were used to assist patients who could not verbally respond, including: "Do you want to continue?", "Is it enjoyable?", and "Do you feel unwell?". The session was discontinued if the patient requested to stop or if adverse effects occurred, such as excessive discomfort, dizziness, or significant changes in vital signs (SpO2 drop > 4%, MAP < / > 20% of baseline, HR < / > 20% of baseline). Standardised feedback tools included, the

Client Satisfaction Questionnaire-8 (CSQ-8), Simulator Sickness Questionnaire (SSQ), and System Usability Scale (SUS). No patient identifying information was collected.
Results: Fourteen VR-assisted cycling sessions were conducted, with none discontinued due to adverse events or patient discomfort. The duration of cycling ranged from 5 to 25 min, while the VR setup and disassembly required approximately 10 min each. All patients rated their experience as good or excellent on the CSQ-8. Regarding simulator sickness, minor issues reported included fatigue (N = 5/14) and increased salivation (N = 6/14). Additionally, general discomfort (N = 3/14), sweating (N = 3/14), and difficulty focusing (N = 4/14) were reported, but most were categorised as slight in severity. Usability assessment using the SUS yielded a median score of 82%, which is classified as "excellent" (> 80.3%) according to usability standards, suggesting this device was easy to use.
Conclusions: Our findings suggest that VR assisted cycling rehabilitation is both feasible and well-tolerated in critically ill patients, enhancing their overall rehabilitation experience. While mild simulator-related sickness, was noted, it did not negatively impact engagement. Although intensity was not formally measured, anecdotally, patients demonstrated increased effort when using VR. Future studies should explore the potential functional gains VR may facilitate in critically ill patients undergoing rehabilitation.

Oxidized albumin postoperatively in liver transplant patients

B. Dabbagh[1]; M. Amouzandeh[2]; G. Nowak[3]; J. Wernerman[2]; Å. Norberg[2]; O. Rooyackers[2]
[1]Perioperative Medicine and intensive Care, Karolinska University Hospital-Huddinge, Stockholm, Sweden; [2]Division of Anesthesiology and Intensive Care, CLINTEC, Karolinska Institute and University Hospital, Huddinge, Stockholm, Sweden; [3]Division of Transplantation Surgery, CLINTEC, Karolinska Institute, Stockholm, Sweden
Correspondence: B. Dabbagh
Intensive Care Medicine Experimental*, *2025;*13(1)**: ***000394

Introduction: Patients with liver failure exhibit significantly reduced albumin levels due to compromised hepatic synthetic capabilities. Albumin, a multifunctional protein, is crucial in regulating osmotic pressure, transporting various substances, and scavenging oxidative stress. Oxidative stress leads to albumin oxidation, impairing its binding capacity to metal ions, metabolites, and drugs. Chronic liver failure is associated with higher proportions of oxidized albumin, correlating with reduced binding capacity, disease severity, and outcomes (1). Notably, hospital-supplied human albumin for supplementation contains approximately 75% oxidized albumin, with unclear implications for patient outcomes.
Objectives: The objective of this study is to describe the oxidative state of albumin following liver transplantation and relate this to preoperative clinical status and perioperative albumin infusions.
Methods: We included 152 liver transplant patients at Karolinska University Hospital from 2018 to 2020 listed for liver transplantation. Blood samples were collected on postoperative days 1 (POD1), 3-6 (POD3), and 7-10 (POD7). For this retrospective analysis, complete data were available for 109 patients. Oxidized albumin levels were quantified using high-performance liquid chromatography (HPLC), focusing on human mercaptalbumin (HMA, reduced), human non-mercaptalbumin 1 (HNA1, reversibly oxidized), and HNA2 (irreversibly oxidized). Mixed models were used for analysing postoperative albumin. Single and multiple regression analyses were performed correlating clinical parameters and oxidized albumin levels (Prism Graphpad 10).
Results: HNA1 levels were approximately normal post-transplantation, with slight increases over time (Fig. 1). HNA2 levels were high post-transplantation but decreased slightly in subsequent days (Fig. 1). HNA1 levels were unrelated to preoperative liver failure status or perioperative albumin infusion. Conversely, HNA2 levels were related to low preoperative albumin and perioperative albumin administration later during the postoperative period (POD3-10).
Conclusions: Post-liver transplant HNA 2 levels are high, whereas HNA 1 are in general in the normal range. However, only during the later postoperative period (after day 3) the high HNA 2 levels were related to the infused albumin, which means that other factors should explain the high levels immediately after transplantation.

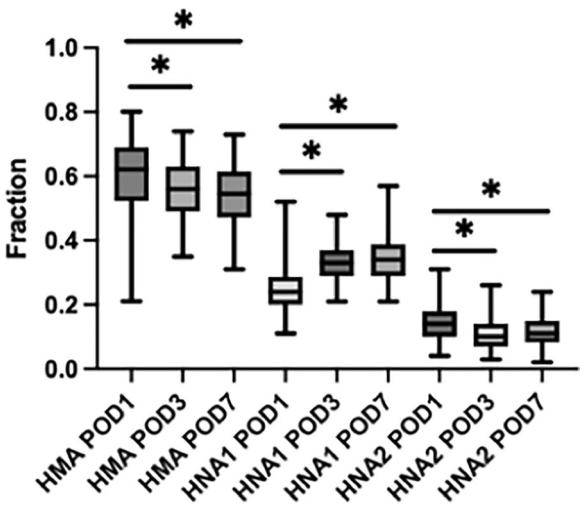

Fig. 1. (abstract 000394) Fractions of human mercaptalbumin (HMA, reduced), human non-mercaptalbumin 1 (HNA1, reversibly oxidized), and HNA2 (irreversibly oxidized) in plasma on postoperative days 1 (POD1), 3-6 (POD3) and 7-10 (POD7). *: significantly different from POD1.

Intensive Care Medicine Experimental*, *2025;*13(1)**: ***000395

Introduction: Femoral artery sheath insertion is a common resuscitation procedure frequently performed in the emergency room and intensive care unit in emergency and intensive care medicine; however, most research on complications has focused on cardiovascular medicine. In cardiovascular medicine, complications associated with femoral artery sheath insertion have been reported to be approximately 1.5–9.0%, but no studies have examined sheath insertion complications in emergency and intensive care settings where fluoroscopy is unavailable. This study investigated complication rate and risks of femoral artery sheath insertion under non-fluoroscopic resuscitation in emergency and intensive care medicine.
Methods: This retrospective, single-center observational study included patients who underwent femoral artery sheath insertion for resuscitation under non-fluoroscopic conditions between April 2014 and August 2024 and subsequently underwent computed tomography (CT). We defined the conditions requiring resuscitation as shock, cardiac arrest (CA), and post-CA. Patients were categorized into the non-complication and complication groups (Fig. 1). Vascular insertion positions were measured using CT, and these were classified as above, upper 1/3, middle, lower 1/3, or below the femoral head, or as unmeasurable (Fig. 2). Based on previous research, a vascular puncture at femoral head height was defined as a safety zone puncture. Vascular insertion positions, patient backgrounds were compared between the two groups.
Results: The study included 127 patients in the non-complication group and 40 in the complication group. The complication rate was 24.0%. In the patient backgrounds, complication group had only a significantly higher body mass index ($p = 0.045$). A significant difference was observed in vascular sheath insertion position ($p < 0.001$). The proportion of sheath insertions at the middle of the femoral head was higher in the non-complication group (34.6% vs. 10.0%), whereas insertions below the femoral head were more frequent in the complication group (18.1% vs. 52.5%). Safety-zone punctures were more frequent in the non-complication group (80.0% vs. 40.0%, $p < 0.001$) (Fig. 3), whereas superficial femoral artery or deep femoral artery punctures were more common in the complication group (12.6% vs. 32.5%, $p = 0.007$).
Conclusions: The complication rate for femoral artery sheath insertion for resuscitation without fluoroscopy was 24.0%. Vascular puncture below the femoral head was more frequent in the complication group than in the non-complication group. These findings highlight the need for improved techniques to minimize complications associated with non-fluoroscopic vascular access. Future studies should evaluate ultrasound guidance and operator experience. Multicenter research is needed to enhance generalizability of the risk factors identified in this study, and standardized protocols may help optimize patient safety and outcomes.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000396***

Introduction: Mechanical ventilation and supplemental oxygen expose lung tissue to potentially injurious energy, quantified as mechanical power (MP) and chemical power (CP), respectively. Both MP and CP are independently associated with lung injury and postoperative complications. Despite this, clinical guidelines recommend high intraoperative oxygen fractions to enhance airway safety and reduce infection risk. Preclinical data suggest MP and CP may synergistically worsen lung injury, though clinical evidence remains unclear.
Objectives: We used the REPEAT database, which harmonizes data from three randomized trials, to evaluate whether intraoperative MP and CP are associated with postoperative pulmonary complications

(PPC). We hypothesized that each independently contributes to PPC risk, and that their combination further increases risk through interaction.

Methods: This secondary analysis of REPEAT did not require supplemental IRB approval in addition to the approval granted to each individual trial. Our study protocol was attached to the clinicaltrials.gov entry for REPEAT (NCT03937375). CP and MP were defined as their intraoperative time-weighted average, calculated as the area-under-the CP or MP time-curve divided by hours of exposure. PPCs were defined as those that occurred within seven days postoperatively, as per the original trials' definition. Confounders were determined a priori and adjusted for in all analyses. Patients missing data for any confounder, who had a surgery shorter than two hours, or MP > 30 J/min were excluded from the analysis. We assessed the association between CP and MP on PPCs using multivariable logistic regression, and standardized coefficients to estimate the effect of a 1 J/min change in CP or MP. We tested the synergistic harm of CP and MP using an interaction term.

Results: Of 3,837 patients, 2,492 were included in the analysis (Fig. 1). Intraoperative average time weighted CP and MP were 10.2 ± 3.9 J/min and 10.5 ± 4.4 J/min, respectively. An increase of 1 J/min in CP was associated with 8% higher odds of PPCs (OR 1.08 [95%CI 1.05 to 1.10]; P < 0.001), while the same increase in MP raised odds by 5% (OR 1.05 [95%CI 1.02 to 1.08]; P = 0.003; Fig. 2). The absence of a significant interaction between CP and MP (P = 0.40) suggests additive rather than synergistic effect on PPC risk (Fig. 3).

Conclusions: Both intraoperative CP and MP are independently associated with PPCs. Their effects are additive, rather than synergistic.

Intensive Care Medicine Experimental, 2025;*13(1)**: ***000398

Introduction: The diagnosis of sepsis remains a major challenge and early and accurate diagnosis are central to improving outcomes. No single biomarker fully captures this syndrome's complexity. Pancreatic stone protein (PSP), C-reactive protein (CRP), and procalcitonin (PCT) each reflect different aspects of the host response to infection. We hypothesized that a combination of biomarkers would prove complementary in enhancing the accurate diagnosis of sepsis.

Objectives: To assess the potential of various combinations of PSP, CRP, and PCT for both the diagnosis and exclusion of sepsis, laying the groundwork for optimized biomarker-based diagnostic algorithms.

Methods: A pooled post hoc analysis was conducted using data from two large ICU clinical studies that followed similar protocols. Sepsis-3 definition was used. The first study (EU) had an adjudicated sepsis prevalence of 21.8% while the second (U.S.) had 48.5%. The pooled cohort included 688 patients. The diagnostic performance of PSP, CRP, and PCT was analyzed individually and in combination.

- For ruling in sepsis, a logical OR method was used, considering a test positive if at least one biomarker exceeded its threshold.
- For ruling out sepsis, a logical AND method was used, considering a test negative only if all combined biomarkers were below

their thresholds. Receiver operating characteristic (ROC) analysis was used to evaluate sepsis detection and exclusion.

Results: PSP demonstrated strong diagnostic performance for sepsis detection, with an AUC of 74.9% (CI95: 71.2%-78.7%). The logical OR combination of PSP with CRP improved the diagnostic accuracy for identifying sepsis, while reliance on PCT added little to either PSP alone or PSP/CRP:

- PSP + CRP: 80.2% (CI95: 76.8%-83.7%)
- PSP + PCT: 78.8% (CI95: 75.3%-82.3%)
- PSP + CRP + PCT: 80.8% (CI95: 77.4%-84.2%)

For sepsis exclusion, PSP alone had an AUC of 75.0% (CI95: 71.5%-78.5%). The logical AND combination of PSP AND CRP led to the highest accuracy for ruling out sepsis while employing PCT in and form of combination did not statistically increase accuracy:

- PSP + CRP: 80.2% (CI95: 77.0%-83.3%)
- PSP + PCT: 78.7% (CI95: 75.4%-82.0%)
- PSP + CRP + PCT: 76.6% (CI95: 73.2%-80.0%)

The ROC curves illustrate the improved diagnostic accuracy achieved when combining PSP with CRP and PCT (Fig. 1).
Conclusions: These findings suggest that the combination of PSP and CRP offers the best diagnostic performance for both identifying and excluding sepsis. PSP + CRP (OR) showed high accuracy for ruling in sepsis, while PSP + CRP (AND) performed best for ruling out sepsis. These results support a biomarker-driven approach using tailored algorithms to improve sepsis diagnosis.

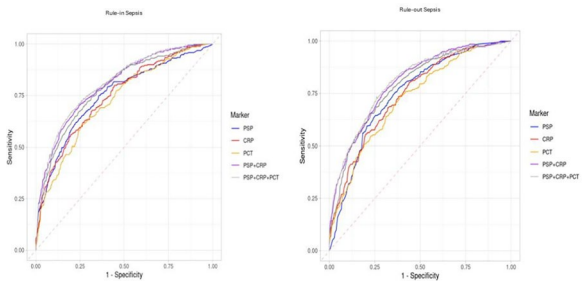

Fig 1 (abstract 000398) ROC curves illustrating the individual and combined diagnostic performance of PSP, CRP, and PCT for ruling in and out sepsis. The left panel shows ROC curves for sepsis detection using the OR combination, while the right panel shows performance for sepsis exclusion using the AND combination

Introduction..
Objectives: To compare ICU, in-hospital and 6-month mortalities as well as functional outcome (as per modified Rankin scale scores at 6 months), of acute ischemic stroke patients with ASPECTS ≤ 7 on computed tomography and treated with mechanical thrombectomy (MT) versus patients with ASPECT > 7.
Methods: Retrospective study (January 2015-May 2024) that includes all patients who underwent MT and were admitted to the ICU of a tertiary university hospital. Collected variables: age, gender, risk factors (hypertension, diabetes, dyslipidemia, smoking/alcohol consumption, atrial fibrillation, antiplatelet/anticoagulant therapy), Rankin score at admission, NIHSS at diagnosis, symptoms-to-hospital and symptom-to-recanalization times, IV fibrinolysis, ICU and hospital lengths of stays and ICU, in-hospital, and 6-month mortalities. Functional dependence was defined as an mRankin score > 3 at 6 months. Quantitative variables: mean ± SD, median (IQR 25–75). Categorical variables: absolute value (%). Statistical analysis: Chi-square, Fisher's test, Wilcoxon test, and logistic regression as appropriate. Statistical significance: $p < 0.05$.
Results: A total of 395 patients were included, of which 120 (30.4%) had ASPECTS ≤ 7. When comparing ASPECTS ≤ 7 vs. ASPECTS > 7, no differences were found in: age (69 ± 14 vs. 72 ± 13 years), gender [male: 57 (48%) vs. 135 (50%)], risk factors, Rankin at admission [0 (0–1) vs. 0 (0–1)], symptoms-to-hospital (3 ± 3 vs. 3 ± 3 h), and symptoms-to-recanalization [5 ± 2 (30% wake-up stroke) vs. 5 ± 2 h (20% wake-up stroke)] times, IV fibrinolysis [30 (25%) vs. 95 (35%)], and hospital length of stay [12 (6–23.5) vs. 11 (7–19.5) days].Differences were found in: NIHSS at diagnosis (18 ± 5 vs. 15 ± 6 points); ICU stay [1 (1–4.25) vs. 1 (1–2) days]; ICU [22 (18.3%) vs. 22 (8%)], in-hospital [39 (32.5%) vs. 49 (17.8%)] and 6-month [48 (40%) vs. 58 (21%)] mortalities; and mRankin > 3 at 6 months [85 (70.8%) vs. 123 (44.7%)]. After adjusting by NIHSS, ASPECTS ≤ 7 was independently associated with: ICU [OR 2.22 (1.15–4.30)], in-hospital [OR 1.71 (1.02–2.86)] and 6-month [OR 1.85 (1.13–3.04)] mortalities as well as with mRankin > 3 at 6 months [OR 2.95 (1.19–7.54)].
Conclusions: A careful evaluation of patients with ASPECTS ≤ 7 who are being considered for MT is essential. The use of complementary tests, such as perfusion CT, in the decision-making algorithm may help improve the identification of those who are most likely to benefit from mechanical thrombectomy while minimizing its associated risks.

Intensive Care Medicine Experimental*, *2025;*13(1)**: ***000402.

Introduction: Prolonged mechanical ventilation (PMV) deteriorates diaphragmatic function, leading to dysfunction (DD) and difficult weaning from MV. Between 13 and 35% of these patients require a tracheostomy (TQT). Although TQT eases disconnection, it may have complications. Inspiratory muscle training (IMT) can reverse DD and reduce TQT duration. This study assesses whether a 2-week individualized IMT protocol combining strength and endurance improves DD in patients with TQT due to PMV compared to a standardized protocol.

Methods: Patients ≥ 18 years old on MV via TQT, with a Glasgow Coma Scale (GCS) score > 11 and S5Q Scale > 3, were included. Informed consent was obtained (Ethics No. 263, CEC Hospital San Juan de Dios). Twenty-four hours after TQT placement (baseline), subjects were randomized into either a control group (CG), receiving strength-based IMT (50% of maximal inspiratory pressure, MIP) once daily, or an intervention group (IG), following an individualized IMT protocol combining strength (60% of MIP) and endurance training (30% MIP) twice a day (Fig. 1). At baseline and on day 15, MIP, maximal expiratory pressure (MEP), and quality of life (EQ-5D) were assessed. DD was evaluated via ultrasound, measuring diaphragm thickening fraction (DTF) and diaphragmatic excursion (DE). Additionally, TQT duration, ICU length of stay, and total hospital length of stay were analyzed.
Results: To date, 34 patients have been recruited, with 13 randomized to CG and 21 to IG. MIP significantly increased in both groups after the training period, from 33.1 ± 10 to 46.6 ± 16 in CG (p = 0,0002) and from 33.3 ± 12 to 49.0 ± 14 in the IG (p < 0,0001). MEP also increased, from 40.9 ± 27 to 60.4 ± 34 in the CG (p = 0,0002) and from 34.6 ± 16 to 48.5 ± 23 in the IG (p = 0,0006). Diaphragmatic thickness increased significantly in the intervention group (from 26.4 ± 12 to 37.7 ± 10, p = 0.0001), whereas in the control group, a trend toward an increase was observed, from 30.7 ± 14 to 44.6 ± 18, with a p-value of 0.0583. However, no significant changes were observed in diaphragmatic excursion in both groups (Fig. 2 and 3). When analyzing the EQ-5D, a significant decrease in the score was observed in the intervention group by day 15 post-intervention (p = 0.0333), indicating an improvement in the patients' quality of life. This finding was not observed in the control group. Finally, there were no differences between groups in tracheostomy days, ICU stay, and hospital length of stay.
Conclusions: An individualized inspiratory muscle training protocol combining strength and endurance significantly improved inspiratory and expiratory muscle strength, diaphragmatic thickness, and quality of life in patients with tracheostomy due to prolonged mechanical ventilation. These findings suggest that a tailored IMT approach may be beneficial in reversing diaphragmatic dysfunction, although further research is needed to assess its impact on clinical outcomes such as ICU and hospital length of stay.

Introduction: Critical Care Outreach Teams (CCOTs) facilitate the management of deteriorating patients on the wards, participate in treatment escalation planning, but also provide staff education and support post-ICU discharge [1, 2]. Over time, CCOTs have expanded their role integrating advanced technologies like ultrasound and echocardiography, further enhancing their capabilities [3]. Nonetheless, the optimal composition of CCOTs, the appropriate activation triggers and their exact role remain under-searched [1].
Objectives: We aimed to quantify the distribution of CCOT time between direct and indirect care (see below), and identify any differences between tasks undertaken by physicians and nurses.
Methods: This observational study was conducted at a large London teaching hospital (950 beds). The CCOT is comprised of a consultant, two senior doctors-in-training and three senior ICU nurses/ day shift, reducing to two nurses/night shift. Independent observers recorded CCOT activities using anonymised standardised documentation. Direct patient care comprised of face-to-face interaction between the clinician and the patient. Indirect care encompassed other patient-relevant activities but not performed in their presence. Observers tracked workflow interruptions, delays, and interdepartmental interactions.

Results: A total of 62.5 h of observation were documented, 28,5hs and 35 h following doctors and nurses, respectively (Fig. 1). Seventeen hours (31%) of CCOT time was dedicated to direct patient care, while 69% (39 h) was spent on indirect tasks. An additional 12% (6.5 h) involved unexpected activities, such as debriefing ward teams after cardiac arrest (13 min), checking bed spaces for equipment (12 min) and waiting with intubated patients for transfer (32 min). The CCOT doctors spent 94% of time (374 min) on clinical examination and 6% on cardiopulmonary resuscitation. In contrast, CCOT nurses spent 66% of their time on clinical examination, 29% (182 min) on resuscitation, and 6% on treatment initiation (setting up high flow oxygen, preparing arterial lines), emphasising their active role in interventions. Documentation occupied the majority of indirect care time, followed by interdepartmental communication (Table 1).
Conclusions: CCOT clinicians spend a disproportionate amount of time on administrative tasks, limiting direct patient care. Nurses play a hands-on role, engaging in both assessments and interventions, while doctors focus primarily on documentation and communication. Understanding the tasks holding the attention of outreach teams may facilitate forward planning around their recruitment and education. It may also promote investment on digital documentation, task delegation, and enhanced coordination to improve efficiency and even patient outcomes. Our work provides valuable insight in the everyday workload of CCOT and can be used for streamlining the team's workflow processes, aiming to enhance its overall effectiveness.

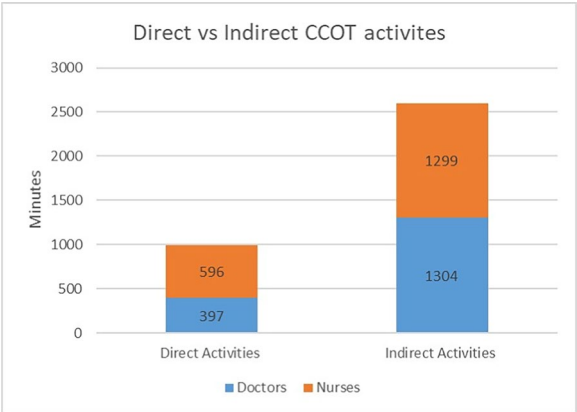

Fig. 1 (abstract 000403) Overview of direct vs Indirect CCOT activities

Table 1 Breakdown of direct and indirect activities for CCOT doctors and nurses

Direct Activity (mins)	**Doctor (%)**	**Nurse (%)**
Clinical Examination	374 (94)	414 (66)
CPR	23 (6)	182 (29)
Total Direct Activities	**397**	**596**
Indirect Activity (mins)	**Doctor (%)**	**Nurse (%)**
Documentation	493 (45)	518 (42)
Professional communication	434 (40)	453 (37)
Assisting Ward Clinicians	45 (4)	102 (8)
Managing Supplies	127 (12)	99 (8)
Review Patient Records	205 (16)	127 (9)
Total Indirect Activities	1304	1299

Introduction: Anemia is a common condition in intensive care units (ICUs), often present upon admission or developing during hospitalization, primarily due to blood loss from frequent sampling. Thirty-seven (37) to 44% of patients are transfused during their ICU stay (1). While transfusions are essential in cases of severe hemorrhage with hypovolemia, their benefits in anemia without significant blood loss remain uncertain. Several studies have reported increased morbidity and mortality due to "storage lesions" of older blood leading to structural, biochemical and metabolic changes (2–4). Moreover, transfusion of 'older' RBCs has been associated by some with an increase in morbidity and mortality in surgical and polytrauma patients (5).
Objectives: This study investigates the impact of RBC storage duration on transfusion outcomes and compares the efficacy of older versus newer blood.
Methods: This is a retrospective descriptive study of patients admitted between January 2014 and January 2021 who received RBC transfusion in a Tunisian ICU.
Data were collected from medical and transfusion records including clinical status, pre-transfusion assessments, transfusion indications, RBC storage duration, and post-transfusion outcomes. Age of the transfused packed RBC was recorded in the transfusion registry. Transfusion yield per episode was expressed as the change in hemoglobin. Statistical analysis was conducted using SPSS software.
Results: Six hundred nine (609) patients were admitted during the study period. Eighty (80) received RBC transfusion. One hundred fifty (150) transfusion episodes were recorded, with a total of 236 packed RBCs. The mean patient age was 57.1 ± 18.5 years.
Acute respiratory failure was the leading cause of ICU admission (65%). The APACHE II score was 20.4 ± 9.4. The mean hemoglobin level at admission was 9 ± 2,7 g/dl, and the mean pre-transfusion hemoglobin level was 6.9 ± 1.1 g/dl. RBC storage duration ranged from 1 to 5 days (14%), 6 to 10 days (30.7%), and 11 to 19 days (39.3%).
The overall transfusion yield per transfusion episode was 2.6 g/dl in the group where the storage duration of red blood cells was less than 5 days. In contrast, when RBCs were 20 days old or more, the yield was 0.8 g/dl ($P = 0.0001$). The average yield per packed RBC was also higher for shorter storage durations (2.23 g/dl vs. 1.6 g/dl, $P = 0.029$).
The ICU length of stay ranged from 1 to 208 days. The overall mortality rate was 47.5%, The main cause was refractory septic shock (63.2%). There was no statistically significant association between RBC storage duration and mortality. Multivariate analysis identified hemodynamic instability as significant predictor of mortality.
Conclusions: RBC transfusions are associated with improved hemoglobin levels, especially for RBCs with shorter storage durations. Age of transfused blood did not significantly impact mortality.

Introduction: Myocardial stunning, a transient impairment of cardiac contractility without irreversible damage, is well-documented in chronic hemodialysis but underexplored during continuous renal replacement therapy (CRRT) in critically ill patients. This study aims to evaluate the incidence of myocardial stunning during CRRT and its association with clinical outcomes.
Objectives: This study aimed to evaluate the prevalence of myocardial stunning in ICU patients undergoing CRRT, describe its echocardiographic characteristics and temporal evolution, and assess its impact on clinical outcomes, including mortality, ICU/hospital length of stay, and vasopressor needs.
Methods: A prospective observational study was conducted over 11 months (August 2023 – June 2024) in the ICU at Mohammed V University Hospital, Oujda, Morocco. Inclusion criteria: adult ICU patients with acute kidney injury (AKI) requiring CRRT. Exclusion criteria: pre-existing severe LV dysfunction, significant valvular disease, arrhythmias, poor echogenicity, and age < 18.
CRRT was delivered as continuous veno-venous hemodiafiltration (CVVHDF). Echocardiographic evaluations (with speckle-tracking) were performed at baseline (H0), 8h (H8), and 24h (H24) post-CRRT initiation. Parameters included LVEF (Simpson's method), GLS, and segmental longitudinal strain. Myocardial stunning was defined as a > 20% reduction in segmental strain per ASE guidelines.
Clinical and laboratory data were collected pre- and post-CRRT. Vasopressor doses, SOFA scores, MAP, and PCO_2 gap were recorded. Statistical analyses included paired tests, logistic regression, correlation analyses, and Kaplan–Meier survival curves. Significance: $p < 0.05$.
Results: Thirty-eight patients were included in the final analysis (mean age: 48 years; 57.9% male). Myocardial stunning occurred in 60.5% of patients and was associated with significantly higher mortality (47.8% vs. 6.7%, $p < 0.001$), increased vasopressor requirements (Δdose $p < 0.001$), and prolonged ICU (median 10 vs. 5 days) and hospital stays (median 14 vs. 8 days). Declines in LVEF and GLS were statistically significant over time. Septic shock, higher SOFA scores, prior stroke, and chronic kidney disease were predictive factors for myocardial stunning.
Despite CRRT's reputation for hemodynamic stability, myocardial stunning was frequent and clinically significant. The underlying mechanisms appear multifactorial, involving ischemia–reperfusion injury, vasopressor-induced oxygen demand/supply mismatch, and systemic inflammation, particularly in septic shock. These findings challenge the assumption that CRRT protects against cardiac stress and highlight the need for targeted cardiac monitoring. The strong correlation between stunning and adverse outcomes underscores its potential as a prognostic marker and therapeutic target.
Conclusions: Myocardial stunning is highly prevalent during CRRT in critically ill patients and is associated with worse clinical outcomes. These findings underscore the need for early identification, optimized hemodynamic management, and potential preventive strategies to mitigate cardiac injury during CRRT.

Table 1 Breakdown of direct and indirect activities for CCOT doctors and nurses

Patient ID	age	sex	BMI	Baseline comorbidities	Admission diagnosis	SOFA	Survival outcome
1	24	Female	23,1	Diabetes	Septic shock	5	Alive, off RRT
2	19	Female	22,1	diabetes	Septic shock	9	Alive, off RRT

Hemoglobin trends during HIPEC cases—spontaneous recovery

M. Ryll[1]; W. Toby[1]; D. Atousa.[1]
[1]Department of Anesthesiology and Perioperative Medicine, Mayo Clinic, Rochester, United States of America.
Correspondence: M. Ryll.
Intensive Care Medicine Experimental*, *2025;*13(1)**: ***000408.

Introduction: During cytoreductive surgery with hyperthermic intraperitoneal chemotherapy (HIPEC), heated chemotherapeutic agents are infused into the peritoneal cavity, leading to thermal stress, fluid/electrolyte shifts, and hemodynamic changes. (1) Although the HIPEC phase typically involves minimal blood loss, patients often experience a decline in hemoglobin (Hgb) level. (2, 3) Our clinical impression is that a spontaneous post-HIPEC Hgb recovery occurs postoperatively. This study examines perioperative Hgb changes in our HIPEC practice.
Methods: Medical records of patients undergoing HIPEC surgeries from 2018 to 2023 were reviewed for perioperative Hgb values, surgical timings, demographics, intraoperative fluid administration, and perioperative transfusions. First intraoperative Hgb, pre-HIPEC, HIPEC nadir, intraoperative nadir, and first postoperative Hgb values were extracted. Patients with intraoperative transfusion, transfusion before first postoperative Hgb, missing HIPEC timestamps, or missing Hgb values were excluded. Hgb features were analyzed univariately and adjusted for baseline Hgb, demographics, fluids, surgery duration, and intra-individual correlation using a mixed effects multivariable linear regression model. Model fit was evaluated by examining the residuals and comparing the results with a residual-outlier-reduced model due to mildly heavy tails on QQ analysis, which did not change results meaningfully.
Results: 191 HIPEC surgeries from 154 patients were analyzed. Median age was 58.7 years, procedure duration 5.3 h, and intraoperative crystalloid use 4.3 L. After adjusting for potential confounders and controlling for baseline Hgb and intra-individual correlation, the mean Hgb change was -1.24 g/dl (95% CI: -1.12 to -1.35; $P < 0.001$) from pre-HIPEC to HIPEC nadir, 0.56 g/dl (0.47 to 0.64; $P < 0.001$) from HIPEC nadir to postoperatively, and 0.76 g/dl (0.62 to 0.90; $P < 0.001$) from intraoperative nadir to postoperatively. Each model fit well and was robust to outliers. The attached figure illustrates the distribution of Hgb features and change in Hgb. Baseline Hgb and surgery duration significantly impacted hemoglobin trends.
Conclusions: We observed spontaneous hemoglobin recovery from intraoperative nadir to postoperative levels after adjusting for confounders. This may be due to hemodilution from fluid administration and perfusate absorption, with hyperthermic HIPEC increasing fluid shifts. Postoperative redistribution likely contributes to hemoconcentration and Hgb normalization. This supports restrictive transfusion practices and has the potential to improve perioperative fluid management, optimize transfusion strategies, and enhance overall patient safety during HIPEC procedures. Further research is needed to fully characterize these fluid shifts and their clinical implications.

Intensive Care Medicine Experimental*, *2025;*13(1)**: ***000409.

Introduction: Acute kidney injury is a common and serious complication of cardiac surgery, often linked to the use and duration of cardiopulmonary bypass (CPB). While novel biomarkers show promise for early detection, their complexity limits routine use. The hemolysis index (HI), a low-cost and widely available parameter, has been proposed as a surrogate marker of hemolysis and a potential predictor of cardiac surgery-associated AKI (CS-AKI).
Objectives: The aim of this study is to retrospectively evaluate the role of the hemolysis index and CPB time as predictive markers for acute kidney injury (AKI) in patients undergoing cardiac surgery.
Methods: This retrospective cohort study included patients admitted to the Cardiothoracic ICU of the University Hospital IRCCS San Gerardo dei Tintori following cardiac surgery between 2019 and 2023. The hemolysis index (HI) was measured at ICU admission. CS-AKI and its severity were defined using KDIGO creatinine-based criteria. Logistic regression, multivariable modeling, and ROC curve analysis were used to assess the association of HI and cardiopulmonary bypass (CPB) time

with CS-AKI. The Cleveland Score, a validated preoperative risk assessment tool that estimates the likelihood of developing acute kidney injury (AKI) after cardiac surgery, was included in multivariable models to adjust for baseline AKI risk.
Results: A total of 1,195 patients were included. Median CPB time was 110 [IQR 80–140] minutes, whereas median HI at ICU admission was 25 [IQR 15–42]. HI was significantly associated with CPB use (27 [16–44] vs. 10 [5–16] in off-pump surgery, $p < 0.001$) and CPB duration (Pearson $r = 0.367$, $p < 0.001$). CS-AKI developed in 102 patients (9%). When integrated into a multivariate model HI and CPB time resulted as significantly associated with a higher risk of CS-AKI (OR per HI 60-unit increase: 1.52, 95% CI 1.04–2.18, $p = 0.027$; OR per hour increase of CPB time 1.32, 95% CI 1.08–1.63, $p < 0.001$). ROC analysis demonstrated limited ability of HI or CPB duration to determine the overall risk of CS-AKI (AUC = 0.55 and 0.63 for HI and CPB, respectively) but improved performance for moderate–severe AKI (AUC = 0.67 for HI and 0.65 for CPB). Adding HI and CPB duration to the Cleveland Score marginally improved AKI prediction (AUC increase from 0.75 to 0.77, $p = 0.09$) but significantly enhanced severe AKI prediction (AUC increase from 0.62 to 0.72, $p = 0.019$).
Conclusions: Both hemolysis index (HI) and cardiopulmonary bypass (CPB) time emerged as independent predictors of cardiac surgery-associated AKI. These findings support further evaluation of CPB time and HI as accessible, perioperative markers for early risk stratification and targeted AKI prevention strategies. Integrating HI and CPB with established risk scores may enhance AKI risk stratification, guiding early interventions and improving patient outcomes.

ROC curves for the prediction of cardiac surgery-associated acute kidney injury (CS-AKI—Panel A) and moderate-to-severe CS-AKI (Panel B). Roc curves of Cleveland Score alone (red line) and the extended model including CPB time and hemolysis index (HI) (blue line) are displayed.

Forest plot of factors associated with the development of CS-AKI. This forest plot displays the odds ratios (OR) and 95% confidence intervals (CI) for each variable included in the multivariable regression model. Abbreviations: CPB, cardiopulmonary bypass.

Introduction: Vasodilation-induced hypotension is a frequent cause of ICU admission and commonly treated with intravenous vasopressors, which may increase cardiac arrhythmias and demand-related ischemia.
Objectives: The primary objective was to assess whether a MAP target of 60–65 mmHg (MAP 60–65), compared to usual care, resulted in lower values of high-sensitivity cardiac troponin T (hsTnT) at day 3 in patients receiving vasopressors for vasodilatory hypotension. Secondary objectives were to assess the effects of MAP 60–65 on other biomarkers and clinical outcomes.
Methods: This was a multi-centre, parallel-group, allocation-concealed trial (7 Canadian ICUs, February 2018–February 2020). Eligible patients aged ≥ 65 years receiving vasopressors for ≤ 12 h for vasodilatory hypotension and expected to need them for ≥ 6 more hours were randomized 1:1 to target MAP 60–65 or usual care. Exclusion criteria included acute brain/spine injury and bleeding. A protocol deviation in the MAP 60–65 group was defined as 3 consecutive hourly MAP values > 65 mmHg without reducing vasopressor dose. The primary outcome was day 3 hsTnT, adjusted for the day 1 value. Secondary outcomes included day 7 hsTnT, other biomarkers (NT-proBNP, lactate, NSE, ALT, FABP2, CKM), SOFA scores, healthcare utilization, adverse

events, mortality, and cognition among 6-month survivors (assessed using Telephone Interview for Cognitive Status [TICS]).

Results: The DSMC recommended early termination based on the contemporaneous 65 trial. 604 patients were screened, with 159 randomized and 157 analyzed (n = 76, MAP 60–65 mmHg; n = 81, usual care). Baseline characteristics were similar. MAP was higher in the usual care arm (Fig. 1), but norepinephrine daily dose was similar (Fig. 2). 24 patients (31.6%) in the MAP 60–65 group had a protocol deviation. There was no difference in day 3 hsTnT adjusted for day 1 values (MAP 60–65: median 45.8 [IQR 29.0–90.0] ng/L; usual care: 47.6 [22.7–90.0] ng/L; p = 0.91) [Fig. 3] or adjusted for (p = 0.91). Level of NT-proBNP, lactate, ALT, FABP2, and CKM were similar. Day 3 NSE was higher in the MAP 60–65 group (3.1 [2.2–4.9] vs 2.4 [1.8–4.0] ng/mL; p = 0.049) but similar at day 7 (2.9 [2.1–4.8] vs. 2.8 [2.1–4.1] ng/mL; p = 0.66). SOFA scores, arrhythmias, myocardial ischemia, acute kidney injury, mechanical ventilation, dialysis, and hospital stay were comparable (p > 0.05). ICU stay was similar (MAP 60–65: mean 6.8 days [SD 6.0] vs usual care: 8.2 [SD 11.3; p = 0.10). 90-day mortality (MAP 60–65: 24/76, 31.6%; usual care: 30/81, 37.0%; p = 0.43) was similar. TICS among 6-month survivors was similar (p = 0.76).

Conclusions. In this trial of patients with vasodilatory hypotension, levels of hsTnT did not differ between target MAP 60–65 mmHg and usual care. However, the trial was stopped early and separation between norepinephrine doses was inadequate. Given contemporaneous evidence that lower MAP targets improve survival, further mechanistic studies are required.

Introduction: Initial shockable cardiac rhythms have been linked to favorable neurological outcomes and survival [1,2,3]. However, there is a limited body of research on neurological outcomes following in-hospital cardiac arrest (IHCA) in Asian populations.
Objectives: To evaluate the effect of initial shockable rhythm on neurological outcome following in-hospital cardiac arrest in a multi-ethnic Asian cohort.
Methods: This retrospective cohort study initially identified 581 patients with an IHCA at Singapore General Hospital (SGH), a tertiary academic centre, from October 2018 to November 2021. Patients who were < 18 years old, with a do not resuscitate status, did not achieve return of spontaneous circulation for > 20 min, as well as those with IHCA in operating theatres, intensive care units and the Emergency Department, were excluded [4]. In the final cohort (n = 352), demographics, hospital location, length of resuscitation and comorbidities including sepsis, renal insufficiency (serum creatinine > 176.8 mmol/L (≤ 24 h post-IHCA)) malignancy and hypotension (systolic blood pressure < 90 mmHg or mean arterial pressure < 65 mmHg (≤ 24 h post-IHCA)) were collected and compared against initial cardiac rhythm. Cerebral Performance Category (CPC) scores were collected at discharge, with good neurological outcomes defined as CPC 1 or 2 [5].
Results: Shockable rhythms represented 14.2% of IHCA. In the univariate analysis, male gender (OR 2.110; 95% CI 1.06–4.18) and shockable rhythm (OR 11.197; 95% CI 5.57–22.53) were significant prognostic factors for favorable neurological outcomes. Poor prognostic factors were admission into a non-monitored unit (OR 0.424; 95% CI 0.22–0.83), hypotension (OR 0.270; 95% CI 0.11–0.65), renal insufficiency (OR 0.447; 95% CI 0.24–0.85), sepsis (OR 0.304; 95% CI 0.13–0.70), prolonged resuscitation of 10–14 min (OR 0.241; 95% CI 0.08–0.74), 15–20 min (OR 0.157; CI 95% 0.05—0.49), and > 20 min (OR 0.063; 95% CI 0.02–0.19).
In the multivariate analysis, shockable rhythms remained significantly associated with favorable neurological outcomes (adjusted OR 9.845; 95% CI 3.98–24.34) while hypotension (OR 0.223; 95% CI 0.07–0.70), and prolonged resuscitation durations (10–15 min: OR 0.178; 95% CI 0.04–0.80, > 20 min: OR 0.074; 95% CI 0.02–0.30) were less likely to have favorable outcomes. Renal insufficiency and location of arrest (non-monitored vs. monitored) were no longer statistically significant in the multivariate analysis. However, the point estimate for renal insufficiency in the multivariate analysis was 0.488 with a 95% CI of 0.21 to 1.11, suggesting that renal insufficiency may serve as a signal for poor neurological outcomes.
Conclusions: While most IHCA are non-shockable, favorable neurological outcomes were associated with initial shockable rhythms. Poor neurological outcomes were also associated with recent hypotension and prolonged resuscitation. The association between renal insufficiency and poor neurological outcomes warrants further investigation.

Intensive Care Medicine Experimental*, *2025;*13(1)**: ***000412.

Introduction: Anesthetic agents can cause hypotension, and be especially dangerous in patients with severe aortic stenosis, which can lead to even circulatory collapse. Remimazolam is known for its hemodynamic stability compared to propofol. This study is designed to compare effects of remimazolam vs. sevoflurane anesthesia on intraoperative hemodynamics in patients with severe aortic valve stenosis.
Methods: Patients were divided into remimazolam (R) and sevoflurane (S) group. Remimazolam group received remimazolam 6 mg/kg/h with remifentanil during induction and were maintained under anesthesia with remimazolam 1-2 mg/kg/h combined with remifentanil throughout surgery. Sevoflurane group received propofol 1% 1-2 mg/kg with remifentanil for anesthesia induction and were maintained under anesthesia with sevoflurane and remifentanil. Primary endpoint was the comparison of the amount of vasopressors used, and secondary endpoints were the comparison of mean arterial pressure (MAP) at fixed time points, hypotensive and bradycardia events, extubation time, and sedation-agitation-scale at ICU.
Results: After excluding one patient with change of surgical plan, sixty-three patients were enrolled. When comparing percentage change from baseline MAP, R group showed smaller fall from initial MAP at the start of CPB [-5.6 ± 14.9 vs. -10.1 ± 21.6; p = 0.047] and at the end of anesthesia[-30.7 ± 13.9%, vs. -38.1 ± 14.3%; p = 0.005] (Fig. 1). Section 1 was defined as start of anesthesia to start of CPB, Sect. 2 from start of CPB to end of CPB, Sect. 3 from end of CPB to end of anesthesia and Sect. 4 from start of anesthesia to the end of anesthesia. Proportion of hypotension was significantly lower in the R group at Sect. 1[34.9 ± 24.3% vs.48.1 ± 21.4; p = 0.025], Sect. 3 [80.2 ± 21.5% vs.91.9 ± 25.2; p = 0.011]and also in Sect. 4 [66.5 ± 16.9% vs.76.0 ± 16.2%; p = 0.007] (Fig. 2). Norepinephrine use was lower during Sect. 1[0.003 ± 0.008 mcg/kg/min vs. 0.017 ± 0.030 mcg/kg/min; p = 0.015], and Sect. 3[0.040 ± 0.051 mcg/kg/min vs. 0.085 ± 0.080 mcg/kg/min; p = 0.007] in the R group. Phenylephrine use was lower in Sect. 1[0.037 ± 0.061 mcg/kg/min vs. 0.073 ± 0.088 mcg/kg/min; p = 0.042] in the R group. Nicardipine use was higher in the R group in Sect. 3 [0.719 ± 0.547 mcg/kg/min vs. 0.233 ± 0.318 mcg/kg/min; p < 0.001], and Sect. 4[0.270 ± 0.185 mcg/kg/min vs. 0.109 ± 0.137

mcg/kg/min; $p < 0.001$] (Fig. 3). Extubation time was significantly shorter in the R group [4.4 ± 3.3 min vs. 9.6 ± 3.0 min; $p < 0.001$]. Sedation agitation score and intraoperative arrhythmia, postoperative complication did not show any significant difference between the two groups (Table 4).

Conclusions: Remimazolam anesthesia resulted in less use of norepinephrine and phenylephrine before start of CPB and less use of norepinephrine after CPB compared to sevoflurane anesthesia in patients undergoing minimally invasive aortic valve replacement surgery.

Intensive Care Medicine Experimental*, *2025;*13(1)**: ***000413.

Introduction: Ventilator-associated pneumonia (VAP) occurred as a result of the dysbiosis observed in patients receiving IMV. Secretory IgA may be involved in the regulation and selection of commensal microorganisms and the establishment of mutualistic host-microbial interactions. Our hypothesis is that patients who develop VAP have lower levels of secretory IgA-coated microbiota in respiratory secretions, leading to a higher inflammatory environment, dysbiosis, and an increase in pathogenic bacteria.

Objectives: This preliminary study aims to assess the feasibility of performing IgA-Seq in endotracheal aspirate samples from patients receiving invasive mechanical ventilation (IMV).

Methods: The respiratory sample was mechanically and chemically disrupted, filtered and centrifuged. Bacterial pellets were separated by centrifugation and resuspended in DPBS. Part of this suspension was reserved as an unstained total microbiome sample and the remainder was stained with a recombinant anti-IgA PE human antibody and sorted by magnetic activation cell sorting (MACS). The unstained microbiome suspension, the unsorted microbiome suspension and the negative and positive fractions of the sorted microbiome suspension were analysed by flow cytometry.
Results: Preliminary results indicate that part of the microbiome present in endotracheal aspirate samples has IgA-coated bacteria. The positive fraction of the sorted pellet has an enrichment in IgA-coated microbiome compared to the unsorted microbiome and the negative fraction of the sorted microbiome. These results are shown in Fig. 1.
Conclusions: MACS sorting can be used to select IgA-coated microbiome from endotracheal aspirate samples.

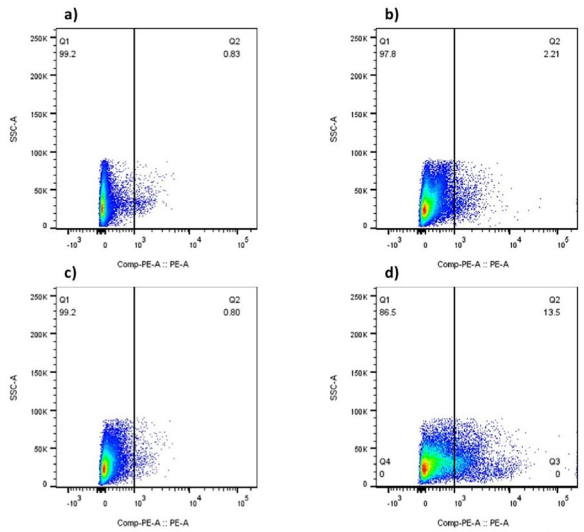

Fig. 1 (abstract 000413) Bacterial flow cytometry analyses, Q1 showing IgA- percentatge and Q2 showing IgA + percentatge of the population. Results are shown for unstained microbiome suspension (a), unsorted microbiome suspension (b), sorted negative fraction of the sorted microbiome (c) and sorted positive fraction of the sorted microbiome (d)

Incidence of adverse incidents in physiotherapy-led rehabilitation in ICU

S. McEntagart[1]; J. Dowds.[1]
[1]Department of Physiotherapy, St James's Hospital, Dublin, Ireland.
Correspondence: S. McEntagart.
Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000413***.

Introduction: Early mobilisation among intensive care unit (ICU) patients is associated with adverse events. This study aimed to identify the incidence of adverse incidents in physiotherapy led rehabilitation sessions in a large ICU in Ireland.
Methods: Approval as sought from the Saint James's Hospital Research and Innovation Office. No identifiable patient details were included in this data collection therefore ethics was not required. Data were collected across five weeks beginning in November 2024. Treating physiotherapists completed a survey for every rehabilitation contact in the general ICU. While all ICU staff were aware of the data collection, no changes in practice were made. Data collected included the rehabilitation activity, respiratory/ renal/cardiovascular support required, physiological abnormalities during intervention, patient-reported outcomes, level of harm to the patient if any, and number of staff required to complete the session.
Results: 600 patients were screened for suitability across the study period with 308 rehabilitation contacts taking place (median 14/day). The unit has a positive mobility culture with the aim of mobilising all patients into an upright position if medically suitable. Reasons for exclusion included low level of arousal, cardiovascular instability, end-of-life care, or medically requested bed rest. Of the 308 rehabilitation contacts, adverse incidents occurred in 99 rehabilitation sessions, all were determined Grade 1- near miss (n = 74) or Grade 2- mild transient harm to the patient (n = 25). In the 99 rehabilitation sessions there were 148 physiological abnormalities. The most common physiological abnormality was desaturation > 4% (n = 57); increase in FiO2/PS (n = 42); changes in mean arterial pressure less or greater than 20% (n = 16); and changes in heart rate less or greater than 20% (n = 11). Other outcomes during rehabilitation sessions included increased patient reported anxiety (n = 32); nausea/vomiting/diarrhoea (n = 8); unplanned lift to bed/chair (n = 1).
Rehabilitation sessions included sitting out to chair (n = 180); mobilising away from bedspace (n = 171); sitting on edge of bed (n = 132); marching on the spot (n = 39); and sit to stand with standing hoist (n = 35); many sessions included more than one rehabilitation activity. Rehabilitation sessions occurred in patients with complex invasive devices including positive pressure ventilation (PPV) via tracheostomy (n = 26); continuous renal replacement therapy (CRRT) (n = 15); vasopressors (n = 14); PPV via endotracheal tube (n = 6). Rehabilitation activities associated with increased risk of adverse event were mobilising (n = 41); sitting out to chair (n = 20); sitting at edge of bed (n = 16); and transferring with use of standing hoist (n = 13). Median number of trained staff per rehabilitation session was 3 (range 1–4 staff).
Conclusions: Rehabilitation activities in the ICU setting is safe. For those on complex support such as CRRT/PPV/ vasopressors there were minimal associated adverse events of no to mild harm. High levels of patient related anxiety were reported during physiotherapy-led rehabilitation sessions. Physiotherapy-led rehabilitation sessions require a high number of trained staff to safely perform. Due to limitations no data was collected on duration or level of intensity of physiotherapy-led rehabilitation sessions.
Staff who lead and assist in physiotherapy-led rehabilitation sessions in ICU need to have the experience and capacity to adapt treatments, manage mild physiological transient events, and to be able to reassure patients who experience anxiety during the intervention. Training of junior staff should highlight the complexity and physical demand of rehabilitation in the ICU setting. No studies to date have researched the effect of such adverse events on the patient's perception of rehabilitation or the effect that this has on staff post-adverse event.

Introduction: Delirium affects up to 80% of mechanically ventilated ICU patients, leading to increased mortality, longer hospital stays, and higher healthcare costs. This study aimed to enhance early detection through standardized assessment and implement evidence-based interventions to reduce delirium incidence in critically ill patients.

Methods: This quality improvement initiative was conducted in a 20-bed medical ICU from January to March 2024. All critical care nurses (n = 85) underwent structured CAM-ICU training with competency validation. A comprehensive delirium prevention bundle was developed following root cause analysis using the "5 Whys" methodology. The bundle encompassed four key domains: cognitive stimulation (including therapeutic music), environmental modification, sleep hygiene protocols, and optimised sedation strategies. Implementation followed a three-phase PDSA cycle with electronic health record integration to facilitate documentation.
Results: Analysis of 194 patients (81 pre-intervention, 113 post-intervention) showed significant improvements. CAM-ICU screening compliance increased from an initial 10% (10 assessments) to 92.2% (472 assessments) in phase one, sustaining at 89.9% (671 assessments) through subsequent phases. Delirium prevalence decreased markedly from 30.6% to 6.3% ($\chi^2 = 145.173$, $p < 0.001$). Run chart analysis confirmed sustained improvement with six consecutive points below the pre-intervention median. The shift towards dexmedetomidine-based sedation and implementation of daily sedation interruption protocols likely contributed to improved outcomes.
Conclusions: A structured, multimodal approach to delirium prevention, combining standardised assessment with evidence-based interventions, significantly reduced delirium occurrence in critical care. This quality improvement framework provides a reproducible model for delirium management in intensive care settings.

Topic: Sedation, analgesia and delirium.

Introduction: The use of inhaled volatile anesthetics for ICU sedation has gained interest due to their favorable pharmacokinetic profile and potential benefits in specific patient populations. We describe our experience implementing sevoflurane sedation using the anesthetic conserving device (ACD) in a medical ICU setting.
Methods: We conducted a prospective observational study of patients receiving inhaled sevoflurane via ACD for sedation or bronchodilation in our medical ICU between 2022 and 2024. Primary outcomes included safety, efficacy, and practical considerations of implementation. Environmental monitoring was performed to assess occupational exposure.
Results: Twenty-two patients (mean age 55 years, range 21–80) received sevoflurane for a mean duration of 107 h (range 0.2–286 h). Primary indications were sedation (68%) and bronchospasm (32%). All patients with bronchospasm showed significant improvement, and all patients demonstrated reduced requirements for intravenous sedatives/analgesics. Adverse events included transient hypotension requiring intervention (n = 4), hypernatremia (n = 2), and emergence agitation/delirium (n = 7). No cases of malignant hyperthermia were observed. Occupational exposure measurements remained within safe limits (maximum 1.2 ppm).
Conclusions: Implementation of inhaled sevoflurane sedation was feasible and safe with appropriate protocols, environmental controls, and staff training. Benefits were observed particularly in patients with bronchospasm and difficult sedation. Further research is needed to evaluate long-term outcomes and cost-effectiveness.

Introduction: The use of BioFire® FilmArray® Pneumonia Panel (FA) (BioMérieux) may help to rapidly identify pathogens responsible for ventilator-associated lower tract infections (VA-LRTIs), offering the possibility to guide antibiotic treatment. Patients with chronic obstructive pulmonary disease (COPD) have a peculiar pulmonary bacterial microbiota, presenting an increased prevalence of pathogen species such as *Pseudomonas aeruginosa*. The benefit of using FA in this population is unknown, and although promising, it could result in overuse of antibiotic therapy.
Objectives: To determine the risks and benefits of using FA in the management of VA-LRTI in intubated COPD patients.
Methods: In this prospective, observational, monocentric study, we collected invasive respiratory samples at the time of VAP diagnosis and processed them with both standard-of-care cultures (SOC) and FA. A detection threshold > 10^4 copies was considered for FA for the analyses. The percentages of detection sensitivity (Sn), specificity (Sp) and percentages of positive and negative agreement (PPA and NPA) were collected in order to compare the diagnostic performances of the two approaches.
Results: We included 97 patients (16 COPD and 81 controls) with no differences in age, sex and demographics. The use of FA was associated with faster results (1.19 h vs 47.08 h; $p < 0.001$, 95%CI 41.49 to 50.4). Table 1 reports the microbiological findings and Fig. 1 depicts the percentages of pathogen detection related to the two diagnostic methods. The use of FA demonstrated higher detection rates in the COPD group when compared to the control group (87.5% vs 59.3%; $p = 0.045$, 95%CI 1.02 to 1.45). Using the two different methods, PPA was low, whereas Sn, Sp and NPA were extremely high, up to 100 percent in the COPD group (Table 2).
Conclusions: The use of FA offers faster microbiological results but may result in overdiagnosis of VA-LRTI in COPD patients due to the extremely high sensitivity of this technique; however, its high specificity and PNA with respect to SOC could be useful to rule out etiological agents and to guide empirical antimicrobial treatment.

Table 1 Microbiological findings

	General population (n=97)		Non-COPD (n=81)		COPD (n=16)

Viruses, n (%)	-	21 (21.6)	-	17 (21.0)	-	4 (25)
***Aspergillus* spp., n (%)**	11 (11.3)	-	8 (9.9)	0 (0.0)	3 (18.7)	0 (0.0)

Abbreviations: COPD=chronic obstructive pulmonary disease; SOC= standard of care cultures; FA= FilmArray. The values for pathogens not tested with a specific technique were marked as strikethrough in the table.

Table 2 Results of sensitivity, specificity and concordance analysis

	FA+/SOC+	FA+/SOC-	FA-/SOC+	FA-/SOC-	Sn	Sp	PPA	NPA
Pathogen detection, n (%)								
Non-COPD	24 (29.6)	23 (28.4)	8 (9.9)	26 (32.1)	85.4%	76.5%	51.1%	76.4%
COPD	5 (31.1)	9 (56.2)	0 (0.0)	2 (12.5)	100%	100%	35.7%	100.0%
Multi-drug resistance detection, n (%)								
Non-COPD	3 (3.7)	1 (1.2)	7 (8.6)	70 (86.4)	36.4%	90.9%	30.0%	98.5%
COPD	0 (0.0)	0 (0.0)	1 (6.2)	15 (93.7)	0%	93.7%	0.0%	100.0%

Abbreviations: COPD=chronic obstructive pulmonary disease; SOC= standard of care cultures; FA= FilmArray; Sn= sensitivity; Sp= specificity; PPA= positive percentage agreement; NPA= negative percentage agreement. The values of sensitivity and specificity were calculated considering an extended gold standard including a positivity for at least one of the two techniques considered.

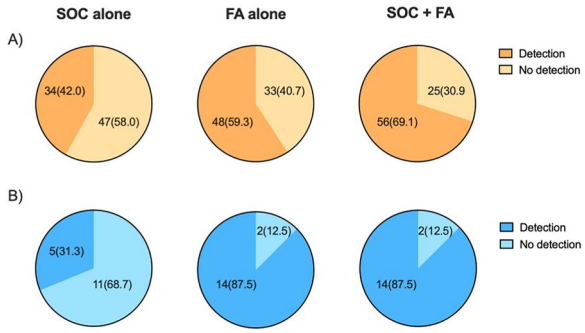

Fig. 1 (abstract 000418) Pathogen detection in the two groups. Incidence is reported as absolute value and percentage (in parentheses). A) Non-COPD patients, n = 81. B) COPD patients, n = 16. In both groups, associating FA to SOC determined a significant increment in detection. However, the percentage increase in detection was substantially greater in the COPD group.

Bioengineering immunomodulatory nanoparticles to augment neutrophil phagocytosis of bacteria

H. Xue[1]; S. Zhang[1]; M. Heydari[1]; S. Mervyn[1]; N. Arulkumaran.[1]
[1]Bloomsbury Institute of Intensive Care Medicine, University College London, London, United Kingdom.
Correspondence: H. Xue.
***Intensive Care Medicine Experimental*, *2025*;13(1): *000419*.**

Introduction: Sepsis represents life-threatening organ dysfunction due to a dysregulated host response to infection (Singer M, JAMA, 2016), representing 20% of all global deaths (Rudd K, Lancet, 2022) and considerable long-term morbidity in survivors.
With the rise in antimicrobial resistance, particularly in low-middle-income countries, infections are becoming much harder to treat (Antimicrobial Resistance Collaborators, Lancet,2024)3. Despite this urgent need, no new antibiotic class has been introduced since the 1980s and novel approaches are desperately required.
Liposome-based therapeutics have transformed global health, as exemplified by the COVID-19 mRNA vaccine that uses liposomes as the delivery vehicle. Empty liposomes also have their own intrinsic activity that can be modified to modulate biological function.
Objectives: The primary objective of this study is to develop liposomes that enhance neutrophils phagocytosis of Gram-negative bacteria.
Methods: 1. Liposomes were formulated to bind to the negatively charged outer membrane of Gram-negative bacteria.
2. Liposomal properties were systematically optimized to maximize neutrophil phagocytosis.
3. Confocal microscopy and flow cytometry were employed to assess liposome binding to bacteria and subsequent phagocytosis by neutrophils.
Results: We conducted a series of gradient screenings of liposomal compositions, and identified two distinct formulations (2134 and 334) (Fig. 1A). Flow cytometry revealed that liposome binding to E. coli occurred within seconds (Fig. 1B). Confocal imaging showed that both 2134 and 334 liposomes (purple) bind to E. coli (green), with the greatest binding observed with 2134 liposomes (Fig. 1C). Flow cytometry confirmed that Cy-5 labelled 2134 liposomes can bind to granulocytes (Fig. 1D). Confocal microscopy further demonstrated that 2134 liposomes can bind to the granulocyte surface (Fig. 1E). In addition, healthy volunteer leukocytes (neutrophils tagged with PE-labelled CD66b; red) were incubated with E. coli K12 (FITC labelled; green) in the presence or absence of Cy5-labelled liposomes (violet). Confocal microscopy showed that E. coli co-localised to intracellular compartments of neutrophils, consistent with phagocytosis (Fig. 1F and Fig. 1G). Flow cytometry was used to quantify E. coli K12 phagocytosis, which demonstrated a dose-dependent increase in neutrophil phagocytosis of E. coli in the presence of liposomes (Fig. 1H).
Conclusions: We have developed cationic liposomes that can enhance the ability of neutrophils to phagocytose Gram-negative bacteria. Future research should focus on optimizing liposome formulations, and exploring efficacy and safety in vitro and in vivo

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000420***.

Introduction: The decision to perform decompressive craniectomy (DC) must be individualized as it is an aggressive treatment, not without complications that can increase survival at the expense of severe disability.
Objectives: To describe the indication and outcomes of decompressive craniectomy (DC) in patients with acute cerebrovascular disease, both ischemic and hemorrhagic, in order to prevent secondary brain injury by reversing the mass effect and displacement of brain tissue.
Methods: A retrospective descriptive study was conducted of patients undergoing DC during the acute phase of ischemic (malignant infarction) and hemorrhagic (lobar, basal ganglia, and infratentorial hemorrhagic stroke) brain injuries. Subarachnoid hemorrhage was excluded due to its specific characteristics. The analysis covers a four-year period (2021–2024) to the ICU of the Reina Sofia Hospital of Cordoba (Spain), a tertiary referral center for neurosurgical conditions in the region. The variables evaluated included age, sex, ICU stay, brain injury severity (measured using the GCS, NIHHSS, HIC, and ASPECT scales), mortality, and functional outcomes (modified Rankin Scale).
Continuous variables were expressed as mean ± SD, ordinal variables as median (interquartile range), and qualitative variables as absolute numbers and percentages. The Chi-square test was used to compare proportions. Binary logistic regression was used for the multivariable analysis, using the stepwise method. $P < 0.05$ was considered significant.
Results: Decompressive craniectomy was performed in a total of 63 patients. In the ischemic stroke group (29 patients), 65% were men, with a mean age of 57 years (SD 13.5; range 18–75 years) and a mean ICU stay of 15 days (SD 10.7; range 2–40 days). ICU mortality was 24%, and good functionality (mRS ≤ 3) was observed in 31% of cases. In the hemorrhagic stroke group (34 patients), 59% were men, with a mean age of 55 years (SD 12.7; range 18–75 years) and a mean ICU stay of 21 days (SD 19.4; range 2–110 days). The distribution of lesions was 59% basal ganglia hematomas, 20% lobar hematomas, and 21% infratentorial hematomas. ICU mortality was also 24%, with functional independence (mRS ≤ 3) achieved in 26% of cases. When comparing observed mortality with that predicted according to the HIC score, the actual mortality was lower than estimated in the infratentorial and basal ganglia hemorrhage groups, although this was not statistically significant.
Conclusions: Decompressive craniectomy may offer the possibility of favorable functional outcome in a small proportion of patients, despite the severity of their initial condition.

Topic: Neurointensive care.

Enhancing critical illness recovery: evaluating the impact of electronic self-reported measures and a new care navigator role in follow-up care

S. Nazeer[1]; G. Mathieson,[1]; ZA. Puthucheary[1]; T. Stephens,[2]
[1]Adult Critical Care Unit, Royal London Hospital, London, United Kingdom; [2]William Harvey Research Institute, Barts and The London School of Medicine & Dentistry, London, United Kingdom.
Correspondence: S. Nazeer.
Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000421***.

Introduction: Seventy percent of patients survive critical illness(1). However this comes with a cost in terms of new chronic diseases and/or permanent disability and within one year over half suffer readmission to hospital despite interventions from critical care follow-up clinics(2–6). These physical, psychological and cognitive aspects of recovery, described as 'post-intensive care syndrome', mean that survivors have a greater dependence on health and social care for up to 5 years post–discharge (7,8). Over the course of a year 93% (153/165) of the patients seen in the critical care follow-up clinic at the study hospital required onward referrals, some of them at 2 years post-discharge from critical care. Ensuring that unmet needs are identified and acted upon early could improve recovery for this at risk population.
Objectives: To evaluate the feasibility and acceptability of a new service intended to identify and respond to unmet needs of critical care survivors earlier through the use of electronic patient-related outcomes (ePROs) and the introduction of a new care navigator role.
Methods: A single-centre qualitative study combining data obtained via an online feedback questionnaire, case notes and from semi-structured interviews with patients and clinicians involved in this pathway.
Results: 1010 critical care survivors (92% requiring support from ≥ 2 services and 47% fulfilling criteria for complex disability at point of hospital discharge) engaged in the new service. 314 of these completed an online feedback questionnaire regarding feasibility and acceptability of the use of ePROs. 96% found the online system easy to use, with 94% able to understand all the questions and 87% able to complete it independently. The new care navigator role was implemented for 127 patients in whom 76% required further actions to be carried out by the care navigator, including onward referrals (62%), signposting to services (65%) and care coordination (92%).
Interviews were conducted with 16 patients who had taken part in this new service and 7 clinicians involved in their care. Insights from patients and clinicians on the care navigator role included that "the care navigator was the key to whole thing", with patients sharing that having a link between the hospital period and returning home has helped them progress and clinicians appreciated the identification of high risk patients earlier and how the care navigator coordinated the patient journey.
Conclusions: The introduction of ePROs and a new care navigator role to compliment an existing critical care follow-up service was feasible and acceptable within this population. The care navigator role was welcomed by both the patients and the clinicians, acting as a link between the hospital teams, the patient and the follow-up care teams. Further investigation is needed to understand the characteristics of those who this service failed to engage so as to start the process of how access and engagement can be improved.

End-of-life antibiotic use in palliative care patients in the ICU

TDP. Guimarães[1]; ICP. Gomes[2]; PG. Campos[2]; PN. Rodrigues[2]; RDC. Pereira.[1]
[1]Intensive Care Unit, Hospital Felício Rocho, Belo Horizonte, Brazil; [2]Internal Medicine, Hospital Felício Rocho, Belo Horizonte, Brazil.
Correspondence: T.D.P. Guimarães.
Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000422***.

Introduction: Infections and febrile episodes are among the most common acute complications experienced by terminally ill patients. (1) There is ample evidence suggesting antibiotics are currently overused in palliative care settings. (2–5) The literature suggests that many clinicians prescribe antibiotics inappropriately for patients who would not benefit from their use. (2) In this context, there is also the risk of the emergence of multidrug-resistant pathogens. (6) Thus, there is an urgent need to critically examine and audit antibiotic use in end-of-life. (2).
Objectives: This study aims to describe the epidemiological profile of patients receiving palliative care who progress to death in an ICU and to examine the practices surrounding antibiotic use within this population. Additionally, it seeks to assess the impact of care provided by a specialized palliative care team in an intensive care unit (ICU).
Methods: We conducted a single-center, retrospective, observational study analysing medical records of patients admitted to the ICU of a private tertiary hospital in Belo Horizonte, Brazil, between January 1, 2024, and December 31, 2024. The inclusion criteria were patients receiving palliative care either before or during their ICU stay who progressed to death while hospitalized.
Results: A total of 151 medical records were analysed, and the baseline characteristics of the study population, along with the time to the palliative care decision, are presented in Table 1. It is notable that 65% of patients were indicated for palliative care after 7 days of ICU admission, which may suggest a therapeutic failure or difficulty in the early assessment of prognosis.
Among patients with a defined palliative care plan who progressed to death during hospitalization, 47% (n = 72) received antibiotics in the last 24 h of life, including 32% (n = 25) of those in the exclusive palliative care subgroup. According to medical literature, between 21% and 72.6% of patients approaching end of life were treated with antibiotics within 24 h of death. (6).
Additionally, 40% (n = 34) of patients with a defined palliative care plan and 29% (n = 16) of patients in the subgroup with a defined exclusive palliative care plan, who were under follow-up by the specialized palliative care team, received antibiotics in the last 24 h of life. This finding is consistent with data from the literature suggesting that when patients in a medical ICU, assessed as high risk for mortality, had a palliative care consultation, they received fewer and shorter courses of antimicrobials (7) (Fig. 1).
Conclusions: This study highlights the potential overuse of antibiotics in ICU patients receiving palliative care and emphasizes the importance of early intervention by specialized palliative care teams. Additionally, it underscores the need for improved guidelines to minimize unnecessary antibiotic use in terminally ill patients and reduce the risk of antimicrobial resistance

Introduction: The burden of antimicrobial resistance (AMR) is substantial, with approximately 500,000 AMR-associated deaths in Europe annually (1). Excessive and incorrect use of antimicrobials promotes resistance. Antimicrobial stewardship (ABS) programs have been shown to reduce the unnecessary use of antimicrobials and, thereby, AMR. While the German guideline on antimicrobial stewardship recommends quarterly surveillance and structured analysis of antimicrobial use and resistance (2), there is no universal implementation due to the necessity of effortful manual data collection. Many hospitals rely on data from the pharmaceutical supplier, which is neither recent nor accurate and does not reflect the actual usage of antimicrobials. Simultaneously, data extraction and harmonization from hospital patient data management systems (PDMS) poses numerous challenges, such as unifying data from different sources and filtering implausible data that likely stems from erroneous data entry. To address these challenges, we propose implementing an antimicrobial dashboard displaying usage on intensive care units from Charité-Universitaetsmedizin Berlin.
Objectives: To design and implement an antimicrobial usage dashboard within a generalizable data pipeline that can be easily implemented at hospitals extracting data in Fast Healthcare Interoperability Resources (FHIR) format. Its primary purpose is to monitor antimicrobial prescribing patterns and thereby identify excessive use of broad-spectrum or last-resort antimicrobials.
Methods: A concept and method for systematically analyzing antimicrobial usage data was developed and tested using data collected at the Charité Health Data Platform. We are extracting data for critical patients using a standardized pipeline. Baseline characteristics of the cohort are extracted to allow for the filtering of patients and visualizations in subgroups. Antimicrobial drugs were classified using the WHO AWaRe classification (3) to represent the standard and reserve drugs. Data were displayed on a Streamlit-based (www.streamlit.io) front end (Fig. 1).
Results: We retrospectively extracted antimicrobial administration data between December 2015 and March 2025 from nearly 13,000 cases admitted to the pulmonological ICU comprising over 70,000 individual antimicrobial administrations from the Charité's Health Data Platform. Each administration of an antimicrobial drug included the name of the drug, dosage, rate and unit of dosage, type of administration, and start and end time. Next, we merged patient data (e.g., age, sex, and diagnosis) onto the antimicrobial data using a common pseudonymized identifier. Various challenges were encountered during the development of an antimicrobial dashboard using data from a PDMS First, data sources need to be identified; next, data entries need to be unified, e.g., "Piperacillin 4 g" and "Piperacillin infusion". As data are extracted using drug administration, they must be correctly mapped to a specific patient. Different modes of applications need to be correctly unified and differentiated so that "i.v.", "infusion" and "oral" are correctly identified as systemic administration, and topical administration is analyzed separately. Moreover, several definitions need to be agreed upon: gaps in what duration still counts as one course of treatment and how the escalation and de-escalation of antimicrobial treatment are defined. We successfully deployed the dashboard, illustrating antimicrobial usage and prescribing patterns in various ICUs (Fig. 2).
Conclusions: Due to PDMS data's raw and heterogeneous nature, various challenges arise when developing an antimicrobial dashboard that require careful review and detailed data extraction and harmonization. A dashboard to display antimicrobial stewardship metrics for intensive care units is a promising tool which may lead to improved quality assurance efficacy and more detailed metrics. Furthermore, it can be expanded with additional modules to identify prescription and administration patterns and gain insights into specific care needs and challenges. Validating this concept in FHIR-associated hospitals is a crucial next step and could lead to easily transferable and widespread applicability. Further research is needed to evaluate the dashboard's effectiveness in enhancing adherence to ABS guidelines.

Introduction: A previously published pilot study found that modifying ICU room design was associated with a decrease in the incidence of delirium and a change in serum melatonin levels [1]. Sleep is significantly disrupted in critically ill patients and plays a crucial role in maintaining circadian rhythms and influencing the pathology of delirium [2, 3].
Objectives: To analyze if a multi-component change in room design influences sleep in critically ill mechanically ventilated patients.
Methods: This is a secondary endpoint analysis of a proof-of-concept pilot study. Two double bedrooms underwent extensive architectural modifications, including a new dynamic lighting system and noise reduction measures [4, 5]. Polysomnography (PSG) was performed in mechanically ventilated patients for a maximum of three 24-h periods. The recordings were manually scored by a sleep specialist blinded to the study, following the criteria of the American Academy of Sleep Medicine (AASM). The depth of sedation was evaluated at least every eight hours using the Richmond Agitation Sedation Scale (RASS). For this analysis, PSG recordings from 10:00 pm to 6:00 am were utilized.
Results: A total of 99 patients were enrolled, with sleep data analyzed for 47 patients (20 in standard rooms, 27 in modified rooms). In this study sample, conventional sleep stage analysis showed that moderate to non-sedated patients treated in modified rooms had a more close to physiological ranges of slow wave sleep (SWS, which refers to N3) at 31.9%. In contrast, patients with more deep sedation and those treated in standard rooms exhibited significantly higher levels of SWS, reaching up to 75.5%. Patients who were less sedated in modified rooms exhibited a typical distribution of N1 and N2 sleep at 14.5% and 52.7%, respectively, while deeply sedated patients in standard rooms showed the lowest values of 0.6% for N1 and 24.0% for N2. Rapid eye movement (REM) sleep was nearly absent in all patients. Deep-sedated patients had a longer total sleeptime (TST), averaging 470 min in modified rooms and 430 min in standard rooms. In contrast, less sedated patients in modified rooms experienced the lowest TST, averaging 284 min (see Fig. 1). Sedation levels, assessed using the RASS, were similar between both groups, with a median of –2 (modified rooms: IQR –3 to 0; standard rooms: IQR –4 to 0; see Fig. 2).
Conclusions. This preliminary analysis indicates that changes in ICU room design may affect the sleep architecture of mechanically ventilated patients. Additionally, the level of sedation could significantly influence sleep staging, which should be considered in future analyses.

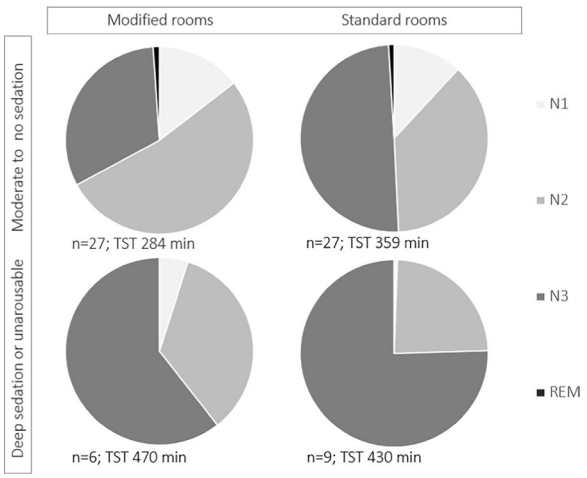

Fig. 1 (abstract 000424) Distribution of sleep stages from polysomnography recordings between 10:00 pm and 6:00 am depending on sedation status for patients in standard and modified rooms. N1, N2, and N3 are the three stages of non-rapid eye movement (NREM) sleep; REM, rapid eye movement sleep; TST, total sleep time. Deep sedation or unarousable is defined as having a Richmond Agitation Sedation Scale (RASS) score below -3.

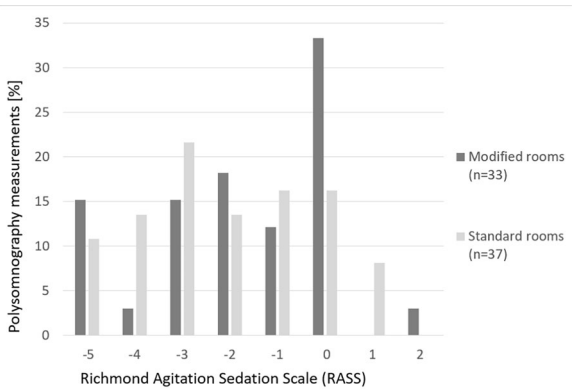

Fig. 2 (abstract 000424) Distribution of polysomnography measurements [%] (n = 70) for different sedation levels. RASS, Richmond Agitation Sedation Scale

Sonographic anatomical variations of internal jugular vein and common carotid artery relationships in a South African Tertiary Hospital.

LG. Germishuys.[1]
[1]Anaesthesiology, University of the Witwatersrand, Johannesburg, Johannesburg, South Africa.
Correspondence: L.G. Germishuys.
Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000425***.

Introduction: The internal jugular vein (IJV) is a preferred site for central venous access due to its anatomical location and accessibility [1,2]. Originating at the base of the sigmoid sinus, the IJV runs through the jugular foramen, paralleling the carotid artery within the carotid sheath, and is often accessible with ultrasound-guided techniques [3–5]. Complications such as bleeding, arterial puncture, pneumothorax, and infection are reduced with proper training [6–9]. Ultrasound has become standard practice for central venous access, as recommended by the Association of Anaesthesiologists, due to its ability to enhance success rates and reduce complications [2]. Anatomical variations of the IJV, such as positional differences, absence, and duplication, are well-documented globally and contribute to up to 15% of complications [10]. While extensive research exists, few studies have compared the incidence of typical anatomy on the right versus left side, which this study aimed to address.
Objectives: Compare anatomy and anatomical variation of the internal jugular vein and common carotid artery on the left and right side of the neck.
Methods: This cross-sectional descriptive study was conducted at Chris Hani Baragwanath Academic Hospital with ethical approval (Certificate M240140) and written informed consent from 178 adult patients. Participants were screened preoperatively, and demographic data, including age, ethnicity, BMI, and neck circumference, were recorded. Ultrasound scans were performed using a GE LOGIQe machine by a single accredited sonographer to reduce inter-operator variability. Patients were scanned supine at three levels: Sedillot's triangle, the cricoid cartilage, and the upper thyroid cartilage. Vessel measurements included diameter, depth, overlap, and radial relationship between the IJV and the common carotid artery (CCA). Atypical variants such as bifurcation, duplication, or absence were also noted.
Results: The IJV was more frequently located in the typical position at superior levels and on the right side ($P < 0.005$). Atypical variants were rare, with medial IJVs found in 1.12% of right sides and 4.49% of left sides. Right-sided duplications (1.12%) and left-sided bifurcation (0.56%) were observed. Vessel overlap was significantly greater on the left and at inferior levels, with correlations to BMI and age. Depth measurements revealed significant right-to-left differences in IJV diameter at all depths, with no significant skin distance differences. IJV-CCA center-to-center distances differed at all depths ($P < 0.05$). BMI was moderately associated with greater IJV depth on the left side and CCA depth on the right. Older age correlated with greater left-sided IJV depth at superior levels.
Conclusions: Variations in the relationship between the IJV and CCA are unpredictable, emphasizing the importance of using ultrasound for IJV central venous access. Given that the IJV is closer to the skin and has less overlap with the CCA on the right side of the neck compared to the left, it may be safer to attempt right-sided IJV access instead of left-sided access.

Dying with or from ARDS? Uncovering the attributable mortality of ARDS

E. Balzani[1]; C. Bianchi[2]; G. Bellani.[3]
[1]Center of Medical Sciences, University of Trento, Trento, Italy; [2]Department of Emergency and Intensive Care, FONDAZIONE IRCCS SAN GERARDO DEI TINTORI, Milan, Italy; [3]Department of emergency and intensive care, University of Trento, Via Calepina, Trento, TN, Italia, Trento, Italy.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000430***.

Introduction: Acute respiratory distress syndrome (ARDS) is a form of acute hypoxemic respiratory failure characterized by bilateral

pulmonary infiltrates and impaired oxygenation, typically triggered by pneumonia, sepsis, trauma, or other critical conditions. Common among patients in intensive care units (ICUs), ARDS is associated with substantial morbidity and mortality (1). However, isolating its independent contribution to patient outcomes remains challenging due to numerous confounding factors.

Objectives: This study aimed to quantify the impact of ARDS on 30- and 60-day mortality, independently of non-respiratory severity, in a large cohort of critically ill patients.

Methods: We analyzed data from the MIMIC-III database. ARDS was defined at 24 h from ICU admission according to the Berlin criteria, based on PaO_2/FiO_2 ratio and PEEP levels (2,3). Missing baseline values were imputed using Multiple Imputation by Chained Equations with predictive mean matching. Propensity scores for ARDS were estimated using logistic regression and applied for 1:1 nearest-neighbor matching without replacement. Matching was performed to balance groups for age, sex, weight, and non-respiratory SOFA scores. Outcomes were evaluated using Cox proportional hazards models.

Results: From the 24-h dataset, 19,567 ICU admissions were included. After matching, 9,952 patients remained (4,976 non-ARDS, 2,613 mild, 2,124 moderate, and 239 severe ARDS, Fig. 1). Mild ARDS was not associated with increased 30-day mortality (Fig. 2A, 2B). Moderate ARDS showed a 1.45-fold increased risk (95% CI 1.30–1.62; $p < 0.001$, Fig. 2A), and severe ARDS a 1.91-fold increased risk (95% CI 1.51–2.42; $p < 0.001$, Fig. 2A). Similar results were found for 60-day mortality (Fig. 2C, 2D).

Conclusions: These findings suggest that it is not merely the presence of ARDS, but its severity that significantly influences patient mortality. While mild ARDS was not associated with worse outcomes, moderate and severe forms were independently linked to substantially higher 30- and 60-day mortality.

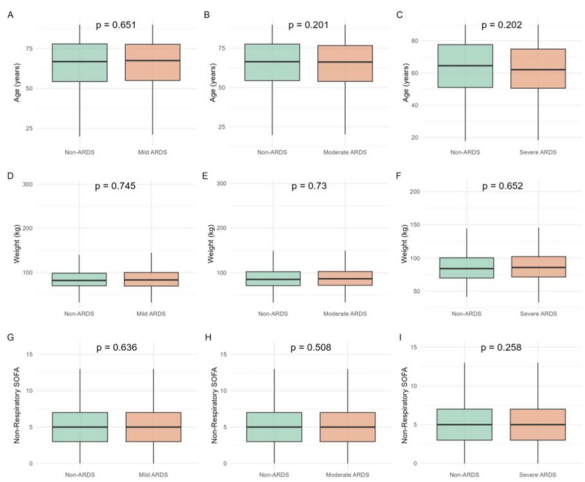

Fig. 1 (abstract 000430) Comparison of matched non-ARDS and ARDS patients across key clinical variables. This figure presents the distribution of age (A-C), weight (D-F), and non-respiratory SOFA score (G-I) among propensity-matched patients with and without ARDS. Each panel compares a specific ARDS severity category with its corresponding matched non-ARDS group, ensuring that each non-ARDS patient included in the analysis has been selected through 1:1 nearest-neighbor matching based on age, gender, weight and non-respiratory SOFA. Statistical comparisons were conducted using two-sample t-tests, and p-values are reported. Non-ARDS patients shown in each comparison represent only the subset of subjects matched to the respective ARDS severity category, rather than the entire non-ARDS population. Boxplots display median values, interquartile ranges, and individual data points, illustrating the balance achieved after propensity score matching. Abbreviations: ARDS—acute respiratory distress syndrome; SOFA—Sequential Organ Failure Assessment

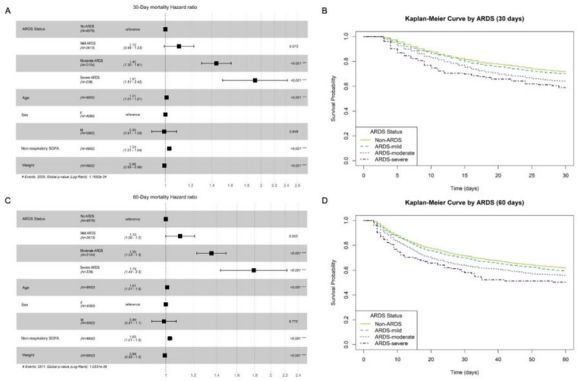

Fig. 2 (abstract 000430) Impact of ARDS severity on 30- and 60-day mortality. Panel A presents a forest plot of hazard ratios for 30-day mortality, stratified by ARDS severity, with non-ARDS patients as the reference group. Panel B shows Kaplan–Meier survival curves for 30-day mortality across ARDS severity groups. Panel C displays a forest plot of hazard ratios for 60-day mortality, following the same stratification as Panel A. Panel D illustrates Kaplan–Meier survival curves for 60-day mortality. Hazard ratios are reported with 95% confidence intervals. Abbreviations: ARDS—acute respiratory distress syndrome; SOFA—Sequential Organ Failure Assessment

Introduction: Severe dengue is a leading cause of morbidity and mortality, especially among critically ill patients requiring intensive care unit (ICU) admission. While individual clinical and laboratory risk factors have been identified, a validated scoring system to predict mortality in this patient population remains unavailable.

Objectives: To develop and validate the Severe Dengue Mortality Risk Score (SDMRS) for critically ill patients with severe dengue by utilizing multivariate logistic regression to identify and quantify independent predictors of in-hospital mortality.

Methods: This retrospective cohort study involved 4,933 ICU patients diagnosed with severe dengue. Data were collected on demographic, clinical, and laboratory parameters, and analyzed through multivariate

logistic regression. Independent predictors of in-hospital mortality were identified, and odds ratios (ORs) for significant predictors were transformed into natural logarithms (ln(OR)) to construct a scoring system. The accuracy of the Severe Dengue Mortality Risk Score (SDMRS) was assessed by stratifying patients into low, moderate, and high-risk categories based on the score.

Results: Among the 4,933 patients, 25 (0.51%) died during hospitalization. Multivariate analysis identified five independent predictors of mortality: autoimmune disease, cardiovascular disease, male sex, hypertension, and age. Specifically, autoimmune disease was associated with the highest risk (OR: 14.87, 95% CI: 2.85–77.53, p = 0.004), followed by cardiovascular disease (OR: 4.13, 95% CI: 1.44–11.86, p = 0.008), male sex (OR: 3.11, 95% CI: 1.05–9.16, p = 0.041), hypertension (OR: 3.00, 95% CI: 1.05–8.53, p = 0.041), and age (OR: 1.04 per year increase, 95% CI: 1.00–1.08, p = 0.034). Based on these predictors, the SDMRS was developed by assigning points according to the ln(OR). Autoimmune disease was given 5 points, cardiovascular disease 4 points, hypertension 3 points, male sex 3 points, and age 1 point for each year of increase.

Patients were stratified into three categories: low risk (0–5 points), moderate risk (6–9 points), and high risk (≥ 10 points). The SDMRS demonstrated a strong association with in-hospital mortality, as higher scores were correlated with increased risk of death.

Conclusions: The Severe Dengue Mortality Risk Score (SDMRS) is a novel, evidence-based tool that predicts in-hospital mortality for critically ill patients with severe dengue. By incorporating key clinical factors such as autoimmune disease, cardiovascular disease, male sex, hypertension, and age, the SDMRS offers a practical framework for identifying high-risk patients and guiding early interventions. Further prospective validation is necessary to confirm its clinical utility and applicability in diverse healthcare settings.

Introduction: Nosocomial lower respiratory tract infections (nLRTIs), including hospital-acquired pneumonia (HAP) and ventilator-associated pneumonia (VAP), remain significant challenges due to high mortality, morbidity, and healthcare costs. Findings from the first analysis of The European Network for ICU-Related Respiratory Infections (ENIRRIs) cohort showed that over one-third of ICU-acquired respiratory infections involved difficult-to-treat pathogens, including methicillin-resistant *Staphylococcus aureus* (MRSA), and were associated with worse outcomes. While some risk factors have been identified for MRSA community-acquired pneumonia (CAP) patients, there is limited data about the risk factors for MRSA nLRTIs. Thus, we used data from a large multinational cohort to identify clinical factors associated with MRSA-associated nLRTIs.

Objectives: To identify independent risk factors associated with MRSA nLRTIs.

Methods: We curated data from 1,060 patients with confirmed MRSA infection in the ENIRRIs study. Variables with > 30% missing data were excluded; those with < 30% missing were imputed using k-Nearest Neighbors (KNN). Random Forest was applied to determine variable importance; top-ranked predictors were entered into a binary logistic regression model. Logistic regression with variable selection was used to confirm model stability. Performance was evaluated using AUC-ROC for discrimination and the Hosmer–Lemeshow test for calibration.

Results: The cohort had a mean age of 60 years (SD 16.61) and was predominantly male (72%). The prevalence of MRSA was 5.2% (55/1060). Within the first 72 h of admission, 53% of patients required invasive mechanical ventilation and 41% required vasopressors. Using Random Forest analysis, the most relevant predictors of MRSA nLRTIs were identified as SOFA score on the first day, 1st day CPIS score, PaO_2/FiO_2 ratio, leukocyte count, and BMI. In the binary logistic regression analysis, a SOFA score ≥ 7 was independently associated with an increased risk of MRSA nLRTIs (OR 3.12, 95% CI: 1.45–6.68, p = 0.004), as were ≥ 5 days of mechanical ventilation (OR 2.78, 95% CI: 1.22–6.31, p = 0.018), and a PaO_2/FiO_2 ratio < 250 mmHg (OR 1.97, 95% CI: 1.07–3.61, p = 0.029).

Conclusions: SOFA score, oxygenation status, and duration of mechanical ventilation were independently associated with the risk of MRSA nLRTIs. These findings highlight early risk stratification's importance in identifying high-risk patients and optimising initial antibiotic selection in critically ill individuals, potentially improving clinical outcomes.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000434***.

Introduction: Assessing fluid responsiveness is problematic for critically ill patients with spontaneous breathing activity, such as during pressure support ventilation (PSV), since spontaneous breathing activity physiologically affects heart–lung interplay. We compared the reliability of two hemodynamic tests in predicting fluid responsiveness in this clinical setting: SIGH35, based on a ventilator-generated sigh applied at 35 cmH2O for 4 s, and the end-expiratory occlusion test (EEOT).
Methods: This prospective monocentric study was conducted in a general intensive care unit (ICU) and enrolled patients ventilated in PSV showing different inspiratory effort—assessed by airway occlusion pressure (P0.1)—and requiring volume expansion (VE). Hemodynamic variables were continuously recorded by means of the MOSTCARE® system. Patients received a volume expansion using 4 ml/kg of crystalloids over 10 min and were considered responders if an increase in cardiac output (CO) ≥ 10% was observed. The sequence of tests was randomly generated. The reliability of SIGH35 and EEOT in discriminating fluid responsiveness was assessed using a receiver operating characteristic (ROC) curve approach and the areas under ROC curves (AUC) were compared. For the EEOT, we considered the percentage changes of CO between baseline and the end of the test, while for the SIGH35 we considered the percentage changes of pulse pressure (PP) between baseline and the lowest value recorded after SIGH35 application (Nadir—Fig. 1).
Results: Sixty ICU patients were enrolled over a 19-months period, 56 of whom were eventually analyzed. Three patients were excluded from data analysis because of extrasystoles during the beat-to-beat evaluation SIGH35, and one because of ventilator triggering during EEOT. The AUC of PP change after SIGH35 was 0.93 (0.84—0.99) [sensitivity of 93.1% (78.0%–98.7%); specificity of 91.6 (73.0%–98.9%)]; best threshold -25% PP from baseline (grey zone—15% / 35%)]. The AUC of CO change after EEOT was 0.67 (0.52–0.81), showing that the CO increase was not significantly different between responders and non-responders [5.6% vs. -0.35%; p < 0.07)]. The AUC of SIGH35 was therefore significantly larger as compared to the AUC of the EEOT in the overall population (p < 0.0008). In the subgroup having a P0.1 lower than 1.5 cmH2O, the AUC of SIGH35 [0.98 (0.94–0.99)] and of EEOT [0.89 (0.72–0.99] were comparable (p-value = 0.26) (Fig. 2).
Conclusions: In this single-center study on a selected ICU population undergoing PSV, the PP change after the application of one sigh at 35 cmH2O for 4 s reliably predicted fluid responsiveness, with a best cut-off of -25% from baseline. In this setting the SIGH35 performed better than the EEOT, which is, however, still reliable in the subgroup of ICU patients having a small extent of inspiratory efforts.

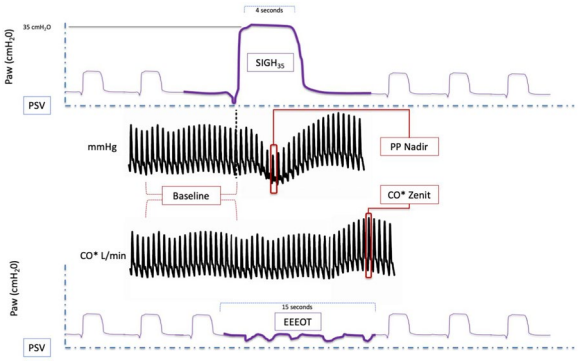

Fig. 1 (abstract 000434) The hemodynamic effect of EEOT was evaluated by considering the mean of cardiac output values of the 10 beats before EEOT start (EEOT_baseline; lower panel of the figure) and highest CO value recorded at the end of the test (CO_zenith). The hemodynamic effect of SIGH35 was evaluated by considering the mean of PP values of the 10 beats before SIGH35start (SIGH35_baseline; upper panel of the figure) and the lowest value of PP recorded after SIGH3 application (PP_nadir)

.

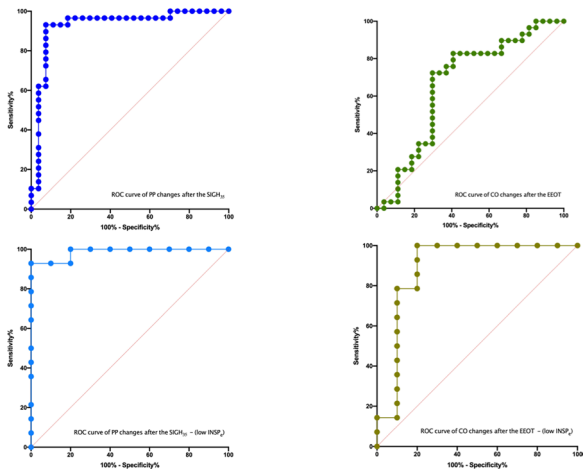

Fig. 2 (abstract 000434) The upper part of the figure shows the ROC curves of the changes of PP after the SIGH35 [AUC = 0.93 (0.84—0.99)] and after the EEOT [AUC = 0.67 (0.52—0.81)] in the overall population. The lower part of the figure shows the ROC curves of the changes of PP after the SIGH35 [AUC = 0.98 (0.94—0.99)] and after the EEOT [AUC = 0.89 (0.72—0.99)] in the subgroup of patients having a small extent of inspiratory efforts

Introduction: Respiratory infections such as severe community-acquired pneumonia (sCAP), hospital-acquired pneumonia (HAP), and ventilator-associated pneumonia (VAP), represent a major cause of ICU admissions and mortality. Rapid etiological identification through molecular syndromic testing may facilitate timely and targeted antimicrobial therapy.
Objectives: To evaluate the diagnostic yield and impact of multiplex PCR-based techniques (BioFire® FilmArray® Pneumonia panel and the Unyvero Hospitalized Pneumonia Panel) on antimicrobial management and clinical outcomes in ICU patients with respiratory infections.
Methods: This retrospective observational study included 27 adult ICU patients admitted between November 2024 and February 2025, diagnosed with sCAP, HAP, or VAP, and evaluated using FilmArray or Unyvero PCR assays for pathogen detection. Data collected included demographics, infection type, APACHE II scores, microbiological results (PCR and cultures), concordance between PCR and culture results, antimicrobial therapy modifications, and clinical outcomes (28-day and in-hospital mortality, PaO_2/FiO_2 improvement, overall clinical improvement, length of ICU and hospital stay, and time on mechanical ventilation). Statistical analysis used Fisher's exact test for categorical variables, with significance set at $p < 0.05$.
Results: A total of 27 ICU patients were included in the study, with a median age of 65 years (IQR: 58–77), and a male predominance (55.6%). Mean APACHE II at sample collection was 18.2 (SD 7.2). FilmArray was used in 24 patients (88.9%) and Unyvero in 3 patients (11.1%), exclusively among VAP cases ($p = 0.008$). PCR testing identified a pathogen in 19 cases (70.4%), while cultures were positive in 14 cases (51.9%). In 2 patients (7.4%), no culture was obtained. Concordance between PCR and culture results was observed in 60% of cases ($n = 25$). Following PCR results, antibiotic treatment was modified in 96.3% of patients, and at least one antimicrobial agent was discontinued in 92.6%. No significant difference was found in the overall rate of positivity between PCR and culture ($p = 0.661$). Concordance between PCR method and culture results was not significantly different between FilmArray and Unyvero ($p = 0.346$).
Regarding outcomes, 28-day mortality was 36%, and in-hospital mortality reached 52%. Although not statistically significant, there was a trend toward lower 28-day mortality in patients with PCR–culture agreement (20% vs 60%, $p = 0.087$). However, in-hospital mortality was significantly lower in this group (26.7% vs 90%, $p = 0.004$). Patients who received targeted antibiotic therapy based on PCR findings showed significantly lower 28-day mortality (25% vs 100%, $p = 0.029$) and a non-significant trend toward lower in-hospital mortality (41.7% vs 100%, $p = 0.098$). Use of targeted antibiotics did not significantly affect ICU length of stay ($p = 0.280$), hospital stay ($p = 0.512$), or mechanical ventilation duration ($p = 0.316$), though trends favored shorter durations.
Clinical improvement, defined by reduction in infection markers, fever, and improvement in PaO_2/FiO_2 ratio, was observed in 80% of patients. Although overall improvement was not significantly associated with PCR–culture agreement ($p = 0.064$), improvement in PaO_2/FiO_2 was significantly more frequent when PCR and culture results were concordant ($p = 0.007$). Higher APACHE II scores at sample collection were significantly associated with both 28-day (23.3 vs 15.7, $p = 0.006$) and in-hospital mortality (23.2 vs 13.6, $p < 0.001$).
Conclusions: Rapid molecular diagnostics significantly influenced the management of ICU patients with respiratory infections. PCR-guided antibiotic modifications occurred in nearly all cases, leading to significant de-escalation. Diagnostic concordance between PCR and culture was associated with better clinical outcomes, including significantly lower in-hospital mortality and improved oxygenation. Additionally, targeted antibiotic therapy guided by PCR results was significantly associated with reduced 28-day mortality and showed a strong trend toward lower in-hospital mortality. No significant reductions in ICU stay, hospital stay, or mechanical ventilation time were observed, possibly due to the small sample size. These findings support the integration of PCR-based diagnostics into routine ICU practice to enhance antimicrobial stewardship and improve patient prognosis.

Introduction: Post-intensive care syndrome family (PICS-F) has usually focused on psychological impairments among relatives of former intensive care unit (ICU) patients (1). Despite its relevance, evidence on PICS-F remains scarce, particularly regarding the presence of physical or cognitive impairments and the factors influencing each PICS-F impairment.
Objectives: To identify variables of associated to PICS-F psychological, physical, and cognitive impairments among relatives of ICU survivors.
Methods: Preliminary data analysis of an ongoing cohort study exploring the incidence and related factors of PICS-F in a public hospital in Santiago, Chile (2). Relatives of ICU patients with 3–10 days of ICU

stay and with respiratory support provided sociodemographic data and completed surveys for anxiety/depressive symptoms (PHQ-4), posttraumatic stress disorder symptoms (IES-6), fatigue (SF-36 Vt), cognitive function (MEFO), resilience (BRCS), and perceived social support (mMOS-SSS) at ICU admission and 3 months after hospital discharge. Frequency of PICS-F was calculated using percentages for psychological (PHQ-4 ≥ 6/IES-6 ≥ 1.75), physical (SF-36 Vt < 45), and cognitive (MEFO < 9) impairments. Least Absolute Shrinkage and Selection Operator (LASSO) logistic regressions were used to identify variables at ICU admission associated with each PICS-F impairment 3 months after hospital discharge. The original study was approved by the Ethics Committee at PUC Chile (ID:220318015).
Results: Within the 233 relatives enrolled to date, 89 (38.2%) had complete 3-month post-hospital discharge data for LASSO regressions. PICS-F psychological (PHQ-4/IES-6), physical, and cognitive impairments were present in 25.8%/27.7%, 39.8%, and 1.1% of the sample, respectively. Regarding psychological impairments, higher PHQ-4 scores at ICU admission were linked with increased odds ratio (OR) of significant anxiety/depressive symptoms (OR≈1.14). Conversely, male gender (OR≈0.55), being spouse/partner (OR≈0.65), higher BRCS (OR≈0.94), and SF-36 Vt (OR≈0.99) scores were related to lower OR. Then, high school education (OR≈1.19), being an adult child (OR≈1.29), prior anxiety/depression diagnosis (OR≈1.57), and higher PHQ-4 scores (OR≈1.24) were associated with higher odds of significant PTSD symptoms. At the same time, male gender (OR≈0.35), incomplete elementary school (OR≈0.73), higher mMOS-SSS (OR≈0.99), BRCS (OR≈0.85), and SF-36 Vt scores (OR≈0.99) were linked to fewer odds. Regarding physical impairment, previous anxiety/depression diagnosis (OR≈2.31), higher PHQ-4 (OR≈1.03), and MEFO (OR≈1.04) scores were associated with a higher risk of fatigue. Conversely, higher mMOS-SSS (OR≈0.99) and SF-36 Vt scores (OR≈0.99) were associated with a lower fatigue risk. Low prevalence of cognitive impairment prevented the identification of potential predictors.
Conclusions: Relatives of ICU survivors experience not only psychological, but also physical impairments after hospital discharge. Early screening of risk and protective PICS-F factors during ICU admission, including psychosocial variables, will assist healthcare providers in identifying relatives at risk of worse outcomes in the post-ICU period. Development of interventions aimed at reducing PICS-F should focus on modifiable factors such as improving relatives´ stress buffers (perceived social support and resilience) during ICU stay. Studies with larger sample sizes at follow-ups are warranted to improve confidence in identified predictors.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000442***.

Introduction: Severe dengue remains a major cause of morbidity and mortality, especially in critically ill patients requiring intensive care. Identifying risk factors for mortality is essential for early intervention and resource allocation in these patients.
Objectives: To identify independent clinical and laboratory predictors of in-hospital mortality in critically ill ICU patients with severe dengue using multivariate logistic regression.
Methods: This retrospective cohort study included 4,933 ICU patients diagnosed with severe dengue. Demographic, clinical, and laboratory parameters were analyzed, and multivariate logistic regression was employed to identify independent predictors of in-hospital mortality. Results were expressed as odds ratios (OR) with 95% confidence intervals (CI). A forest plot was created to visualize the strength of associations between significant predictors and mortality. Statistical significance was set at $p < 0.05$.
Results: Of the 4,933 patients, 25 (0.51%) died during hospitalization. Multivariate analysis identified autoimmune disease (OR: 14.87, 95% CI: 2.85–77.53, $p = 0.004$), cardiovascular disease (OR: 4.13, 95% CI: 1.44–11.86, $p = 0.008$), male sex (OR: 3.11, 95% CI: 1.05–9.16, $p = 0.041$), hypertension (OR: 3.00, 95% CI: 1.05–8.53, $p = 0.041$), and age (OR: 1.04 per year increase, 95% CI: 1.00–1.08, $p = 0.034$) as independent predictors of mortality. Other variables, including hepatopathy, thrombosis, pneumonia, neoplasia, coagulopathy, renal disease, diabetes, and dyslipidemia, were not significantly associated with mortality.
Conclusions: In critically ill patients with severe dengue, autoimmune disease, cardiovascular disease, male sex, hypertension, and older age were found to be independent risk factors for mortality. Despite the low overall mortality rate (0.51%), these findings highlight the importance of early identification and targeted management for high-risk patients. Further prospective studies are necessary to validate these results and enhance prognostic stratification for severe dengue.

The amphiregulin–epidermal growth factor receptor axis as a theragnostic target in sepsis

R. Walsh,[1]; T. Snow[1]; M. Singer[2]; A. Das[3]; D. Brealey[4]; N. Arulkumaran.[5]
[1]Intensive care department, University College London, London, United Kingdom; [2]Experimental & Translational Biology, University College London, London, United Kingdom; [3]Division of Infection and Immunity, University College London, London, United Kingdom; [4]Bloomsbury institute of intensive care medicine, University College London, Gower Street, London, UK, London, United Kingdom; [5]Intensive care department, University College London Hospital, London, United Kingdom.
Correspondence: R. Walsh,
Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000443***.

Introduction: Amphiregulin, a tissue-protective growth factor and epidermal growth factor receptor (EGFR) ligand, is a hallmark of bacterial sepsis in neonates (1), identifying a sub-cohort with infection with greater sensitivity than C-reactive protein.

The role of amphiregulin in adult sepsis and immune dysregulation has not been previously explored. Animal models indicate that immune function may be modulated by EGFR signalling, especially in the setting of inflammation (2). Thus, we hypothesize that EGFR signalling, via amphiregulin, modulates immune function in adult sepsis.
Objectives: To (i) assess the association between serum amphiregulin and mortality in adults with sepsis (ii) evaluate levels of amphiregulin and EGFR in monocytes and lymphocytes across disease severity, and (iii) investigate any association with known markers of activation in sepsis.
Methods: Prospective, observational cohort study of patients presenting to the Intensive Care Unit (ICU) with bacterial sepsis. Blood samples taken from healthy volunteers (HV) acted as a reference. Clinical and laboratory variables were collected. Serum immune parameters: interleukin (IL)-1β, IL-6, IL-10, tumor necrosis factor (TNF)-α, PD-1, PD-L1 and amphiregulin were measured by ELISA. Immunophenotyping of peripheral blood mononuclear cells (PBMC) was carried out in a subset of samples using spectral flow cytometry. Data were analysed in GraphPad Prism 10.
Results: ICU non-survivors (n = 19) had significantly higher serum amphiregulin levels on ICU admission ($p < 0.001$), day 1 ($p < 0.05$), and day 5 ($p < 0.01$) compared to survivors (n = 44). When combined with 14 other routinely collected clinical variables, only admission serum amphiregulin was significantly higher in ICU non-survivors compared to survivors ($p < 0.01$).
Flow cytometry analysis carried out on a subset identified an increase in expression of amphiregulin and EGFR in both CD4 + and CD8 + lymphocytes when comparing HV (n = 20) to the ICU cohort (n = 35). Correlation analysis found that CD4 + lymphocyte EGFR expression was associated with elevated levels of IL-10, PD-1, CTLA-4, and decreased IL-17A.
Conclusions: Serum amphiregulin levels differentiates between ICU survivors and non-survivors. CD4 + and CD8 + lymphocytes were identified as being the key immune cells in amphiregulin and EGFR expression, with CD4 + lymphocyte EGFR expression being associated with an immunosuppressive phenotype.
Activation of the amphiregulin–EGFR axis may contribute to immunosuppression in sepsis by promoting an anti-inflammatory phenotype in CD4 + lymphocytes. Amphiregulin could serve as a theragnostic biomarker of immune dysregulation in sepsis. The effect of therapeutic modulation of amphiregulin in sepsis warrants further exploration.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000444***.

Introduction: Traumatic brain injury (TBI) is a significant public health concern due to high mortality rates and its contribution to long-term disability. Nearly 50% of intensive care units (ICU) admitted TBI patients develop delirium, which is associated with prolonged hospitalization and higher healthcare costs. While systemic inflammation has been linked to delirium, its role in TBI-related delirium remains poorly studied despite its higher incidence in this population.
Objectives. This study investigates the association between systemic inflammatory markers and delirium in ICU-admitted TBI patients and its impact on 2-month outcomes:
Methods: This prospective cohort study enrolled ICU patients with moderate-to-severe TBI at a trauma center (2019–2023). Inflammatory biomarkers were measured at admission, day 3, and day 7. Delirium was assessed with CAM-ICU, and outcomes were evaluated at 2 months using GOSE and NSI. Random Forest modeling was used to identify variables for inclusion in the multivariate logistic regression analysis.
Results: A total of 112 ICU-admitted TBI patients were enrolled between 2022 and 2024 at a trauma center in Bogotá, Colombia. The median age was 31.5 years (IQR 20–48), and 79.5% were male. Delirium occurred in 47.3% of patients and was associated with older age (median [IQR] 37 years [26–50] vs. 27 years [22–44], $p = 0.036$), more severe head injuries (head AIS median [IQR] 4 [3–4] vs. 3 [2–4], $p = 0.001$), lower GCS scores (median [IQR] 9 [6–13] vs. 12 [9–14], $p = 0.022$), and higher APACHE II scores (median [IQR] 12 [9–14] vs. 8 [6–12.78], $p = 0.025$). The IMPACT score predicted a higher risk of mortality (14% [9–21] vs. 7% [5–13], $p = 0.001$) and unfavorable functional outcomes (29% [15–37] vs. 13% [8–23.5], $p < 0.001$) in delirium patients. IL-1β levels on day 7 were significantly elevated in delirium patients (median [IQR] 2.07 [2.07–27.26] vs. 2.07 [0.00–2.07], $p = 0.001$). IL-1β levels > 8.2 pg/dl on day 3 were independently associated with delirium (OR 2.72, 95% CI 1.06–7.13, $p = 0.036$) and mechanical ventilation use (OR 3.05, 95% CI 1.14–8.14, $p = 0.025$). IL-6 and TNF-α showed clearance tendencies rather than an increase over time. Higher IL-1β levels at baseline were associated with a lower risk of unfavorable outcomes at 2 months (OR 0.95, 95% CI 0.91–0.99, $p = 0.01$). Delirium was linked to unfavorable outcomes at 2 months (GOSE ≤ 4, OR 2.64, 95% CI 1.05–6.88, $p = 0.038$) and increased neurobehavioral symptoms (NSI > 20, OR 2.68, 95% CI 1.13–6.76, $p = 0.026$) (**Table 1**).
Conclusions: Delirium was linked to older age, severe injury, prolonged hospitalization, and worse functional outcomes at 2 months. Elevated IL-1β suggests a key role of inflammation in its pathogenesis and long-term effects. These findings support delirium as a secondary brain injury, highlighting the need for early identification and targeted interventions.

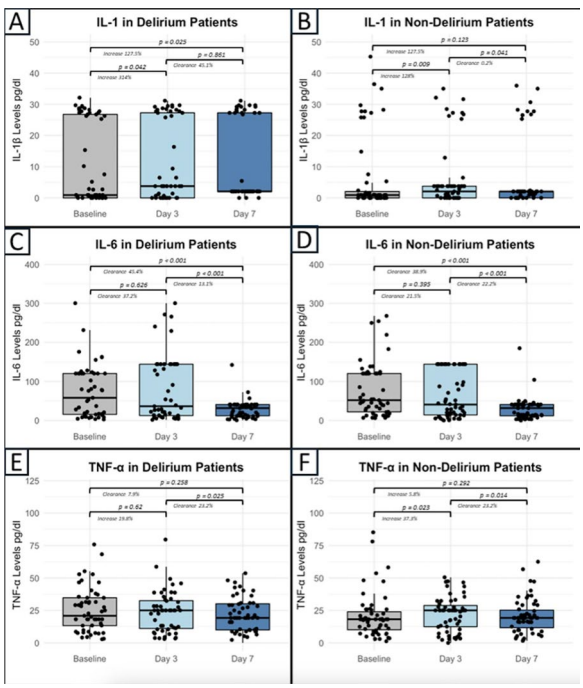

Fig. 1 (abstract 000444) Wilcoxon test for cytokine values between timepoints in delirium and non-delirium patients

Introduction: Invasive mechanical ventilation (IMV) is a revolutionary intervention that has saved millions of lives during the last decades. However, it has been associated with several complications due to the disturbance of the normal physiology of the respiratory system. It has been proposed that the IMV may affect the lung microbiome. However, it is unclear if the microbiome in the upper, middle, and lower respiratory tracts is differently affected by IMV. Given that upper airway, samples are more straightforward to collect and frequently used for pneumonia diagnosis, a comprehensive comparison is essential to understand whether the whole respiratory tract microbiome could be considered a unit or if each part should be considered separate.
Objectives: This study aims to compare the microbiome composition of nasopharyngeal (NP), endotracheal aspirate (ETA), and bronchoalveolar lavage (BAL) samples in patients undergoing IMV to identify differences across respiratory tract sites.
Methods: This observational study included patients admitted to the Intensive Care Unit requiring IMV for ≥ 48 h. Nasopharyngeal swabs, tracheal secretions, and BAL specimens were collected, frozen at -80 °C, and analyzed for 16S rRNA gene PCR. DNA was extracted using the DNeasy® Blood & Tissue Kit and sequenced on Illumina MiSeq. Microbial diversity was assessed using Shannon diversity, Bray–Curtis dissimilarity, Wilcoxon rank-sum test, and PERMANOVA, with analyses conducted in R.
Results: 141 individuals were included; microbiome analysis showed significant differences in beta diversity across sample types (NP, ETA, BAL) (PERMANOVA: $p < 0.01$). PCoA and NMDS analyses confirmed distinct clustering of NP samples (Fig. 1A). Alpha diversity was highest in ETA and lowest in BAL (Kruskal–Wallis: $p < 0.01$) (Fig. 1B). Relative abundance analysis revealed significant differences for *Staphylococcus spp.* (p_adj = 0.0274). Multivariate analysis confirmed microbial composition variation across tissue types ($p = 0.003$), with *Acinetobacter spp.* as a key differentiator ($p = 0.008$). Random Forest classification identified *Staphylococcus spp.*, *Prevotella spp.*, and *Acinetobacter spp.* as the most relevant OTUs, reinforcing their role in microbial differentiation.
Conclusions: The lung microbiome composition differs significantly across the upper (NP), middle (ETA), and lower (BAL) respiratory tract during the first 24 h of IMV. Beta diversity analysis confirmed distinct clustering of NP samples, while alpha diversity was highest in ETA and lowest in BAL. Key taxa, including *Staphylococcus spp.*, *Prevotella spp.*, and *Acinetobacter spp.*, contributed to these differences. These findings highlight the need for site-specific analysis when assessing the respiratory microbiome and its clinical implications in mechanically ventilated patients.

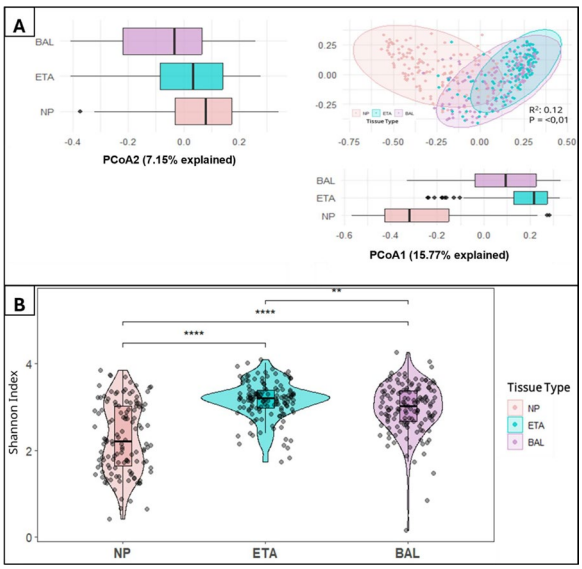

Fig 1 (abstract 000445) Comparison of respiratory microbiota by sampling site. **A.** PCoA based on Bray–Curtis distances shows significant differences in microbial composition among NP, ETA, and BAL samples ($R^2 = 0.12$, $p < 0.01$). **B.** Shannon diversity index differs significantly across sites (**** $p < 0.0001$; ** $p < 0.01$).

Intensive Care Medicine Experimental*, *2025*; 13(1)**: ***000446.

Introduction: New-onset atrial fibrillation (NOAF) is a common arrhythmia in critically ill patients, occurring in 5–11% of those admitted to the intensive care unit (ICU). It is associated with significant morbidity and mortality. Despite the use of various management strategies, evidence regarding optimal treatment is limited, with most data primarily coming from non-ICU populations.
Objectives: To characterize ICU patients with new-onset atrial fibrillation and evaluate the preferred management strategies.
Methods: A retrospective, single-center observational study was conducted on patients with NOAF admitted to a multidisciplinary ICU between January 2020 and June 2022. Clinical and demographic data were collected.
Results: Out of the 3,692 patients admitted to the ICU, 161 (4.4%) were diagnosed with NOAF, including 101 males with a mean age of 69.5 ± 11.8 years. Among these patients, 67% had hypertension, 35% had diabetes, 21% were obese, 13% had ischemic heart disease, and 15% had a history of heart failure. Additionally, 30% were previously treated with beta-blockers, and 4% had been using antiarrhythmic medications.
The primary reasons for ICU admission included sepsis or septic shock (73%), trauma (10%), and cardiogenic shock (7%). During their hospital stay, 79% of patients developed cardiovascular dysfunction. The most commonly used first-line strategy for managing NOAF was rhythm control (85%), followed by observation (7.5%) and rate control (7.5%). In the rhythm control group, 27 patients underwent electrical cardioversion combined with amiodarone, 5 received electrical cardioversion alone, and the remaining 104 were treated solely with amiodarone. No other antiarrhythmic medications were administered. There was no significant difference in the use of beta-blockers and digoxin within the rate control strategy.
Anticoagulation therapy was initiated in 72 patients (39% with enoxaparin and 6% with unfractionated heparin). A recurrent episode of atrial fibrillation occurred in 50% of patients during their hospital stay. During the ICU admission, 33% of patients died; however, recurrence of atrial fibrillation was not associated with increased ICU mortality. No specific predictors of ICU mortality were identified in the NOAF cohort. At the time of discharge, only 45% of patients were prescribed anticoagulation therapy. Of these, 24% were on beta-blockers, and 14% were on a combination of amiodarone and beta-blockers. During a follow-up period of 428 days (range 1–1705), 47% of patients experienced recurrence of atrial fibrillation, and 35% of patients died, with 13 deaths attributed to cardiovascular causes. Additionally, 10 patients were readmitted to the hospital for cardiovascular reasons, including 2 patients for heart failure decompensation due to atrial fibrillation with a rapid ventricular rate, and 1 patient for a cardioembolic stroke.
Conclusions: In patients with NOAF in the ICU, rhythm control is the preferred management strategy. Recurrence rates of atrial fibrillation remain high both during the ICU stay and in the follow-up period, despite the limited use of anticoagulation therapy. The acute, severe illness that led to ICU admission may serve as a trigger for underlying atrial disease, high

Intensive Care Medicine Experimental*, *2025*;13(1)**: ***000448.

Introduction: Orthotopic liver transplantation (OLT) enhances survival and quality of life but is associated with neurological complications (NCs) in 30–60% of patients, leading to increased mortality and healthcare costs. Identifying preoperative and perioperative risk factors, such as age, MELD score, comorbidities, sodium fluctuations, and medication use, can aid in predicting NC risk. (1) (2) (3).
Objectives: To assess the incidence and causes of NCs in OLT recipients and identify independent perioperative risk factors to improve risk stratification and patient outcomes.
Methods: In this retrospective study, we reviewed the medical records of adult patients who underwent OLT between June 2014 and October 2021, focusing on acute NCs during hospitalization (e.g., encephalopathy, seizures, drug toxicity, stroke, and CNS infections). We compared patients with and without NCs to identify risk factors associated with an increased likelihood of NCs. Preoperative, intraoperative, and postoperative factors were analyzed, with outcomes including hospital/ICU stay, complications, rehabilitation needs, and mortality. Ethical approval and informed consent were obtained, and descriptive statistical analysis was performed.
Results: Among 376 patients undergoing OLT, 97 (25.8%) developed NCs, including delirium (14.1%), seizures (3.7%), and neurotoxicity (3.7%). Diagnostic evaluations in 71 patients identified structural abnormalities in 7.2% and mild EEG changes in 65%. Preoperative factors linked to NCs included higher MELD scores (25.8 vs. 22.95, $p = 0.0003$), lower albumin levels (3.2 vs. 3.44, $p = 0.0205$), and a history of chronic renal impairment (37.9% vs. 23.2%, $p = 0.0147$, OR = 2.02). HCV infection was associated with a lower risk of NCs ($p = 0.0405$, OR = 0.61). Perioperative factors included higher sodium levels on postoperative day 2 ($p = 0.0291$) and greater sodium fluctuations ($p = 0.0024$). NC patients had significantly higher rates of acute renal impairment ($p < 0.0001$, OR = 3.74), required continuous renal replacement therapy ($p < 0.0001$, OR = 7.1), and experienced more postoperative infections ($p < 0.0001$, OR = 4.48), graft rejection ($p = 0.0006$, OR = 3.19), and multiple systemic complications ($p < 0.0001$, OR = 4.39). They also had longer hospital (57.28 vs. 19.61 days, $p < 0.0001$) and ICU stays (25.94 vs. 6.45 days, $p < 0.0001$), higher odds of ICU readmission (OR = 6.65), in-hospital death (OR = 7.67), and rehabilitation needs (OR = 8.7), all $p < 0.0001$.
Conclusions: NCs in liver transplant recipients are significant, with risk factors including advanced liver disease, renal failure, and intraoperative issues like sodium shifts and renal impairment. NCs, including

drug-induced neurotoxicity and osmotic demyelinating syndrome, lead to increased morbidity, extended hospital stays, and higher post-transplant disability. Identifying these risk factors preoperatively could enhance patient management and outcomes, guiding surveillance and clinical decisions.

RESULTS OF THE INCIDENCE OF NEUROLOGICAL COMPLICATIONS

	DELIRIUM/ METABOLIC ENCEPHALOPATHY	SEIZURES	ODS	NEUROTOXICITY	COMPLICATION PNS	ISCHEMIC STROKE
Incidence rates of NC n (%)	53 (14,1%)	14 (3.7%)	11 (2,8%)	14 (3,7%)	11 (2.8%)	4 (1,1%)

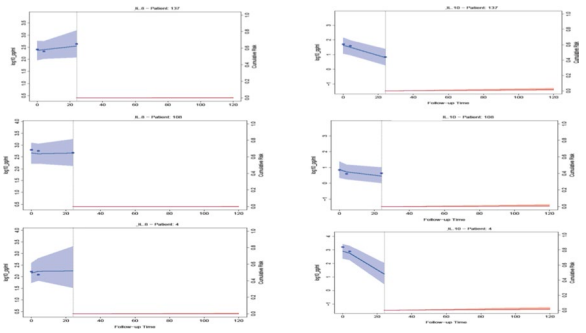
Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000452***.



Introduction: Sepsis is a heterogeneous syndrome caused mainly by respiratory infections. Current efforts to reduce the global burden of sepsis focus on improving public and healthcare worker awareness of markers to avoid delays in diagnosis and treatment, prompt treatment with appropriate antibiotics, and supportive care bundles focused on the common bacterial causes of sepsis. Unfortunately, there are few or no useful tools to allow early identification of those patients at high risk of poor outcome. Cytokines are useful in identifying patients with different inflammatory subphenotypes, but the dynamics of these markers over time and their impact on outcomes are not fully understood.

Objectives: The objective of this study is to evaluate the utility of kinetics of biomarker levels in predicting survival.

Methods: Prospective observational cohort of patients with risk of sepsis (defined as infection suspected and NEWS score equal or higher than 3) attending the emergency department of the Parc Tauli University Hospital. Blood samples and severity scores were obtained at baseline, 4 h and 24 h. We used joint models for longitudinal and survival data to determine the association between repeated measurements of cytokines (IL-10, IL-6, IL-8, IL1-RA, MCP.1 and TNF.RI) and survival probabilities.

Results: We analysed data from 170 patients. The median age was 76 years (IQR 64; 85), and the median SOFA score for the highest score in the first 24 h was 3 (IQR 2; 5). The mortality rate was 17% (n = 29), and 15% of patients (n = 27) were admitted to the ICU. Among the six biomarkers, IL-10 levels (hazard ratio 1.09, credible interval 95% 1.01 to 1.20) and IL-8 levels (hazard ratio 0.68, credible interval 0.61 to 0.80) were predictive of survival during follow-up, adjusted for age and SOFA. Hourly change or other functional forms for IL-6, MCP-1 and TNF-RI did not predict survival. Figure 1 shows dynamic predictions (posterior mean and 95% credible band at hours 0, 4, and 24 h after attending the ED for 3 patients).

Conclusions: The kinetics of IL-10 and IL-8 can predict survival. No other cytokine was useful for this prediction.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000453***.

Introduction: Indications for renal replacement therapy (RRT) in critically ill patients with acute kidney injury (AKI) are typically categorized

as either urgent (life-threatening hyperkalemia, metabolic acidosis, or pulmonary edema) or non-urgent, such as a serum urea concentration > 40 mmol/L or oligo-anuria lasting more than 72 h. However, whether these distinct categories of RRT indications are associated with different clinical outcomes remains unclear.
Objectives: To describe the distribution of RRT initiation criteria among critically ill patients with AKI and to compare the clinical characteristics and outcomes of patients receiving RRT based on the indication for initiation: urgent, serum urea concentration > 40 mmol/L, or oligo-anuria lasting more than 72 h.
Methods: This post hoc analysis pooled data from the delayed RRT initiation strategy arms of the AKIKI and AKIKI-2 trials (1,2). Patients who received RRT were included and subsequently categorized according to 3 categories of RRT indication: urgent indication or serum urea concentration > 40 mmol/L or oligo anuria > 72 h. Baseline characteristics were compared between groups. Sixty-day mortality was analyzed using Cox models with propensity score weighting and multiple imputation for missing data.
Results: Among the 413 patients included, 184 (45%) received RRT for urgent indications (uremic group), while 229 (55%) received RRT for non-urgent indications (126 (30%) for serum urea > 40 mmol/L (uremic group) and 103 (25%) for oliguria/anuria > 72 h (oligo-anuric group)). Baseline severity scores (SOFA score) and the need for organ support (invasive mechanical ventilation and/or vasopressor infusion) did not differ significantly between the 3 groups. Serum urea concentration at admission was higher in the uremic group (median 19 [9.2–29.8] mmol/L) compared to the urgent (12 [7–19] mmol/L) and oligo-anuric (11 [7–17] mmol/L) groups ($p < 0.001$). The time from occurrence of AKI stage 3 to fulfillment of RRT criteria was shortest in the urgent group (median 1 [1–3] day), followed by the uremic group (2 [1–4] days) and the oligo-anuric group (3 [2–3] days). Day-60 mortality was highest in the urgent group (62.5%), compared to 52.4% in the oligo-anuric group and 41.3% in the uremic group. After adjustment, the hazard ratios for day-60 mortality were 0.64 [0.46–0.88] for the oligo-anuric group and 0.49 [0.35–0.68] for the uremic group, both relative to the urgent group.
Conclusions: Among critically ill patients receiving RRT, indications for initiation were predominantly non-urgent and associated with lower mortality compared to urgent indications. These findings suggest that the underlying reason for RRT initiation may reflect differing clinical trajectories and prognoses in severe AKI.

Rapid multiplex PCR for the etiological diagnosis of ventilator-acquired pneumonia (VAP) and severe hospital-acquired pneumonia (HAP): performance in a low multi-drug resistant bacteria incidence setting.

A. Delgado Barroso; FJ. Reina-Martínez[1]; M. Adriaensens-Perez[1]; P. Egea-Miranda; E. Fernandez-Delgado; M. Bellido-Barquero; R. Amaya Villar[1]; JA. Lepe-Jimenez[2]; J. Garnacho Montero.[1]

Correspondence: F.J. Reina-Martínez.
Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000454***.

Introduction: Hospital-acquired pneumonia (HAP) and Ventilator-acquired pneumonia (VAP) are associated with high morbidity and mortality (1). The risk of multidrug-resistant bacteria (MDR), given the proven benefit of prompt and effective antibiotic initiation (2), supposes the use of broad-spectrum antibiotics until microbiological results which may take as long as 72-96 h. Novel molecular diagnostic techniques, such as rapid multiplex PCR (m-PCR), have been proposed as a method to further improve antimicrobial stewardship (AMS) with a faster etiological identification (3).
Objectives: To determine the diagnostic performance of m-PCR on bronchoalveolar lavage (BAL) from patients with suspicion of VAP or severe HAP and the effect of its results on the antimicrobial empirical treatment provided on a real, clinical, low MDR ICU setting.
Methods: Retrospective analysis of VAP and severe HAP (i.e. requiring endotracheal intubation) cases on a third level ICU between 2022 and 2024. BAL sample were collected for m-PCR testing (*BioFire*® FilmArray® Pneumonia Panel) and conventional culture. Any sample was defined as positive by detection of any bacteria with a threshold of 10e3 copies/mL on the semi-quantitative analysis as stated by the manufacturer.
Test metrics, such as sensitivity, specificity, accuracy, positive and negative predictive values of m-PCR for each pathogen were calculated against culture as gold-standard. Median copies of positive m-PCR were compared against culture result using t-test. Treatment modification after m-PCR was analyzed by Chi-squared test.
The present study was previously approved by the local Ethics Committee (SICEIA-2024–001437).
Results: 150 BAL samples from 117 patients were collected, 34% percent corresponded to severe HAP requiring ICU admission and intubation. No difference were found between HAP and NAVM groups, nor on in-ICU mortality (37%). In-hospital mortality was reported higher but not significantly different on de VAP group (44% vs. 37%).
From the BAL samples, 83 (55%) reported identification of any microorganism by m-PCR technique, of which only 54 (65%) had a positive culture. Culture-documented pneumonias were 43%; *P. aeruginosa and S. aureus* the most frequent isolations, followed by other microorganisms not included on the m-PCR panel (28%), mostly *S. maltophilia.*
Overall sensitivity of m-PCR was 97%, with 96% specificity and negative predictive value of 99%. Complete concordance between molecular testing and culture was found on 54% of samples and partial on 21%. Partial and non-concordance was explained found either by negative culture on positive m-PCR samples or isolation of bacteria not included on the m-PCR panel. Only 2 cases were found of negative m-PCR for a microorganism that was later isolated in conventional culture. The number of copies was significantly lower on patients with m-PCR positive/culture negative group compared to both tests yielding a positive result (10e3 vs. 10e6, $p < 0.01$)(Fig. 1).
Only 10 MDR genes were found detected on m-PCR (8%): 6 MEC-A *S. aureus*, 2 OXA-48 *K. pneumoniae*, 1 VIM *A. baumannii* and 1 CTX-M *E. cloacae*; consistent with previous local epidemiological data.
A significant antimicrobial treatment modification was performed after m-PCR, with a change of drug towards detected bacteria on the 34,7% of positive results or narrowing spectrum by suspension of some antibiotic on negative results (15%).

Conclusions. Rapid multiplex PCR testing on BAL was found to have high sensitivity, specificity and NPV on the microbiological diagnosis of VAP and severe HAP. Its use in our setting has impacted on the AMS by narrowing antibiotic spectrum in over half of the patients within the first hours of treatment.

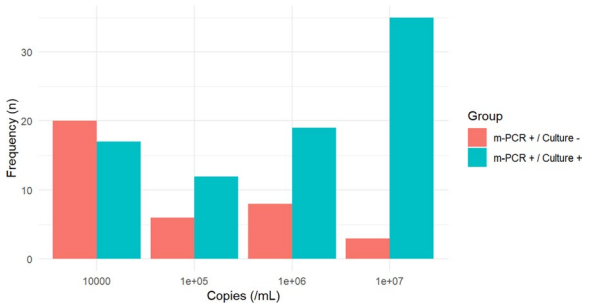

Fig 1 (abstract 000454) Distribution of Rapid Multiplex PCR (m-PCR) positive results by number of copies per milliliter on quantitative analysis. Red bars represent negative culture group and blue bars represent positive culture for the same microorganism. Difference of distribution was founded significant by Mann–Whitney–Wilcoxon test = 815.2.

Post-intensive care syndrome—family: results from a 3-month follow-up program in Portugal

MB. Dias Vieira[1]; M. Almeida[1]; S. Rua[1]; R. Grave[1]; N. Silva[1]; J. Mateus[1]; E. Ribeiro[1]; M. Melo[1]; A. Oliveira.[1]

[1]Intensive Care Unit, Unidade Local de Saúde da Região de Aveiro, Aveiro, Portugal.

Correspondence: M.B. Dias Vieira.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000455***.

Introduction: Post-intensive care syndrome—family (PICS-F) is a life-altering experience involving psychological, physical, and socio-economic challenges, beginning with the emotional toll on families when a patient is admitted to the Intensive Care Unit (ICU). Despite its significant impact on ICU survivors' recovery, assessing PICS-F remains challenging, as recent reviews often lack comprehensive summaries and report varying prevalence due to differences in assessment methods. Regarding our ICU, the 3-month follow-up consultation involves a doctor and 4 nurses, assessing both the patient and their designated family member. In 2024, 118 consultations were conducted for patients meeting referral criteria (mechanical ventilation > 48 h, ≥ 4 days in ICU, or neurological dysfunction during ICU stay). After discharge, the designated family member completes a questionnaire, including the Hospital Anxiety and Depression Scale (HADS), EQ-5D-3L, and Carers Assessment of Difficulties Index (CADI). Based on these results, which are evaluated during the follow-up consultation, cases of PICS-F are identified and addressed accordingly.
Objectives: This study aimed to identify and characterize cases of PICS-F among designated family members of patients eligible for the 3-month follow-up consultation, using validated tools.
Methods: A retrospective study was conducted using data from questionnaires completed by designated family members and evaluated during the 3-month follow-up consultations in 2024. Incomplete or contradictory questionnaires were excluded.
Results: A total of 80 questionnaires were evaluated, and results from the three validated tools were analyzed. Regarding the HADS results, definite cases of anxiety were identified in 26% of respondents, while 4% showed definite signs of depression. Possible (doubtful) cases were observed in 24% for anxiety and 19% for depression. Finally, non-cases accounted for 50% of family members in terms of anxiety and 77% in terms of depression. For the EQ-5D-3L, 23% of participants reported minor mobility issues, with 77% indicating no mobility problems. In terms of personal care, 6% experienced some difficulty, while 94% reported no issues. Regarding the impact of the family member's ICU admission, 78% reported no effect on their daily activities, 21% reported a minor impact, and 1% reported a major impact. Pain and discomfort were noted in 47% of respondents, with 43% reporting some impact and 4% indicating a significant impact. For anxiety and depression, 55% of participants reported no symptoms, 41% reported mild symptoms, and 4% reported severe symptoms. When comparing their current health status with six months ago, 45% reported it was the same, 32% reported improvements, and 23% reported a decline. Overall, anxiety/depression and pain were the most negatively impacted domains among family members as assessed by the EQ-5D-3L. Regarding the CADI, 10% of respondents reported significant difficulties (≥ 45 points) in caregiving, mainly due to financial challenges (22.4%), lack of support from employers (20%), inadequate family support (17.6%), avoidant responses from the patient (12.9%), social life restrictions (11.8%), physical demands of caregiving (10.6%), and interpersonal difficulties with the patient (4.7%). After a thorough review, 18 family members (22.5%) were referred for individual follow-up consultations by our team.
Conclusions: This study was important to raise awareness within our ICU team about the prevalence of PICS-F in our community and establish it as a key area for improvement. Consistent with other studies, anxiety, pain, and discomfort were the most frequently reported issues by family members and caregivers. It is essential to recognize that PICS-F goes beyond psychological effects, encompassing physical and socioeconomic consequences that can hinder a patient's recovery. To prevent long-term impairments, a comprehensive, multidisciplinary approach is required, starting with early identification during the ICU stay and continuing through follow-up consultations. In this context, it is crucial that healthcare teams are trained to identify and appropriately refer families affected by PICS-F. Our follow-up team is currently working to correlate the findings of this study with specific aspects of each patient's ICU stay, aiming to better understand and manage the risk factors associated with PICS-F.

Safety on the scales: a UK national survey of ICU patient weighing practices and challenges

R. Mehta[1]; S. Curran[1]; J. Gaynor[1]; L. Wandrag[1]; R. Moodley[1]; A. Wong.[1]
[1]King's Critical Care, King's College Hospital, London, United Kingdom.
Correspondence: R. Mehta.
Intensive Care Medicine Experimental, 2025;**13(1)**: 000456.

Introduction: A patient's body weight is central to numerous clinical decisions on the Intensive Care Unit (ICU), including drug dosing, fluid balance and nutritional assessment)$_{1,2}$ However, the evidence suggests that patient weights are estimated and often inaccurate, with a tendency to underestimate.[3]·.[4]
A pilot study conducted in United Kingdom (UK),[3] revealed that 62% of the patients had a significant error in their estimated weight. During this pilot, actually weighing the patient, led to no line/tube dislodgements or unintended consequences, confirming that it is safe and feasible.
Despite national UK guidance[5] recommending weighing patients on hospital admission and weekly thereafter, limited data are available on its compliance.
Objectives: A national survey was sent to healthcare professionals (HCPs) to:

1. Determine the standard practice for obtaining patient weights
2. Investigate the perceived barriers in measuring accurate patient weights
3. Examine concerns regarding safety risks connected to weighing ICU patients
4. Assess healthcare professionals' attitudes toward the frequency of patient weighing

Methods: An anonymous web-based survey using REDCap[6] was disseminated through national networks to nurses, dieticians, pharmacists and physiotherapists working across UK ICUs. The survey instrument consisted of 22 questions, systematically categorized into demographic information, knowledge and perception based queries. Descriptive analyses were conducted using SPSS.
Results: In a survey of 526 respondents with representation across all regions of the UK, nurses made up the majority of respondents (57%). 71% of respondents weigh patients during ICU admission, often within the first 48 h, this indicates that a significant minority do not follow this practice. Key barriers identified, such as equipment limitations (65.77%) and concerns over patient instability (63.01%), underscore the challenges in achieving consistent and accurate weight measurement. Figure 1 shows the importance of the main barriers to weighing patients. Dislodgment of IV lines/tubes (74.8%) was identified as the most prevalent potential safety risk associated with weighing an intubated stable patient, with patient anxiety and discomfort (68.2%) identified in a non-intubated stable patient. Respondents felt that ICU patients should be weighed at least, once a week.
Conclusions: However, accurate and regular weighing in the ICU is critical, as emphasised by guidelines and literature, for precise drug dosing, nutritional management, and fluid balance monitoring. These factors directly impact patient outcomes, potentially reducing ICU stay and improving overall care. To optimise patient management and align with best practices, addressing the identified barriers through improved equipment provision and standardised protocols is essential to ensure that weighing patients becomes a routine and accurate procedure in the ICU.

Acute carbon monoxide poisoning: development of an experimental rat model for delayed neuropsychiatric sequelae and therapeutic intervention

Y. Kang[1]; S. Choi[2]; M. Lee.[3]
[1]Biomedical Sciences, Soonchunhyang University College of Medicine, Cheonan, Republic of Korea; [2]Emergency Department, Soonchunhyang University Bucheon Hospital, Bucheon, Republic of Korea; [3]R&D, IBEX MEDICAL SYSTEMS CO.,Ltd., Weonju, Republic of Korea.
Correspondence: S. Choi.
Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000457***.

Introduction: Delayed neuropsychiatric sequelae (DNS) are a well-known yet understudied complication following acute carbon monoxide (CO) poisoning. Despite their clinical significance, no established animal model exists to investigate the underlying pathophysiology or to evaluate potential therapeutic interventions. This study aimed to develop the first reproducible rat model of DNS induced by acute CO exposure and to assess the therapeutic efficacy of two novel interventions: ziprasidone and carbon monoxide-releasing molecule-3 (CORM-3).
Methods: Male Sprague–Dawley rats (250–350 g) were exposed to carbon monoxide (CO) gas at concentrations of 4000, 6000, or 8000 ppm for 20 min. Among these concentrations, the optimal CO concentration for establishing a delayed neuropsychiatric sequelae (DNS) model was identified. Rats exposed to the selected concentration and exhibiting signs of DNS were randomly assigned to one of three groups: ziprasidone (5 mg/kg, oral; $n = 6$), CORM-3 (4 mg/kg, intraperitoneal; $n = 6$), or control ($n = 5$). Treatments were administered once daily from post-exposure week 2 to week 3. Cognitive and

sensorimotor functions were assessed at 0, 2, 4, and 6 weeks post-exposure using a battery of behavioral tests, including the Y-maze, adhesive removal, olfactory discrimination, open field, and muscle strength tests.
Results: Exposure to 6000 ppm of carbon monoxide (CO) for 20 min was identified as the optimal condition for inducing delayed neuropsychiatric sequelae (DNS). By 4 weeks post-exposure, the majority of CO-exposed rats (> 95%) exhibited cognitive impairments and sensorimotor deficits. Performance in the Y-maze and adhesive removal tests at 6 weeks post-exposure was significantly improved in the ziprasidone group (41.8 ± 9.6% and 50 ± 50%, respectively) compared to the control group (8.3 ± 6.1% and 0%, $p < 0.001$). Similarly, the CORM-3 group demonstrated significantly higher scores (54.8 ± 15.4% and 67.7 ± 47.1%) than controls (7.2 ± 6.3% and 0%, $p < 0.001$) 6 weeks post-exposure. Total distance traveled in the open field test was also significantly greater in both treatment groups compared to control group (ziprasidone: 289.2 ± 85.4 cm; CORM-3: 324.3 ± 88.6 cm; control: 118.7 ± 23.4 cm; $p < 0.001$) at 6 weeks post-exposure.
Conclusions: This study introduces the first validated rat model of DNS following CO poisoning and provides preclinical evidence that ziprasidone and CORM-3 may effectively reverse DNS-associated cognitive and behavioral dysfunction. These findings offer a novel experimental platform for therapeutic discovery in post-CO brain injury.

Comparison of meropenem elimination in albumin-based ADVOS dialysis versus conventional CVVHD in critically ill patients

J. Triebelhorn[1]; M. Dibos[2]; U. Mayr[3]; T. Lahmer.[3]
[1]Innere Medizin 2, Technical University of Munich, Faculty of Medicine, München, Germany; [2]Innere Medizin II, TUM Klinikum Rechts der Isar, München, Germany; [3]Medizinische klinik und poliklinik ii, Klinikum rechts der Isar; Technische Universität München, Munich, Germany.

***Intensive Care Medicine Experimental*, *2025*;13(1): *000459*.**

Introduction: Effective antibiotic treatment is crucial in critically ill patients, especially when extracorporeal therapies such as dialysis may alter drug pharmacokinetics. Meropenem—a carbapenem antibiotic with a relatively low plasma protein binding (1.4–24.4%)—might demonstrate different clearance rates during albumin-based Advanced Organ Support (ADVOS) compared to conventional continuous venovenous hemodialysis (CVVHD) [1]. Given the requirement to maintain serum concentrations above the minimum inhibitory concentration (MIC) of 2 µg/mL for sensitive bacteria, understanding these differences is essential. To date, no in vivo data exists on meropenem elimination in patients treated with albumin-based dialysis systems [2].
Methods: This study analyzed 18 dialysis cycles in ICU patients, including 6 cycles with CVVHD and 12 cycles with ADVOS. Patients received meropenem doses ranging from 1000 to 2000 mg every 8 h, with dosing adjusted according to the severity of illness. Meropenem clearance was assessed by comparing pre- and post-filter drug concentrations. Serum levels were measured at 1, 3, and 7 h post-administration to determine adherence to the MIC threshold. Statistical analysis was performed using Student's t-test to compare clearance differences between CVVHD and ADVOS.
Results: The ADVOS system demonstrated a significantly higher clearance of meropenem (67.2 ± 10.1 ml/min) compared to CVVHD (34.5 ± 16.8 ml/min; $p < 0.001$). Importantly, no instances of serum meropenem concentrations falling below the MIC threshold were observed in either dialysis modality.
Conclusions: Albumin-based ADVOS yields significantly higher meropenem clearance than conventional CVVHD without compromising therapeutic serum levels. These findings underscore the need for further studies to refine pharmacokinetic models and optimize dosing regimens in critically ill patients undergoing extracorporeal therapies. Future research should aim to include larger sample sizes, detailed patient demographics, and stratification based on disease severity to further elucidate these effects and guide individualized therapy.

Introduction: Critical care echocardiography (CCE) has become fundamental in the management of critically ill patients. Point-of-care ultrasound (POCUS) is performed by a growing number of emergency care providers because it allows rapid bedside diagnosis [1]. Transthoracic echocardiography (TTE) represents the first-line tool to assess patients in shock state [2]. Transesophageal echocardiography (TEE) has gained importance, particularly in hemodynamically unstable patients under mechanical ventilation [3]. Indications of CCE in the intensive care unit (ICU) include assessment of hemodynamic instability, hypoxemia, cardiac arrest, LV systolic/diastolic function and filling pressures, RV function and pulmonary artery pressures, hemodynamic monitoring and optimization, acute aortic syndrome, procedural guidance [4].
Objectives: The purpose of this article is to illustrate the key role of CCE in our experience and to promote its use in the ICU for diagnosis, monitoring and clinical decision-making.
Methods: This is a single-center prospective cohort study of 135 patients receiving CCE-guided management. Investigated echocardiographic parameters included variables detailed in the TTE/TEE report template developed by the ESICM for the European Diploma in Advanced Critical Care Echocardiography (EDEC) curriculum. TEE was performed when TTE images were inadequate because of low echogenicity, obesity, wounds, chest wall devices, mechanical ventilation, or when more detailed analysis of cardiac structures was required. Adjunctive therapies and changes in resuscitation management included intravenous fluids, vasopressor, inotrope and diuretics.
Results: 135 patients (median age 74, 66% male) underwent CCE-guided management. TTE was performed in 100 cases and TEE in 35 cases. 56 patients were examined under mechanical ventilation. The most common indications for CCE were circulatory shock (50%) and respiratory distress (37%). Septic shock was the main type of shock (41%), followed by cardiogenic shock (26%), obstructive shock (22%), and hypovolemic shock (11%). Assessment of fluid responsiveness was performed in 33 cases (25%). Impaired left ventricular systolic function was diagnosed in 57 patients (42%). Left ventricular diastolic dysfunction with elevated filling pressure was diagnosed in 47 patients (35%). Suggested change in resuscitation management was observed in most cases (95%), including adjustment in vasopressor (50%) and inotrope initiation (15%) when cardiac dysfunction was believed to be responsible of inappropriate organ perfusion. Working diagnosis changed in 88% (n = 119) of patients. The next step of our analysis is to compare the effect of CCE-guided therapy to standard management in terms of survival, fluid/vasopressor/inotropic prescription, ventilator free-days and ICU length of stay. This work is under development and we hope that the results will be proposed as abstract for LIVES 2026 in Lisbon.
Conclusions: CCE represents an increasingly important skill for the modern ICU physician. In this article, we described 135 clinical situations in which TTE/TEE examinations where used in managing unstable patients. Our experience illustrates that CCE can be instrumental in the diagnosis, monitoring and treatment guidance of critically ill patients. Further explorations of the impact of CCE in the ICU appear warranted. Finally, we are convinced that training experience and interpretation in appropriate contexts are key for the safety of the patients. In this regard, the European Diploma in Advanced Critical Care Echocardiography (EDEC) represents an ESICM certification for intensivists with basic echocardiography skills who want to develop their expertise and advance optimal care with clinical practice guidelines.

Transesophageal ultrasound imaging of the ascending aorta (135° probe rotation). This image recorded during cardiac arrest resuscitation demonstrates a Stanford Type A aortic dissection

Transesophageal ultrasound imaging of the bicaval view (115° probe rotation). This image recorded in a postoperative cardiac surgery patient with shock demonstrates a compression of the right atrium (RA) and the superior vena cava (arrowhead) by a 'hidden' posterior pericardial clot (arrow).

Cardiac POCUS imaging with the subcostal approach in a patient with hemodynamic instability in the emergency department. This image demonstrates a massive pericardial effusion responsible for cardiac tamponade

Intensive Care Medicine Experimental, 2025*;13(1)**: ***000461.

Introduction: Dyspnea affects approximately 35–50% of mechanically ventilated (MV) patients and is among the most distressing experiences in the ICU [Demoule]. The Mechanical Ventilation Respiratory Distress Observation Scale (MV-RDOS), with a threshold of ≥ 2.6 indicating dyspnea [Decavèle], is a validated assessment tool but relies on intermittent clinician observation and subjective interpretation. Given that dyspnea is associated with accessory muscle activation, we hypothesize that patient-initiated inspiratory efforts during the insufflation phase may serve as an objective physiological marker of dyspnea.
Objectives: To evaluate whether continuous measurements of the pressure–time product of inspiratory muscle effort (PmusPTP) during the insufflation phase of a ventilator-delivered breath correlates with MV-RDOS and could serve as an objective surrogate for dyspnea in MV patients.
Methods: This IRB-approved, prospective observational study enrolled MV adults with respiratory failure of varying etiologies at three academic medical centers. Airway pressure and flow waveforms were sampled at 32.25 Hz via the ventilator data port and analyzed using a single-compartment model of the respiratory system [Otis] to compute breath-by-breath PmusPTP, both inspiratory and expiratory, during the insufflation phase [Gutierrez]. Inspiratory PmusPTP values were summed across all breaths within consecutive 131-s windows (epochs) to yield an epoch-level inspiratory PmusPTP. MV-RDOS scores were obtained twice daily by trained clinicians for up to five days. The correlation between MV-RDOS and concurrent epoch-level inspiratory PmusPTP was evaluated using Pearson's R^2.
Results: In 86 paired observations from 16 patients (Fig. 1), inspiratory PmusPTP demonstrated a strong positive correlation with MV-RDOS scores ($R^2 = 0.58$, $p < 0.0001$). Using an MV-RDOS threshold of ≥ 2.6 to indicate dyspnea, a PmusPTP cutoff of > 20 $cmH_2O{\cdot}s$ identified dyspnea with 76% sensitivity and 89% specificity.
Conclusions: Inspiratory PmusPTP correlates with MV-RDOS and may enable automated, continuous dyspnea monitoring in MV patients. Further validation is warranted.

Introduction: While patients with advanced age have an increased mortality risk after an out-of-hospital cardiac arrest (OHCA) [1], less is known about the impact of frailty. Frailty is described as a state or syndrome of reduced physical, physiologic and cognitive reserve with an increased vulnerability to sudden changes in health status caused by a minor illness [2]. Frailty occurs in a third of adults admitted to critical care [3], and is closely related to adverse outcomes [4], but few studies have investigated how frailty affects outcomes after an OHCA.
Objectives: We aimed to explore how frailty is associated to mortality, functional outcome, and quality of life after an OHCA.
Methods: This is an extended analysis of frailty prior to an OHCA within the Targeted Hypothermia versus Targeted Normothermia after Out-of-Hospital Cardiac Arrest (TTM2) trial. Frailty was assessed with Clinical Frailty Scale (CFS), defined CFS ≥5 and divided into fit (CFS 1–3), prefrail (CFS 4), frail (CFS 5) and severely frail (CFS 6–9). We used logistic regression to explore the association between frailty and 6-months mortality and poor functional outcome (modified Rankin Scale 4–6). At 6-months follow-up, we assessed functional decline in prefrail, frail, and severely frail survivors using Glasgow Outcome Scale – Extended, comparing it to their retrospective functional status. In all patients, we evaluated quality of life using EQ-VAS and Life Satisfaction.
Results: Out of 1861 patients, 240 (13%) were prefrail and 81 (4%) frail and 107 (6%) severely frail before the OHCA. 911/1861 (49%) were deceased at 6 months. Mortality was significantly higher with greater frailty, starting from prefrail (adjusted OR 2.85 (95% CI: 2–4.07)), with the highest odds for severely frail (adjusted OR 10.05 (95% CI: 4.82–20.95)) (Fig. 1). Withdrawal of life-sustaining therapies (WLST) was performed in 373 (26%) of fit patients, 124 (52%) of prefrail, 52 (64%) of frail and 71 (66%) of severely frail patients. Poor neurological prognosis was the reason for WLST in 214 (58%) of fit, 50 (40%) of prefrail, 20 (38%) of frail and 14 (20%) of severely frail patients. 988/1861 (53%) had a poor functional outcome at 6 months. Frailty was associated with poor functional outcome, starting from the prefrail (adjusted OR 3.15 (95% CI: 2.16—4.6)) and with the highest odds for severely frail (adjusted OR 40.92 (95% CI 9.8—170.79)) (Fig. 1). In survivors, functional decline was more pronounced with greater frailty (Fig. 2). Prefrail and frail survivors reported overall good quality of life, but slightly lower general health and life satisfaction compared to fit survivors (Fig. 3a-b).
Conclusions: Frailty was significantly associated with mortality and poor functional outcome after OHCA. When surviving, frail survivors may report acceptable quality of life.

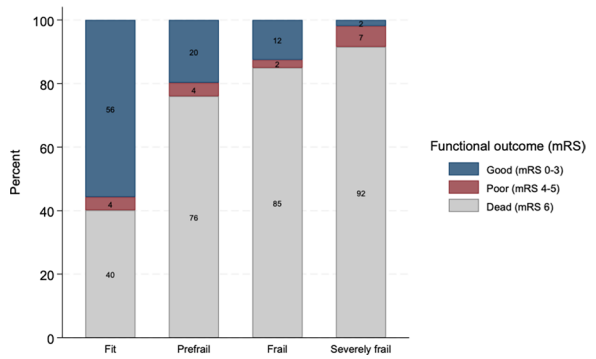

Fig. 1 (abstract 000462) Mortality and functional outcome according to mRS at 6 months

mRS modified Rankin Scale.

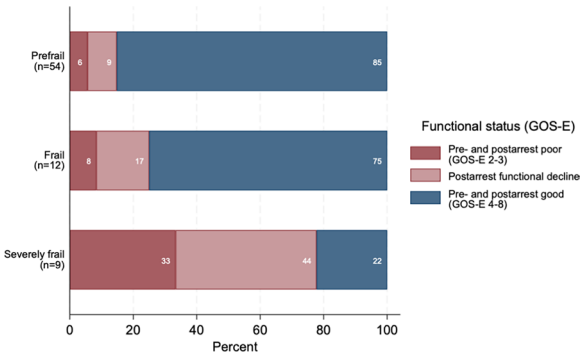

Fig. 2 (abstract 000462) Functional decline according to GOS-E at 6 months compared to pre-arrest functional status. GOS-E 2–3 was considered a poor functional status, GOS-E 4–8 a good functional status and a change from good to poor was defined as a functional decline GOS-E Glasgow Outcome Scale—Extended.

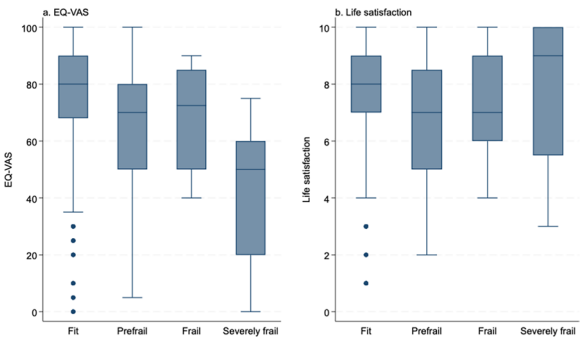

Fig 3 (abstract 000462) a-b Boxplot of patient-reported outcome of general health (EQ-VAS) and life satisfaction at 6 months. EQ-VAS: fit survivors reported in median self-rated health to 80 (IQR 68–90), prefrail in median 70 (IQR 50–80), frail in median 72.5 (IQR 50–85) and severely frail in median 50 (IQR 20–60). Life satisfaction: fit survivors reported in median life satisfaction to 8 (IQR 7–9), prefrail in median 7 (IQR 5–8.5), frail in median 7 (IQR 6–9) and severely frail in median 9 (IQR 5.5–10).
747/858 (87%) of fit survivors, 49/59 (83%) of prefrail survivors, 10/13 (77%) of frail survivors and 5/9 (56%) of severely frail survivors reported on EQ-VAS. 736/858 (86%) of fit survivors, 48/59 (81%) of prefrail survivors, 9/13 (69%) of frail survivors and 4/9 (44%) of severely frail survivors reported on life satisfaction.
EQ-VAS EuroQol-visual analogue scale.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000463***.

Introduction: In the intensive care unit (ICU), drug dosing presents challenges due to variable pharmacokinetics, such as expanded apparent volume of distribution, owing to fluid resuscitation, which can result in inadequate dosing, and end-organ dysfunction, which impacts drug clearance or metabolism. Pharmacists in the ICU are positioned to advise on individual drug dosing using therapeutic drug monitoring to maximise the efficacy of medications while minimising drug toxicity(1). Achieving therapeutic serum concentrations for medications with a narrow therapeutic range is crucial for critically ill patients.
Objectives: The aim of this study was to evaluate the impact of a pharmacist-managed therapeutic drug monitoring service in a mixed ICU of an acute general hospital on dosing optimisation and minimisation of potential adverse drug events (ADEs).
Methods: The study was conducted over three months in 2023, where clinical pharmacists reviewed the medication charts of patients admitted to the ICU and participated in daily ward rounds as part of the multidisciplinary team. Data about TDM activities carried out by pharmacists were compiled. The pharmacists provided clear guidance on timing of TDM in relation to drug administration, interpreted TDM results and provided specialised pharmacological advice following TDM results, including adjustments in dose or frequency for subsequent doses, in collaboration with ICU clinicians. Recommendations by pharmacists also took into account the patient's clinical condition, changes in renal replacement therapies, administration modes, and drug-drug interactions. All pharmacists' recommendations were evaluated by a panel of experts for their potential to prevent a potential ADE.
Results: Over the three-month period, among 164 patients admitted to the ICU, 35 patients needed TDM recommendations from pharmacists, resulting in a total of 93 interventions. The medications most frequently involved in TDM were antimicrobials (71%), comprising aminoglycosides and vancomycin, anti-epileptics (13%) and digoxin (12%). Pharmacist recommendations included requesting TDM (52%), adjusting daily dosage (16%), modifying dosing intervals or infusion rates (17%), withholding medications in cases of supratherapeutic levels (12%), changing method of administration (2%) or proposing alternative therapy in case of severe interactions (1%). The expert panel assessed the interventions to have a medium (20%) or low (80%) probability of preventing a potential ADE. Interventions with a medium probability of preventing a potential ADE included omitting the planned dose of aminoglycoside in a patient with kidney injury who was receiving a continuous replacement therapy free period, and carrying out TDM until the trough was within range; requesting TDM and proposing the need for alternative treatment due to interaction between sodium valproate and meropenem; stopping vancomycin infusion and requesting TDM due to sudden decline in renal function and development of an acute kidney injury in a patient being treated with vancomycin continuous infusion.
Conclusions: A pharmacist-managed TDM service helped optimise medication doses for drugs with a narrow therapeutic range and those with a high incidence of toxicity. Timely interpretation and appropriate management of TDM assisted in preventing potential ADEs in critically ill patients.

Introduction: Distinguishing bacterial from viral meningitis remains a major challenge in emergency and intensive care settings due to overlapping clinical and biological features. While cerebrospinal fluid lactate (CSF) and serum procalcitonin analysis is a cornerstone in diagnosis, conventional markers such as white blood cells and protein levels lack specificity.
Recent studies suggest that CSF lactate and serum procalcitonin (PCT) may provide superior diagnostic accuracy.[1,2,3] However, recent studies have highlighted the potential superiority of cerebrospinal fluid lactate as a more sensitive and specific biomarker in this context.
Objectives: This study aims to compare the sensitivity and specificity of CSF lactate and serum PCT in differentiating bacterial from viral meningitis, with a focus on their respective receiver operating charasteristic (ROC) curves.
Methods: We conducted a retrospective cohort study including 220 patients (110 bacterial meningitis and 110 viral meningitis) admitted for acute meningitis to University hospital ICU between 2018 and 2023. All patients were 40 + -15 years old and underwent lumbar puncture within the first hour.
Bacterial meningitis was confirmed based on CSF culture and/or PCR positivity for bacterial pathogens whereas viral meningitis was diagnosed via viral PCR and negative bacterial cultures. CSF lactate and serum PCT were measured at admission.
Diagnostic performance was assessed using ROC curve analysis, comparing the area under the curve (AUC), sensitivity and specificity of both biomarkers.
Results: Statistical analysis used Mann–Whitney test and results expressed as mean +—standard deviation.
CSF lactate levels were significantly higher in bacterial meningitidis patients (6.2 + -1.8mmol/L) compared to viral cases (2.3 + -0.9mmo/L) $P < 0.001$.
Serum PCT was also elevated in bacterial cases compared to viral cases, respectively (4.8 + -2.5ng/ml vs 0.6 + -0.4ng/ml, $P < 0.001$).
ROC curve analysis revealed that CSF lactate had a higher area under curve AUC (0.98) compared to serum PCT AUC (0.88) with a superior sensitivity (94%) and specificity (91%) at an optimal cut-off of 3.5mmol/L (Fig. 1).

Conclusions: CSF lactate outperforms serum PCT for differentiating bacterial from viral meningitis demonstrating higher sensitivity and specificity. Its rapid availability and superior diagnostic accuracy make it a valuable biomarker in acute meningitis management. However, combining both biomarkers may enhance diagnostic accuracy particularly in early or atypical presentations.
Integrating CSF lactate into diagnostic protocols may improve early decision-making, especially in critically ill patients.

Introduction. Background: Scheduling a hemodialysis (HD) immediately prior to a renal transplant in stable end-stage renal disease patients involves extra cost, time, equipment and personnel commitment to both the healthcare system and the patients. We conducted this study to investigate if we could safely avoid dialysis 16 h prior to a scheduled live related renal transplant (LRRT).

Methods. Methods: This study was a randomized parallel arm clinical trial which recruited 75 adults on thrice weekly HD presenting for LRRT to our tertiary care center between January 2022–June 2023. Forty-eight hours prior to the planned LRRT the consenting patients were allocated to terminate elective HD at either 36 h or 16 h prior to the scheduled transplant time. Blood gases and electrolytes were sampled before induction of general anaesthesia (T0) to evaluate *non-inferiority at a margin of -5* for the mean difference (36 h-16 h) in *apparent strong ion difference* (SIDa). The intraoperative management of anaesthesia and goal-directed fluid management was as per institute protocol. The patients were followed up for intraoperative hemodynamics and post-operative graft function (creatinine, urine output and dialysis requirement till day 7).
Results: Of 191 screened, 75 (38 in 36 h vs 37 in 16 h group) patients completed the study. The mean difference of SIDa at T0 was -1.03 [95% CI, -4.15 to 2.09] demonstrating non-inferiority of 36 h HD. There was no difference in the pH or potassium at this time point. The 36 h group had higher CVP and lower PPV at T0 and maintained better MAP throughout the surgery. There was no difference in the intraoperative fluid, vasopressor requirement, acid–base balance or in the postoperative graft function.
Conclusions. Conclusion: Dialysis done 36 h before renal transplant is non-inferior to dialysis done 16 h before transplant in terms of SIDa.

Effect of different ventilatory settings on mechanical power and [(4xΔP) + RR] index under isocapnic conditions

E. Benidis[1]; E. Kaniaris[2]; A. Sakagianni[1]; G. Gavriilidis.[2]
[1]Intensive Care Unit, Sismanoglio Hospital, Marousi, Greece; [2]Intensive Care Unit, 1st department of Respiratory Medicine, National & Kapodistrian University, Sotiria Hospital for Chest Diseases, Athens, Greece.
Correspondence: E. Benidis.
Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000469***.

Introduction: Mechanical power (MP) reflects the transfer of energy from the ventilator to the respiratory system per unit of time [1]. It consists of three components: Elastic Dynamic MP, Elastic Static MP, and Resistive MP, with only the first being positively associated with mortality. Amato's group found that of the variables considered for calculating MP, only the driving pressure (ΔP) and respiratory rate (RR) were associated with mortality. In fact, it was found that the magnitude of the effect on mortality of each unit of ΔP is approximately four times the magnitude of the effect on mortality of each unit of RR, which led to the creation of the index [(4xΔP) + RR] [2].
Objectives: To determine the changes in mechanical power, its three components and the [(4xΔP) + RR] index, resulting from the simultaneous modification of tidal volume (VT) and respiratory rate while maintaining isocapnic conditions.
Methods: The study was carried out in 2024 in the ICUs of the "Sotiria" and "Sismanogleio" General Hospitals of Athens. The study included hemodynamically stable, intubated and mechanically ventilated adult patients, without their own respiratory effort. Patients were ventilated with 6, 8 and 10 ml/kg of predicted body weight (in random order) in Assist Volume Control mode, while simultaneously varying the respiratory rate to achieve isocapnic conditions, i.e. PaCO2 with a deviation of less than 5% of the initial value. The other ventilatory settings remained unchanged. Subsequently, for each tidal volume, MP [0.098 × MV x (Ppeak—ΔP/2)], elastic static MP [0.098 × MV x PEEP], elastic dynamic MP [0.098 × MV x ΔP/2], resistive MP [0.098 × MV x (Ppeak—Pplateau)], and the index [(4xΔP) + RR] were calculated [2,3]. The statistical significance level was set at $p < 0.05$.
Results: The study enrolled 36 patients. The mean age was 66.75 ± 14.09 years and the mean compliance 45,71 ± 15,57 ml/cmH2O. 36% had pneumonia. Mechanical power, elastic static MP and resistive MP, all are decreased statistically significantly as the tidal volume increases from 6, to 8 and finally to 10 ml/kg of PBW (p-value < 0.005 between all three tidal volumes). Changes in VT from 6 to 8 ml/kg of PBW as well as from 6 to 10 ml/kg of PBW are significantly associated with an increase in elastic dynamic MP (p-value < 0.005 for both) (Fig. 1). A significant positive association was found between VT changes and the [(4xΔP) + RR] index, both when VT increased from 6 to 10 ml/kg of PBW (p-value < 0.005) and from 8 to 10 ml/kg of PBW (p-value = 0.011) (Fig. 2).
Conclusions: As the tidal volume increases under isocapnic conditions, mechanical power decreases due to the decrease in minute ventilation, which in turn causes a decrease in elastic static MP and resistive MP. On the contrary, the indices that are best associated with both mortality and the pathophysiology of ventilator-induced lung injury, namely elastic dynamic MP and the [(4xΔP) + RR] index, show an increasing trend as the driving pressure increases.

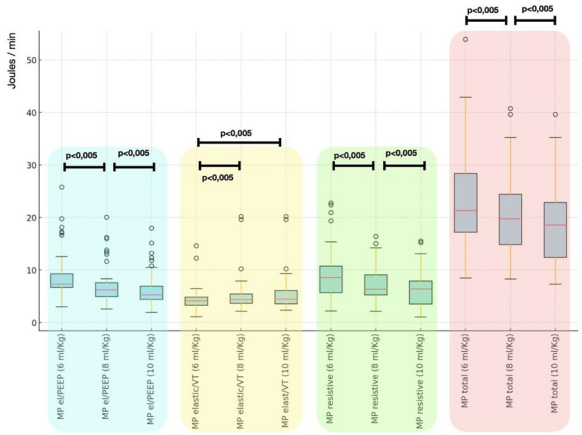

Fig. 1 (abstract 000469) Box plot for elastic static MP (blue), elastic dynamic MP (yellow), resistive MP (green) and total mechanical power (red) for tidal volumes of 6, 8 and 10 ml/kg of PBW.

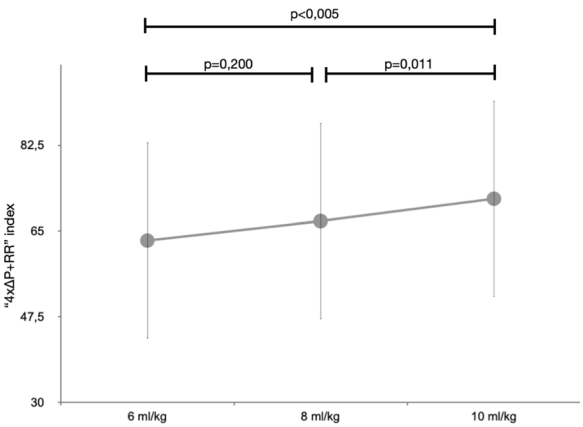

Fig 2 (abstract 000469) The mean and standard deviation of the [(4xΔP) + RR] index for tidal volumes of 6, 8 and 10 ml/kg of PBW

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000473***.

Introduction: The indiscriminate use of antibiotics has resulted in the rise of multidrug-resistant (MDR) organisms in intensive care units (ICU) and the global threat of antibiotic resistance. Antimicrobial Stewardship Programs (ASPs) are coordinated efforts designed to promote the judicious use of antimicrobials, improve patient outcomes, decrease microbial resistance, and reduce the spread of multidrug-resistant infections. (1–3).
Objectives: This study aimed to evaluate the impact of an ASP on antibiotic consumption and antimicrobial resistance in a tertiary cardiac center in Egypt.
Methods: A quasi-experimental study was conducted in the adult critical care unit at our centre from July 1, 2023, to June 30, 2024, comparing antimicrobial consumption estimated by defined daily dose (DDD) per 1000 patients and antimicrobial resistance before and after the implementation of the ASP.
Results: During the pre-intervention phase, 1000 patients were admitted to the ICU, while in the post-intervention period, 982 patients were admitted to the ICU. Following the Antibiotic Stewardship Program (ASP) implementation, the mean monthly antimicrobial utilization decreased by 23%, from 14,414 to 11,012 DDD per 1,000 bed days ($p = 0.097$).
Colistin consumption significantly decreased, dropping from 817 to 53 DDD per 1,000 bed days after the intervention ($p = 0.006$). Colistin is one of the most frequently used drugs for treating multidrug-resistant organisms (MDRO), and this decrease in consumption may be attributed to a reduction in resistance rates.
Additionally, there was a drop in tigecycline use, with a mean reduction of 36 DDD per 1,000 bed days ($p = 0.16$). Ceftazidime–avibactam consumption decreased from 163 to 27 DDD per 1,000 patient days ($p = 0.2$).
There was also a slight increase in meropenem consumption, from 1,169 to 1,258 DDD per 1,000 patient days. This increase in meropenem usage may be due to a decrease in the percentage of carbapenem-resistant Enterobacteriaceae.
The consumption of levofloxacin, trimethoprim–sulfamethoxazole, and linezolid also increased, but not significantly. The mean total monthly consumption of these three drugs increased by 59 DDD per 1,000 patient days for levofloxacin ($p = 0.9$), 147 DDD per 1,000 patient days for trimethoprim-sulfamethoxazole ($p = 0.97$), and 12 DDD per 1,000 patient days for linezolid ($p = 0.73$). This increase may be attributed to a rise in the IV to oral switch rate. (Figure A).
There was a significant reduction in the percentage of carbapenem-resistant Enterobacteriaceae from 40 to 30% ($p < 0.001$). (Figure B).
Conclusions: Implementing an ASP in the critical care unit significantly improved antibiotic consumption and reduced antimicrobial resistance, emphasizing its value in addressing the challenges of antimicrobial misuse and resistance in resource-limited settings.

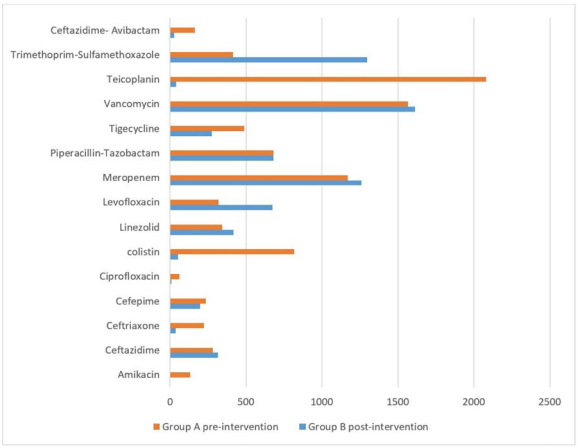

Figure A (abstract 000473) Comparison of total monthly antimicrobial consumption, expressed as defined daily doses (DDD) per 1,000 bed-days, during the pre-intervention and post-intervention phases

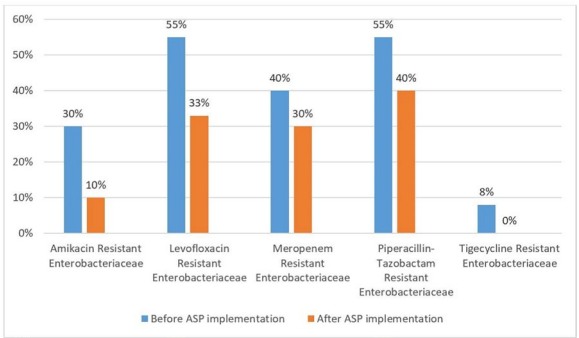

Figure B (abstract 000473) Comparison of antibiotic resistance patterns in the pre-intervention and post-intervention phases

Introduction: Invasive pulmonary aspergillosis (IPA) represents a severe fungal infection with high morbimortality among individuals (1). The diagnosis, based on EORTC criteria, supposes a challenge on clinical practice, since cultures are often unreliable given the slow growth of *Aspergillus* species in vitro *(2)*. Moreover, the detection of galactomannan antigen (GM) by ELISA is not usually available 24 h a day, which also makes rapid diagnosis difficult. Novel qualitative molecular techniques such as the lateral flow assay (LFA) may provide the detection of galactomannan on the bedside and further determine the prompt initiation of antifungal therapy.

Objectives: To evaluate the performance of lateral flow assay for galactomannan (LFA) on bronchoalveolar lavage (BAL) samples for the diagnosis of IPA among critical care patients and its impact on antifungal use.

Methods: Multicentric, retrospective analysis of BAL samples gathered from ICU patients between July 2022 and December 2024 in whom IPA was suspected and galactomannan determination were performed: Lateral Flow Assay (IMMY™, Norman Oklahoma USA) and quantitative ELISA (Platelia®, BioRad®); as well as conventional culture. ELISA GM was considered positive using an optical index threshold of ≥ 1.

Risk factors for fungal infections, epidemiological characteristics as well as microbiological testing results and treatment before and after the results were collected. IPA diagnosis was established by BM-AspICU criteria (3).

Overall performance of each test was calculated and compared, using Cohen's Kappa. Statistical analysis was performed by classical T and Chi-squared test.

Approval from the local ethics committee was obtained (SICEIA-2024–002428).

Results: In total, 243 BAL samples from 194 ICU patients were collected. The main admission diagnosis recorded was acute respiratory failure (69%) followed by sepsis or septic shock (25%). 45% of patients presented immunosuppression, being high doses of corticosteroids (45%), active immunosuppressive treatment (31%) and onco-hematological malignancy (21%) the most common. A total of 34 cases of probable IPA (17,5%) were diagnosed. Neutropenia (OR 5.1, 95% CI 1.3–22), solid neoplasia (OR 4.31, 95% CI 1.09–16) and HIV infection (OR 5.15, 95% CI 1.04–26) were found as risk factors for IPA.

Test performances are shown in Table 1. As stated, LF-GM yields a consistent NPV value for either ELISA or culture, over 90% in both cases. PPV, however, was found low in both Lateral Flow and ELISA compared with culture (Fig. 1). There was an association between a discordant LF + /ELISA-case with lower median optical indexes on ELISA when compared to LF + /ELISA + (2,32 vs. 5,2, p < 0.05) (Fig. 2).

Table 1.(abstract 000475) Performance statistics of the different methods studied

	Accuracy	Kappa	Sensitivity	Specificity	PPV	NPV
LF vs. ELISA	0.88	0.56	0.65	0.92	0.62	0.93
LF vs. culture	0.87	0.46	0.74	0.89	0.40	0.97
ELISA vs. culture	0.91	0.62	0.91	0.91	0.53	0.99

Regarding the consequences of LF results, its result had a statistically significant effect on antifungal treatment. LF positiveness led to antifungal initiation or maintenance on 75% of cases, whereas on negative LF withholding antifungals or suspension if started were the most frequent actions (90%). On the 17 cases where ELISA was found negative after prior positive LF, treatment was suspended on 83% of patients.

Conclusions: Lateral flow galactomannan assay presents a high negative predictive value and concordance with ELISA and fungal culture, providing support on the physician decision to treat suspected IPA patients in the ICU. Higher positive predictive values may be obtained with higher optic index positive threshold although more evidence is necessary. In our series, false-positive LF does not induce antifungal overtreatment and its use had an overall positive effect on rationalized antifungal use.

Plasma calprotectin as a marker of infection in patients requiring intensive care or undergoing major surgery—a prospective observational study

T. Zimmermann[1]; T. Snow[1]; N. Arulkumaran[1]; A. Al-Hindawi[1]; M. Singer[1]; D. Brealey.[1]
[1]Bloomsbury Institute of Intensive Care Medicine, University College London, London, United Kingdom.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000477***.

Introduction: Differentiating infection from sterile inflammation is often difficult, particularly when underlying inflammatory processes are active, e.g. during chemotherapy or after surgery/trauma. To prevent unnecessary antibiotic prescriptions and needless investigation, a reliable and rapid diagnostic tool is required. Calprotectin is released into the circulation by activated immune cells and could represent a useful diagnostic option.
Objectives: To assess the diagnostic performance of calprotectin for an adjudicated diagnosis of infection, and to compare it against established biomarkers in two specific patient populations.
Methods: Patients undergoing major elective non-cardiac surgery and patients in whom infection was suspected during their intensive care unit (ICU) admission were prospectively enrolled in this observational single-centre study. Diagnostic adjudication was performed retrospectively by experienced physicians after reviewing patient files including microbiology data, blinded to calprotectin measurements. For patients undergoing surgery, post hoc adjudication was performed according to the Standardised Endpoints in Perioperative Medicine (StEP) initiative.[1] For ICU patients, an adjudicated diagnosis was made of no infection, low probability, high probability, or definite infection.
Results: 84 patients (median age 65 years [IQR 55–71]), of whom 74 (88%) had active cancer, were recruited after major non-cardiac surgery. 34 (40%) were adjudicated to have post-operative infection. Plasma calprotectin levels were low pre-operatively (median 0.34 mg/l [IQR 0.12–0.75]) with a clear rise in the post-operative samples (Fig. 1A). However, the calprotectin level could not discriminate between infection and inflammation (Table 1). By comparison, C-reactive protein (CRP) showed higher concentrations in patients with infection from postoperative day 1–2 onwards and better diagnostic discrimination.
98 ICU patients (median age 58 years [IQR 46–70]) were also enrolled, of whom 34 (34%) had an adjudicated post hoc diagnosis of high probability or confirmed infection. Overall median plasma calprotectin level in the first sample taken was 3.0 mg/l [IQR 2.0–6.0], again with poor ability to differentiate infectious from non-infectious processes (Fig. 1B). This remained the same over subsequent days. No other measured biomarker (CRP, white cell count, neutrophil count, interleukin-6) was able to consistently differentiate between definite/high probability infection and zero or low probability infection.

Table 1: (abstract 000477) Diagnostic discrimination of calprotectin and CRP for an adjudicated diagnosis of infection in patients undergoing major non-cardiac surgery at different sample timepoints.

Biomarker	Sample time	AUC [95%-CI]
Calprotectin	Post-op d0	0.54 [0.41–0.67]
CRP	Post-op d0	0.51 [0.35–0.66]
Calprotectin	Post-op d1-2	0.58 [0.42–0.73]
CRP	Post-op d1-2	0.70 [0.58–0.82]
Calprotectin	Post-op d5-7	0.65 [0.42–0.88]
CRP	Post-op d5-7	0.77 [0.66–0.88]

Conclusions. In this study, calprotectin could not discriminate reliably between infectious and sterile inflammation in two cohorts from different hospital settings. While CRP concentrations were more useful from days 1–2 onward in surgical patients, rapid and accurate diagnosis of infection in ICU patients remains a major challenge.

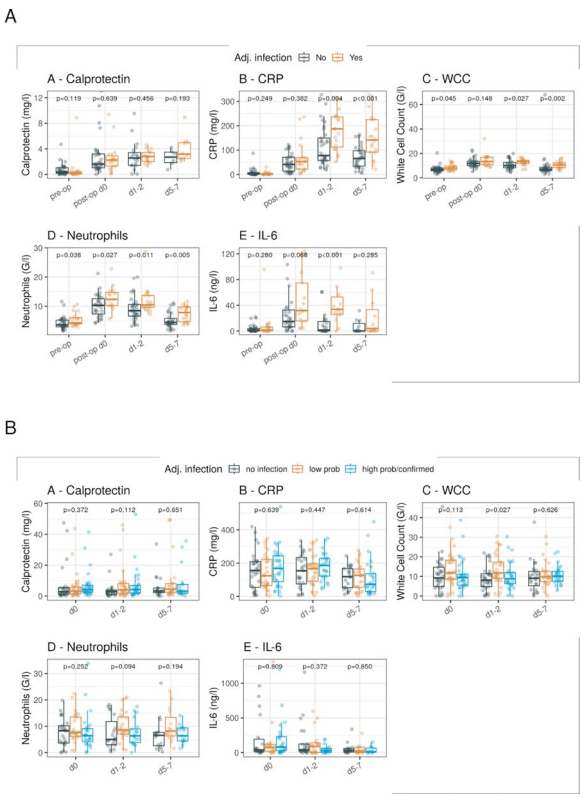

Figure 1 (abstract 000477) Longitudinal dynamic of biomarkers in patients undergoing major non-cardiac surgery (A) and patients with suspected infection on the intensive care unit (B). Patients are stratified by their adjudicated diagnosis

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000478***.

Introduction: Interventional therapies for pulmonary embolism (PE) are becoming increasingly prevalent for the treatment of intermediate and high-risk PE, including catheter directed thrombolytics (CDT) and mechanical thrombectomy (MT). There is widespread evidence in other endovascular interventional therapies that high volume centers have improved outcomes and less complications, including percutaneous coronary intervention, and interventional stroke thrombectomy.1–3 However, it is unknown if these benefits of higher volume translate to interventional therapies for PE.
Objectives: To investigate the relationship between increasing yearly hospital case volume for interventional therapies and all-cause in-hospital mortality in patients admitted with PE across the United States.
Methods: We conducted a retrospective cohort analysis of all adults (^{3}18 years) admitted to hospital in the US with PE that received interventional therapies between 2016 and 2022. Both the diagnosis of PE and the use of interventional therapies were identified using ICD10 codes. If patients had both CDT as well as MT, we characterized them as belonging to the MT group. For classification of case-volume, we utilized a continuous variable as well as creating the following annual case volume categories: 1–25 cases per year, 26–50 cases per year, 51–75 cases per year, > 75 cases per year. Multivariate logistic regression modelling was used to model adjusted all-cause in-hospital mortality and included mechanical ventilation, cardiac arrest, age, sex, and co-morbidities.
Results: We identified 24,122 patients who underwent interventional therapies while hospitalized for PE from the 2016–2022 NIS samples. Of these patients, 14,691 (60.1%) underwent CDT, whereas 9,431 (39.1%) underwent MT. The total number of procedures at each type of hospital was: 1–25 cases 14,899 (61.8%), 26–50 cases 6,183 (25.6%), 51–75 cases 2,040 (8.5%), > 75 cases 1,000 (4.2%). Mortality in the low-volume (1–25/year) centers was 8.9% compared to 5.7% at the high-volume (> 75/year) centers ($p < 0.01$). After multivariate adjustment, increasing hospital-case volume was associated with a significantly reduced risk of mortality (odds ratio (OR) 0.96 per 10 case/year increase, 95% confidence interval (CI) 0.94–0.98, $p < 0.01$). Patients were transferred in from other hospitals to high-volume (> 75/year) centers more frequently than low-volume centers (18.6% vs 33.3%, $p < 0.01$).
Conclusions: Performance of interventional therapies for PE at higher volume centers was associated with lower risk of all-cause in-hospital mortality. Further studies are needed to better characterize this relationship.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000481***.

Introduction: In acute respiratory distress syndrome (ARDS), setting an appropriate level of positive end-expiratory pressure (PEEP) is critical, yet the optimal method for determining PEEP remains unclear. Recently, electrical impedance tomography (EIT)-based methods for PEEP titration have been investigated; however, no standardized approach regarding ventilator mode has been established. An interim analysis of this study was presented at the ESICM 36th annual congress, and the current report presents the final analysis.
Objectives: To compare the optimal PEEP levels determined by decremental PEEP titration using EIT across three different mechanical ventilation modes.
Methods: This study enrolled adult patients (aged $\geq$ 18 years) with ARDS who were admitted to the intensive care unit of Tokyo Bay Urayasu Ichikawa Medical Center and received continuous neuromuscular blockade. Exclusion criteria included pregnancy, the presence of a chest drain, recent thoracic surgery (within 1 week), contraindications to EIT, and hemodynamic instability. Decremental PEEP titration was performed from 22 cmH_2O to 4 cmH_2O in 3 cmH_2O steps. Three ventilation modes—pressure-controlled ventilation (PCV), volume-controlled ventilation with a square waveform, and volume-controlled ventilation with a decelerating waveform—were tested in random order in each patient. The overdistension-collapse (O/C) cross point and the anteroposterior (A/P) point, defined as the PEEP level at which ventilation is evenly distributed between ventral and dorsal lung regions, were identified via offline EIT analysis and compared across modes.
Results: Seventeen patients were included (13 men [77%], mean body mass index 27.0 $\pm$ 6.75). The pre-titration P/F ratio was 124 $\pm$ 36.6, and respiratory compliance was 33.3 $\pm$ 10.0 mL/cmH_2O. The A/P points were 11.1 $\pm$ 4.27 cmH_2O in PCV, 12.9 $\pm$ 4.55 cmH_2O in square waveform VCV, and 11.9 $\pm$ 4.21 cmH_2O in decelerating waveform VCV. The square waveform VCV had significantly higher A/P points than the other two modes ($P < 0.05$). The O/C points were 11.9 $\pm$ 2.75 cmH_2O in PCV, 12.71 $\pm$ 2.94 cmH_2O in square waveform VCV, and 13.2 $\pm$ 3.04 cmH_2O in decelerating waveform VCV. PCV showed significantly lower O/C points compared to the other modes ($P < 0.05$).
Conclusions: This study demonstrates that the optimal PEEP determined by EIT-based titration may vary depending on the ventilator mode used. These findings suggest that ventilator mode should be considered when setting PEEP in patients with ARDS.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000482***.

Introduction: Mean arterial pressure to norepinephrine equivalent dose ratio (MAP/NEQ index), has recently gained attention as a prognostic tool in critical care, including for predicting intensive care unit (ICU) mortality [1] and guiding nutritional or renal support interventions [2; 3] However, its outcome prediction utility in the setting of blood purification therapies, particularly devices such as the Oxiris hemofilter, remains underexplored. Beyond its renal support function, the Oxiris filter has demonstrated potential in sepsis management by adsorbing cytokines and pathogen- or damage-associated molecular patterns, potentially improving immunological response and reducing septic shock. Early identification of patients who are likely to benefit from Oxiris-based continuous renal replacement therapy (CRRT) may improve clinical outcomes and survival predictability.
Objectives.
To assess the prognostic value of the MAP/NEQ index and its dynamic change (Δ) over time during CRRT in predicting short-term ICU mortality.
To evaluate MAP/NEQ index association with immunological response severity (indicated by interleukin-6 (IL-6) levels) and microcirculatory dysfunction (serum lactate levels).
Methods: This retrospective observational study included 15 critically ill sepsis patients treated with Oxiris-based CRRT in the ICU in Pauls Stradins Clinical University hospital from 2022 until 2025. MAP, NEQ, IL-6, lactates were recorded at 0, 6, 12, and 24 h after initiation of CRRT. NEQ dose was calculated as: norepinephrine (μg/kg/min) + 2.5 × vasopressin (U/min) [4]. The primary endpoint was 7-day mortality following CRRT treatment initiation. The ΔMAP/NEQ index was defined as the difference between the final (24 h) and initial (0 h) recorded values. SPSS v29 was used for statistical analysis.
Results: CRRT was initiated at a median of 4 h (IQR: 2.00—18.75) following ICU admission. Four patients (27%) died within the first week of ICU admission and CRRT initiation due to complications of septic shock. In two cases (13%), vasopressor support was no longer required to maintain adequate blood pressure 24 h after CRRT initiation. Survivors demonstrated a significantly higher ΔMAP/NEQ index (754.80 ± 404.50 mmHg·min/kg/μg) compared to non-survivors (–97.11 ± 145.35 mmHg·min/kg/μg), as determined by the Mann–Whitney U test ($U = 6.000$, $p < 0.05$) (Fig. 1). ROC analysis yielded an AUC of 0.864 (95% CI: 0.665–1.000; $p < 0.05$), indicating good discriminative ability (Fig. 2). A cutoff of ≥ 94.4 for ΔMAP/NEQ index predicted 7-day survival with 72.7% sensitivity and 75% specificity. Spearman correlation analysis revealed significant negative associations between initial MAP/NEQ index and lactate (rho = -0.486, $p < 0.05$), initial MAP/NEQ index and IL-6 (rho = -0.609, $p < 0.05$), and ΔMAP/NEQ index and 7-day mortality (rho = –0.558, $p < 0.05$).
Conclusions: Dynamic changes in the MAP/NEQ index during CRRT may serve as a non-invasive, real-time indicator of treatment response and short-term prognosis. Higher ΔMAP/NEQ index was associated with better survival outcomes and inversely correlated with inflammatory markers and microcirculation dysfunction. These findings support the integration of MAP/NEQ index monitoring into clinical decision-making for patients undergoing Oxiris-based CRRT. Although the sample size is limited, ROC analysis suggests ΔMAP/NEQ index may have prognostic utility, meaning further research is needed.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000483***.

Introduction: Optimal fluid management in ICU patients with congestive heart failure (CHF) remains unclear. Recent studies in general CHF populations suggest that early net fluid removal may improve symptoms, preserve organ function, and reduce adverse outcomes [1]. However, evidence in ICU-specific CHF cohorts is limited. We aimed to evaluate whether 24-h net fluid balance is associated with hospital mortality in critically ill CHF patients requiring intensive care.
Objectives: To assess the association between 24-h net fluid balance after ICU admission and hospital mortality in CHF patients requiring critical care.
Methods: We conducted a retrospective observational study in a tertiary hospital ICU in Japan. Adult patients admitted between April 2016 and March 2023 with CHF who received diuretics or active fluid removal within the first 24 h were included. Patients were divided into two groups based on their 24-h net fluid balance. The cutoff value used for stratification was determined during analysis. The primary outcome was hospital mortality. Secondary outcomes included ICU mortality, ICU-free days (defined as 28-day minus ICU stay, with deaths scored as 0), hospital-free days, and 24-h urine output. Crude and adjusted absolute differences (95% CI) were reported.
Results: Among the 191 patients included, the median age was 75 years (IQR: 63–82), 126 (66.0%) were male, 118 (61.8%) received invasive mechanical ventilation, and 36 (18.8%) were chronic hemodialysis patients at ICU admission. Based on a cutoff of − 1070 mL, 96 patients were classified into the More Negative balance group and 95 into the Less Negative or Positive balance group. Hospital mortality was 8.3% in the More Negative group vs. 15.8% in the Less Negative or Positive group (p = 0.025), and ICU mortality was 1.0% vs. 5.3% (p = 0.209). ICU-free days were 25 vs. 24; crude difference + 2.8 days (95% CI: 1.1 to 4.4). Hospital-free days were 8 vs. 4; crude difference + 1.6 days (95% CI: − 0.4 to 3.7). Furosemide dose over 24 h was higher in the Less Negative group (median 60.0 vs. 40.0 mg, p = 0.158). After adjusting for baseline characteristics, hospital mortality was slightly higher in the More Negative balance group (adjusted difference: + 3.2%, 95% CI: − 2.1 to + 8.5), although the confidence interval included zero. In contrast, ICU mortality was slightly lower (− 1.3%, 95% CI: − 4.8 to + 2.2). The More Negative group also had more ICU-free days (adjusted difference: + 1.7 days, 95% CI: 0.3 to 3.0), while hospital-free days were similar between groups (+ 0.6 days, 95% CI: − 1.3 to 2.6).
Conclusions: In critically ill CHF patients who received early diuresis or fluid removal, a more negative 24-h net fluid balance was associated with more ICU-free days and lower unadjusted hospital mortality. However, adjusted analyses did not confirm a significant mortality benefit.

	24-h Net Fluid balance			
	Less negative or positive balance (n= 95)	More Negative balance (N= 96)	Crude absolute difference	Adjusted absolute difference
In total (ml)	1099 (776, 1547)	773 (564, 1039)	-384 (-563, -205)	-411 (-600, -222)
Out total (ml)	1385 (1086, 1739)	2623 (2190, 3464)	1462 (1218, 1706)	1437 (1181, 1693)
ICU death, n (%)	5 (5.3)	1 (1.0)	-4.2 (-9.2, 0.7)	-1.3 (-4.8, 2.2)
Hospital death, n (%)	15 (15.8)	8 (8.3)	-7.5 (-16.6, 1.7)	3.2 (-2.1, 8.5)
28-ICU-free days (days)	24 (21, 25)	25 (24, 26)	2.8 (1.1, 4.4)	1.7 (0.3, 3.0)
28-hospital free days (days)	4 (0, 13)	8 (0, 14)	1.6 (-0.4, 3.7)	0.6 (-1.3, 2.6)

Crude and adjusted absolute differences in clinical outcomes between patients with a more negative versus less negative or positive 24-hour net fluid balance after ICU admission. Adjusted absolute differences were calculated after accounting for baseline characteristics.

Introduction: In active ARDS patients, double triggering and breath stacking may promote lung injury due to increased lung stress and strain. In this animal model study, we tested the hypothesis that double triggering under volume control ventilation (VCV) would result in more severe lung injury compared to pressure control ventilation (PCV).
Methods: Seventeen pigs (average weight approximately 30 kg) were studied and allocated to either the VCV group (n = 9) or the PCV group (n = 8). Mild lung injury was induced by saline lung lavage followed by 1 h of injurious ventilation. Subsequently, inspired CO_2, flow rate, and inspiratory time were adjusted to achieve a double-triggering rate of 50–70% over a 3-h mechanical ventilation period. In the VCV group, tidal volume was set at 7 ml/kg, while in the PCV group, inspiratory pressure was titrated to achieve a tidal volume of 6–8 ml/kg.
Results: During double triggering, the VCV group exhibited higher tidal volume, airway and transpulmonary plateau pressure, and driving pressure. This resulted in greater minute ventilation and smaller spontaneous efforts, as assessed by ΔPes and Pmus (Table 1).
Lung injury scores tended to be higher in the PCV group (VCV: 2.00 [2.00–3.00] vs. PCV: 3.00 [3.00–5.25], p = 0.170), although the difference was not statistically significant. However, the Cliff's delta value of 0.60 suggests a moderate to large effect size, indicating a trend toward more severe lung injury in the PCV group compared to the VCV group.

Pmus (cmH2O)	7.75 [5.08–9.23]	10.56 [8.66–11.71]	0.0592

MV: minute ventilation, Paw: airway pressure, PL: transpulmonary pressure, plt: plateau, Pes: esophageal pressure, Pmus: muscular pressure.
Conclusions: Double triggering induced higher lung stress and strain in the VCV group compared to the PCV group. Conventional protective thresholds for volume and pressure were exceeded because of breath stacking in VCV but not in PCV. Paradoxically, the PCV group tended to develop more severe lung injury, although the difference did not reach statistical significance, possibly due to limited statistical power. Double triggering markedly increased minute ventilation in the VCV group but not in the PCV group, promoting stronger inspiratory efforts in the PCV group to compensate for CO_2 retention. While intra-tidal recruitment was not directly assessed, we speculate that in the PCV group, spontaneous effort may have contributed to lung injury through atelectrauma, even in the absence of overt lung overdistension.

Introduction: Donation after Circulatory Death (DCD) has emerged as effective strategy to expand abdominal donor pool. Despite initial skepticism about the viability of organs exposed to warm ischemia, the implementation of Normothermic Regional Perfusion (NRP) with extracorporal membrane oxygenation (ECMO) improved functional outcomes allowing for restoring oxygenated blood flow post-mortem.(1–4).
Objectives: The study aims to explore the correlation between perfusion flows during NRP and the metabolic and organ biomarkes (ph, pao2, pCo2, lactates, alanine transaminase (ALT), aspartate aminotransferase (AST) and creatinine). All of these parameters are routinely used to assess organs suitability and quality of perfusion.
Methods: In this retrospective study, we analyze all abdominal DCD performed in our hospital between 2023 and 2025. Eligible donors were selected both from uncontrolled (uDCD) and controlled c-DCD. For cDCD a decision of withdrawal of life supports (WLST) is made ensuring patient comfort during the dying process. Before WLST vascular access is obtained inserting guidewires in both arterial and femoral arteries. After asystole, the no-touch period begins, after which death is formally declared. Functional warm ischemia time (FWIT) is the defined period from drop of arterial systolic pressure under 50 mmHg and asystole. The agonal period is from asystole to start NRP. ECMO arterial and venous cannulas, along with an aortic occlusion balloon are inserted over the previously positioned wires; NRP is initiated and maintained until cold perfusion is achieved. Blood gas analyses and laboratory tests are collected at basale, at start NRP and then hourly.
Results: A total of 19 potential donors were selected, 16 from cDCD and 3 uDCD. NRP was not performed for one uDCD. Of the 18 NRP performed, 17 donor organs retrieval and transplantation were completed. Median donor age was 68 years and body mass index (BMI) 27; anoxic brain injury and cerebrovascular accidents were the major causes of death. In cDCD mean FWIT 58 min, the mean agonal period was 28 min, NRP duration was 3 h 07 min, mean NRP duration was 6 h 01 min for uDCD. Only 2 donors needed 5 h of NRP. As expected pH dropped and lactates increased after circulatory arrest compared to baseline, during NRP pH improved at every time point, while lactates decreased over time significantly at 4 h. PaO2 remained stable, paCO2 decreased over time during NRP significantly at 2 and 3 h. ALT AST and creatinine increased not significantly over time, creatinine worsen significantly compare to baseline at 2 h of reperfusion.
Conclusions: The data suggest that maintaining ECMO flow above 2 L/min during NRP may exert a protective effect on abdominal organs, as indicated by lactate clearance and progressive pH normalization. Flow reduction observed during some procedures may be attributed to bleeding and vasoplegia. Preserving adequate flow is essential to ensure optimal organ perfusion and metabolic recovery.

Introduction: Extubation failure is associated with an inability to manage secretions and ineffective cough, both of which depend on expiratory muscle strength and peak expiratory flow (PEF). Despite their relevance, there is no standardized method to assess cough strength in mechanically ventilated patients. Measuring PEF directly from the ventilator has emerged as a promising tool, with values above 60 L/s associated with higher extubation success rates.
Objectives: To evaluate interprofessional correlation using a semiquantitative cough scale and to determine its relationship with ventilator-measured PEF as a predictor of extubation success.
Methods: This was a prospective, observational, descriptive study conducted in a 20-bed polyvalent intensive care unit between June and November 2024. Patients aged over 18 years, intubated for more than 48 h, capable of passing a spontaneous breathing trial (SBT), and able to follow commands were included. The SBT was conducted in pressure support mode for 30 min, followed by a 30–60 min rest period. Maximal inspiratory pressure (MIP) was used as an indicator of inspiratory muscle strength. Cough strength was assessed by the care team using a previously validated semiquantitative scale, while PEF was measured directly from the ventilator; the best value of three attempts was recorded. Extubation failure was defined as the need for reintubation within 48 h.
Results: A total of 14 patients were included, 65% of whom were male, with a mean age of 59 years, an average APACHE II score of 13, and an average ICU stay of 7.5 days. Patients had a mean MIP of -32 cmH_2O and a mean PEF of 80 L/s. Two patients required reintubation: one due to uncontrolled delirium and another due to bronchoplegia—the latter being the only patient with a PEF of 40 L/s.
A statistically significant correlation was found between advanced age and decreased MIP and PEF, with an increased need for noninvasive ventilatory support post-extubation in this subgroup.
Interprofessional evaluation of cough capacity using the semiquantitative scale demonstrated an intraclass correlation coefficient of 0.82. When comparing the cough scale with PEF, a correlation coefficient of 0.79 was observed.
Conclusions: PEF measurement directly from the ventilator is a simple and effective technique that significantly correlates with the semiquantitative cough scale, providing an objective and practical parameter for predicting extubation success in mechanically ventilated patients. However, further studies with larger sample sizes are required to validate and standardize this tool as a clinical predictor of extubation outcomes.

Introduction: Resting energy expenditure (REE) varies among ICU patients and across time, necessitating repeated assessment to tailor nutritional support. Indirect calorimetry (IC) is the gold standard for measuring REE and also provides the respiratory quotient (RQ), an indicator of substrate metabolism. While amino acid oxidation via nitrogen losses (NL) usually contributes to a steady portion of REE, the relationship between REE and NL has not been extensively studied in the ICU setting.
Objectives: The primary objective was to evaluate the association between REE, measured by IC, and daily nitrogen losses via urinary nitrogen or plasma urea (with preserved renal function) in ICU patients. Secondary objectives included exploring temporal changes and associations among REE, RQ, and nitrogen balance (NBAL) throughout the ICU stay.
Methods: This prospective, single-center observational study was conducted in the ICU of XX Hospital. Adult patients eligible for IC, initiated no later than day 3 of ICU admission, were included. The primary exclusion criterion was the need for renal replacement therapy. REE was measured using IC on days 3, 5, 7, 10, and 14. Nitrogen losses for 24 h were calculated from urinary nitrogen and adjusted for plasma urea. Data collected included SOFA scores, RQ, NBAL, and patient characteristics. Associations were analyzed using linear and mixed-effects models.
Results: Data from 83 patients were analyzed. Median age was 66 [58 – 76] years, with 59% male and a median BMI of 26.0[22.3 – 29.8] kg/m^2. The most frequent comorbidities included hypertension (44.6%) and chronic pulmonary disease (28.9%). The majority of patients required vasopressors (73.5%) and mechanical ventilation (79.5%). REE remained relatively stable during the ICU stay (from 1607 kcal on day 3 to 1878 kcal on day 14; $p = 0.205$). A non-significant trends to an increase RQ was found over time (from 0.76 to ~ 0.86; $p = 0.051$), suggesting evolving substrate utilization. Nitrogen losses were highest on day 3 (11.33[7.59; 15.18] g/day) and decreased over time ($p = 0.080$). NBAL improved significantly, transitioning from −4.71 g/day on day 3 to + 3.64 g/day on day 14 ($p = 0.002$). A weak but statistically significant association was observed between nitrogen losses and REE ($p = 0.024$; $R^2 = 0.03$). However, in multivariate models, nitrogen losses were not significantly associated with REE ($p = 0.41$). Factors independently associated with higher REE included male sex, higher BMI, increased SOFA scores, and respiratory comorbidities, while older age and renal comorbidities were linked to lower REE.
Conclusions: Although a weak association exists between nitrogen losses and REE, nitrogen loss alone is an inadequate predictor of REE. These findings support continued reliance on indirect calorimetry for individualized nutritional management, and further research is needed to validate surrogate markers of metabolic demand in critically ill patients.

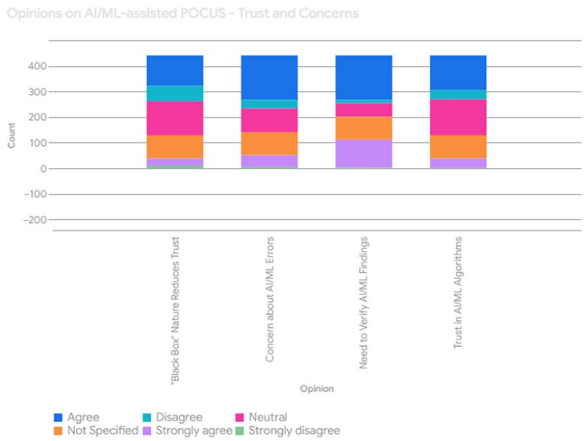
Introduction: Point-of-care ultrasound (POCUS) has become an indispensable tool in a variety of clinical settings, including emergency medicine, critical care, and primary care. Because POCUS examinations can be performed rapidly at the bedside and integrated seamlessly into routine clinical workflows, they have the potential to expedite diagnosis and guide immediate therapeutic decisions. In parallel, the field of artificial intelligence (AI) has advanced considerably in recent years, driven by innovations in deep learning, computational power, and the availability of large medical imaging datasets. These advances have sparked interest in AI-driven algorithms that can enhance the diagnostic accuracy, consistency, and efficiency of POCUS.
Objectives: This study investigated the global perceptions, familiarity, and adoption of AI/ML in POCUS among healthcare professionals.
Methods: An international, web-based survey was conducted with healthcare professionals involved in POCUS. The survey covered demographics, AI/ML familiarity, and opinions on AI/ML-assisted POCUS. Data were analyzed using descriptive statistics and frequency distributions.
Results: A total of 422 healthcare professionals participated. Respondents were primarily from Asia (39.6%) and Europe (29.4%), with intensive care (53.3%) and emergency medicine (28.4%) being the main specialties. While many respondents were familiar with AI/ML in daily life (39.3% very familiar), familiarity in healthcare varied (16.4% very familiar, 36% slightly familiar, 35.6% somewhat familiar). AI/ML tool use in patient care was reported by 27.3%. Overall, there was enthusiasm for AI/ML in POCUS, with significant agreement that it could improve diagnosis speed and interpretation accuracy. However, concerns about training (36.5% disagreed/12.1% strongly disagreed they had sufficient training), trust in algorithms (41.2% neutral), and implementation barriers such as cost (49.8% agreed/strongly agreed) were prominent. A total of 422 healthcare professionals participated. Respondents were primarily from Asia (39.6%) and Europe (29.4%), with intensive care (53.3%) and emergency medicine (28.4%) being the main specialties. While many respondents were familiar with AI/ML in daily life (39.3% very familiar), familiarity in healthcare varied (16.4% very familiar, 36% slightly familiar, 35.6% somewhat familiar). AI/ML tool use in patient care was reported by 27.3%. Overall, there was enthusiasm for AI/ML in POCUS, with significant agreement that it could improve diagnosis speed and interpretation accuracy. However, concerns about training (36.5% disagreed/12.1% strongly disagreed they had sufficient training), trust in algorithms (41.2% neutral), and implementation barriers such as cost (49.8% agreed/strongly agreed) were prominent.
Conclusions: This global survey highlights healthcare professionals' interest in AI/ML for POCUS, alongside critical concerns about training, trust, and implementation. These findings emphasize the need for



targeted strategies to support responsible and effective AI/ML adoption in POCUS.

Opinions on AI/ML-assisted POCUS—perceived benefits

Opinions on AI/ML-assisted POCUS—training and resources

Opinions on AI/ML-assisted POCUS—trust and concerns

Intensive Care Medicine Experimental*, *2025*;13(1)**: ***000492.

Introduction: Extubation failure is associated with increased in-hospital mortality. Body mass index (BMI) greater than 30 kg/m2 is known as one of the reintubation risk factors. (1) However, previous studies have not been evaluated the association between lower BMI and reintubation.
Objectives: This study aimed to address the association between lower BMI and reintubation among critical ill patients.
Methods: We performed a multicenter retrospective cohort study using the Japanese ICU database. From April 2018 to March 2023, we included adult patients (> 18 years) who received mechanical ventilation for at least 24 h from ICU admission until their first extubation attempt. Patients who underwent tracheostomy before ICU admission or before the first extubation attempt were excluded. BMI was collected at ICU admission. Reintubation was defined as the re-implementation of mechanical ventilation within 72 h after extubation.
A multivariable logistic regression analysis was performed to assess the association between BMI and the risk of reintubation. The models were adjusted for age, sex, Sequential Organ Failure Assessment (SOFA) score at ICU admission, duration of first mechanical ventilation, and number of comorbidities (e.g., heart failure, liver cirrhosis, and immunosuppression). BMI was treated as a continuous variable and modeled using a natural spline function. Based on these results, BMI were categorized into five groups: underweight (≤ 18.5 kg/m2), slightly underweight (18.5–21.9 kg/m2), normal (22.0–24.9 kg/m2), overweight (25.0–29.9 kg/m2), and obesity (≥ 30.0 kg/m2).
Results: Of the 21,516 eligible patients from 95 ICUs, 7,074 (32.9%) were female. Their mean (standard deviation [SD]) age was 68.0 (14.1) years, the mean (SD) BMI was 23.9 (4.8) kg/m2, and the median (interquartile range) SOFA score was 8 (7–11). The number of patients in each BMI group was 2,297 (10.7%) in the underweight, 5,347 (24.9%) in the normal weight, 6,073 (28.2%) in the reference, 5,682 (26.4%) in the overweight, and 2,117 (9.8%) in the obesity, respectively. Reintubation was performed in 1,375 (6.4%) patients.
After adjustment using the multivariable regression model, the reintubation rate decreased with increasing BMI below 25 kg/m2, whereas the decline became more gradual above 25 kg/m2 (Figure). Using BMI 22.0–24.9 kg/m^2 (normal weight) as the reference, the underweight group was associated with higher risk for reintubation (OR 1.69, 95% confidential interval [CI] 1.42–2.00, P < 0.001), whereas the obesity group with lower risk for reintubation (OR 0.62, 95% CI 0.48–0.78, P = < 0.001).
Conclusions: In this study, we investigated the association between BMI and reintubation. These results indicate that underweight is significantly associated with an increased reintubation risk, while obesity was associated with a decreased risk.

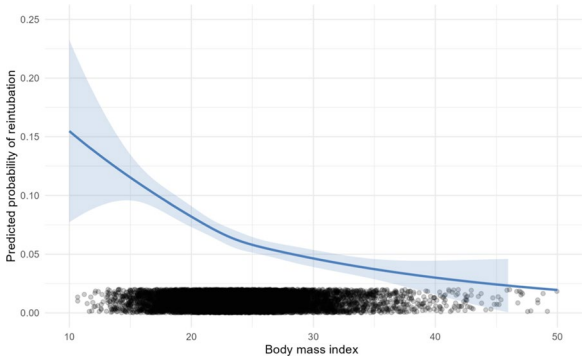

Figure (abstract 000492) Spline curve illustrating the predicted probability of reintubation across the continuous range of body mass index (kg/m2). The solid line represents the estimated reintubation rate, and the shaded area indicates the 95% confidence interval.

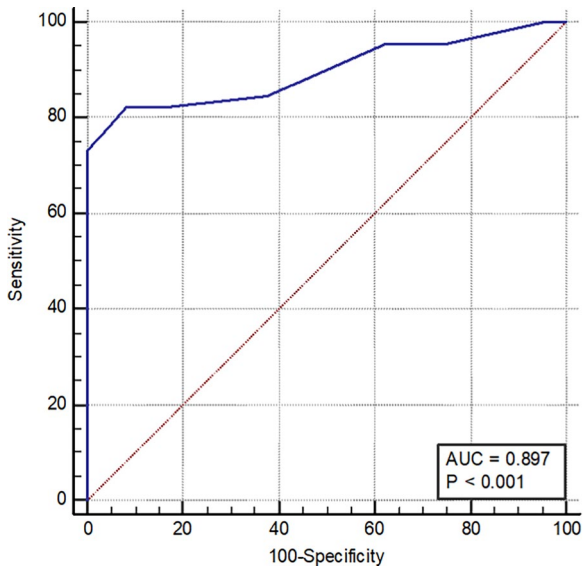
Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000493***.



Introduction: Long-term ventilated stroke patients are at a high risk of death and poor neurological outcome. They mostly need tracheostomy, especially when weaning from mechanical ventilation and extubation is difficult or delayed. The rate of tracheostomy is higher in stroke patients compared to the general intensive care unit (ICU) population. The stroke-related early tracheostomy score (SET score) was used in the pilot trial SETPOINT (stroke-related early tracheostomy versus prolonged orotracheal intubation in neurocritical care trial) and is essentially related to the previously proposed TRACH (clinical and radiological predictors of tracheostomy in supratentorial spontaneous intracerebral hemorrhage) score. In subsequent studies involving ventilated cerebrovascular neurocritical ICU patients, the SET score has demonstrated a moderate accuracy in predicting the ICU length of stay (LOS), ventilation duration, and tracheostomy need in neurocritical patients. The SET score was initially developed as an in-house screening tool based on tracheostomy predictors identified in several retrospective studies. These were combined under the categories: (1) neurological function (maximum 10 points), (2) neurological lesion ((maximum 22 points), and (3) general organ function/procedure (maximum 16 points). detailed SET score points calculation (table I).

Objectives: This research is aiming at externally validating a standardized tool (SET SCORE) for unifying the need for tracheostomy in stroke patients who are ventilated and expected to have a difficult weaning from mechanical ventilation and *to study the predictive value of SET score in the prediction of ICU length of stay and 28 days mortality.*

Methods: The study is a prospective observational cohort study where tracheostomy was performed for mechanically ventilated stroke patients in ICU. The timing was dictated as per the standard of care in ventilator dependent patients. ***Primary outcome****: to study the predictive value of SET score in the prediction of the need for tracheostomy in stroke patients.* ***Secondary outcome****: to study the predictive value of SET score in the prediction of ICU length of stay and 28 days mortality.* ***Inclusion criteria:*** stroke ventilated patients more than 18 years old. ***Exclusion criteria:*** stroke patients less than 18 years. The study was held in Kuwait Hospital Dubai and Al Qassimi Hospital/Emirates Health Services in United Arab of Emirates. Ethical committee approval was taken according to rules and regulations.

Results: In our study, we have enrolled 114 cerebral stroke patients who were admitted to the ICU and fulfilled the eligibility criteria. Regarding the type of stroke, most of the patients had MCA infractions 39.5%, while 23.7% and 19.3% had basal ganglia and cerebral hemorrhage, respectively. Subarachnoid hemorrhage and cerebellar infarction/hemorrhage were reported in 10.5% and 7.0% of patients. SET-score offered a good discrimination power (AUC = 0.897) to predict the need for tracheostomy. With an optimal cutoff point of 8, the SET score provided a sensitivity of 82.22% and a specificity of 91.67%. Regarding the ROC curve analysis of the discrimination power for predicting prolonged ICU stay (> 10 days) in cerebral stroke patients. SET-score offered a discrimination power (AUC = 0.767) to predict prolonged ICU stay. With an optimal cutoff point of 11, the SET score provided a sensitivity of 73.85% and a specificity of 72.09%, with reference to the ROC curve analysis of the model to distinguish patients who die from patients who survived cerebral stroke. SET-score gave a poor discrimination power (AUC = 0.516) to predict death. With an optimal cutoff point of 16, the SET score provided a sensitivity of 76.92% and a low specificity of 34.09%.

Conclusions: SET-score offered a good discrimination power (AUC = 0.897) to predict the need for tracheostomy in stroke patients admitted to ICU.

Practices in the management of the physiologically difficult airway in an intensive care unit

S. Prada[1]; L. Melo[2]; PT. Freitas.[1]

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000494***.

Introduction: Orotracheal intubation in critically ill patients is associated with a high incidence of adverse events, with major complications reported in approximately 45% of cases during the peri-intubation period, such as hemodynamic instability (42.6%), severe hypoxemia (9.3%), and cardiac arrest (3.1%). While most guidelines focus on anatomically difficult airways, the physiologically difficult airway (PDA) is of particular relevance in critically ill patients. This condition is characterized by physiological alterations that increase the risk of hemodynamic instability, severe hypoxemia, and cardiac arrest, regardless of airway anatomy. Managing the PDA requires structured assessment and targeted preparation, with a focus on pre-induction optimization.
Objectives: The primary objectives are to characterize peri-intubation procedures in an intensive care unit (ICU); assess vital signs before and after intubation; correlate pre-induction parameters with complications; and analyze drug and device choices according to the patients' physiological profile.
Methods: This is a prospective observational study. Data were collected through questionnaires completed by physicians. Adult patients admitted to the ICU of a district hospital between 01/10/2024 and 31/01/2025, requiring advanced airway management during their stay, were included. Patients already intubated at admission were excluded.
Results: A total of 43 intubations were analyzed, with a mean age of 62 years. Males accounted for 69.8% of cases. The most frequent indications were respiratory failure (58.1%) and altered mental status (32.6%). Most airways were considered anatomically easy, with Cormack–Lehane grade I–II views. The main physiological factors identified as contributors to a difficult airway were hypoxemia (n = 30) and hemodynamic instability (n = 19). An airway management checklist was used in only 3 cases, and pre-intubation echocardiography was performed in only 6. Preoxygenation methods included high-flow nasal cannula (34.9%), non-rebreather mask (30.2%), bag-valve-mask (25.6%), and non-invasive ventilation (7%); the median peripheral oxygen saturation (SpO_2) prior to induction was 95%. Intubation was performed using a videolaryngoscope in 100% of cases, with a first-attempt success rate of 93%. Induction was mainly achieved with propofol and ketamine, and 93% of patients received neuromuscular blockade with rocuronium. After intubation, 7 patients developed severe hypoxemia ($SpO_2 \leq 85\%$) and 15 experienced severe hypotension (MAP < 50 mmHg). One case of cardiac arrest was recorded.
Conclusions: In this patient cohort, a high first-attempt intubation success rate and a low incidence of peri-intubation complications were observed, although there remains room for improvement in preoxygenation and hemodynamic monitoring. Despite the high prevalence of factors associated with physiologically difficult airways (PDA), the use of structured assessment and management tools was infrequent. The adoption of these tools and the systematic integration of PDA-focused approaches may contribute to reducing complications and enhancing the safety of intubation procedures in the ICU.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000497***.

Introduction: Acute kidney injury (AKI) is a frequent complication in patients with cardiogenic shock (CS) and is associated with increased morbidity and mortality. Renal resistive index (RRI) has emerged as a potential early marker of renal dysfunction.[1,2,3] RRI,a non-invasive ultrasonographic marker derived from intrarenal blood flow patterns, reflects renal vascular resistance and has shown promise as a dynamic indicator of renal perfusion impairment. However its utility as a predictive tool in cardiogenic shock remains underexplored.
Objectives: This study aims to evaluate the predictive value of RRI for AKI development in patients with cardiogenic shock.
Methods: We conducted a prospective observational study from January 2020 to December 2023 in a tertiary intensive care unit. A total of 110 patients with CS (mean age 67 + -12 years,68% male) were included and enrolled consecutively. RRI was measured in interlobar arteries of both kidneys at: T0 or H3(3 h after admission), T1 (24 h post-admission), T2 (48 h post-admission) and T3 (72 h post-admission).RRI was calculated as (peaksystolic velocity - end diastolic velocity)/peak systolic velocity.
Patients were stratified into 2 groups based on the RRI at T0 (3h post-admission): RRI < 0.74 and RRI > 0.74.
The primary endpoint was the development of AKI within 3 days and secondary endpoint was 28 day mortality.
AKI was defined according to the KDIGO criteria and assessed at T3 (72h post-admission). Comparisons were made between patients developing AKI and those without AKI.
Statistical analysis used Mann–Whitney test and results expressed as mean +—standard deviation.

A ROC curve analysis was performed to compare the diagnostic performance of RRI, NGAL and serum creatinine.
Results: Patients who developed AKI at Day 3 had significantly higher RRI values at T0 (3 h post-admission) compared to those without AKI (T0:0.75 + -0.04vs0.69 + -0.003, P < 0.001).
Using ROC curve analysis, RRI at T0 or H3 (3h post-admission) showed the highest predictive value for AKI (AUC = 0.89 95%CI:0.84–0.94), outperforming NGAL (AUC = 0.81) and creatinine (AUC 0.78) (Fig. 1).
A cutoff value of RRI > 0.74 at T0 was associated with a sensitivity of 86% and specificity of 84% for AKI at DAY 3.
Regarding mortality, 28 day mortality was significantly higher in patients with RRI > 0.74 compared to those with RRI < 0.74, respectively, 52% vs19% p < 0.001.
Conclusions: RRI measured within the first 3 h (T0) after ICU admission serves as an early predictor of AKI at Day 3 in CS patients, with superior performance compared to NGAL and serum creatinine. In this prospective study of 110 patients with CS, an elevated RRI measured as early as 3 h after admission was strongly associated with both AKI and 28 day mortality.
These findings support the integration of renal Doppler ultrasound for early AKI risk stratification in critically ill patients [4,5].

Introduction: Candidemia is a life-threatening fungal infection in intensive care unit (ICU) patients, which can be complicated by secondary localizations (SL). SL can occur in patients with candidemia in various sites: vascular (thrombosis), abdominal (notably hepatosplenic or renal), cardiac, ophthalmic, pulmonary, and/or osteo-articular, which influences the management of these critical patients. However, the prevalence, risk-factors and outcomes of patients with SL are still poorly understood.
Methods: The CandidICU study was a retrospective multicenter cohort study conducted in 16 French ICUs. All adult patients hospitalized from January 2015 to January 2023 with at least one positive blood culture for Candida spp. were enrolled. We assessed the prevalence and risk-factors for SL. In addition, we explored the clinical courses according to the screening and occurrence of SL were.
Results: Among 492 patients with at least one positive blood culture for Candida spp., 376 were screened for SL (76.4%). At least one SL was diagnosed in 82 patients (21.8%). Competing risk analysis identified the SAPSII score and the duration of positive blood cultures as independent risk factors for SL (sdHR 1.01 [95%CI 1.00–1.02]; p = 0.031 and sdHR 1.05 [95%CI 1.02–1.08]; p = 0.003, respectively). Age and Candida glabrata infection were protective factors against SL (sdHR 0.98 [95%CI 0.97–1.00]; p = 0.016 and sdHR 0.38 [95%CI 0.15–0.99]; p = 0.048, respectively). Finally, patients with SL received longer antifungal treatment (18 [11–30] versus 14 [6–18] days; p < 0.001) and had a higher rate of antifungal escalation (27.8% versus 12.3%; p = 0.002).
Conclusions: In this cohort, 76·4% of ICU patients with candidemia were screened for SL and at least one SL was diagnosed in 21·8%. The severity at ICU admission and duration of positive blood cultures were identified as independent risk factors for SL, whereas age and Candida glabrata infection were protective. Finally, the screening and occurrence of SL were associated with significant changes in the management of patients. These results support the need for extensive and systematic screening for SL in critically ill patients with candidemia.

Introduction: Fulfilling end-of-life care is a global issue in intensive care settings. In Japan, where life support discontinuation is generally recognized as not allowed once it is administered, most facilities are conservative and reluctant to implement treatment withdrawal in the intensive care unit (ICU) even when it is obvious that the patient's life is not to be saved. Discontinuation of unwanted life support and terminal extubation (TE) are implemented after discussions with patients or families by the multidisciplinary team in the ICU of hospital A in Japan, following the institutional policy of providing patient-centered medicine reflecting each patient's value. However, no clinical guidelines have clearly indicated the method of TE in Japan currently; thus, appropriate intervention seems uncertain as to how those nurses of the hospital recognize, feel, and cope with uncertainty in their practice.
Objectives: The aim of this study is to explore the emotions and perceptions regarding TE of ICU nurses, who care for patients and their families undergoing the intervention.
Methods: This study used a qualitative design based on the content analysis approach. Data were collected from 11 purposefully selected ICU nurses at a hospital in Japan using a semi-structured interview guide.
Results: The study identified four main categories regarding perceptions: 1) beneficial and could become the utmost palliative care to patients who wish not to remain on ventilators; 2) the family's wishes should also be respected as well as the relevant surrounding people's consensus besides the patient's value and intention; 3) essential to build organizational infrastructure, including education, adherence to the process indicated by the organization's manual, and multidisciplinary collaboration with psychological safety; and 4) as not common, necessary to understand the diversity of feelings in medical staff besides concerns over public reaction and legal aspects. Four main categories regarding emotional experiences include 1) being shocked initially, but TE implementation alleviates the ethical dilemma one once had; 2) being distressed under certain circumstances, such as when the patient's values are unclear, when one's understanding of the whole picture is inadequate, or when one feels the process is being rushed; 3) difficulty in optimizing care for patients and families undergoing TE due to unfamiliarity with providing palliative care in ICU; and 4) as TE being inseparable from death, enabling TE implementation at the facility makes one more aware of readiness to face death than ever.
Conclusions: The study revealed the tendency of ICU nurses' perceptions and emotions regarding TE, demonstrating important implications to better mutual understanding among a medical team and to clarify issues to be resolved in the future when implementing TE appropriately at a facility.

Introduction. Invasive pulmonary aspergillosis has emerged as an opportunistic fungal infection complicating severe COVID-19. However, the effect of antifungal treatment in COVID-19-associated pulmonary aspergillosis (CAPA) remains poorly explored while severe diseases still exist in immunocompromised patients.
Methods. We aimed to explore the impact of antifungal treatment on day-60 mortality including possible and proven CAPA cases from a large French multicenter study along with all consecutives CAPA cases from 5 major intensive care units (ICU). Patients were compared according to antifungal treatment. Survival analysis was conducted using a Cox regression analysis. Additionally, to account for potential imbalance in baseline characteristics, an inverse probability of treatment weighting (IPTW) based on a propensity score along with an emulated targeted trial analyses were conducted.
Results. In total, 259 CAPA patients were included. Of these, 237 patients (91.5%) received antifungal treatment for CAPA, with 215 (90.7%) receiving azole antifungal drugs. Baseline characteristics were similar between patients who received antifungals and those who did not. Multivariable Cox regression analysis in the raw population evidenced that patient's age (HR 1.02, 95%CI 1.00–1.04, p = 0.025), immunosuppressive treatment (HR 2.16, 95%CI 1.46–3.19, p < 0.001], and remdesivir use (HR 2.07, 95%CI 1.17–3.69, p = 0.013) were independently associated with increased 60-day mortality. Male sex (HR 0.63, 95%CI 0.41–0.97, p = 0.037) and antifungal treatment (HR 0.39, 95%CI 0.21–0.73, p = 0.003) appeared to be a protective factor against 60-day mortality.
Both Cox weighted regression and Cox regression conducted in the emulated trial analysis evidenced a decreased 60-day mortality in patients receiving antifungal treatment (Weighted HR 0.33 [95%CI 0.18–0.59], p < 0.001and HR 0.39 [95%CI 0.18–0.82], p = 0.0131, respectively).
Conclusions. In this large European multicenter study of CAPA patients, we observed a significant improved survival in patients receiving antifungal therapy. The high mortality rate observed in CAPA in immunocompromised patients, as well as the improved outcome in treated patients, should encourage clinicians to actively screen for CAPA to enable rapid diagnosis and treatment. This may also apply to other viral–fungal coinfections.

Weighted survival analysis of probable and proven CAPA patients according to antifungal treatment.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000504***.

Introduction. In the general population, females show a higher life expectancy than males. Additionally, it is evident that mortality increases with increasing age.
OBJECTIVES. The objective of this study is to evaluate the impact of sex and age in ICU patients, and specifically whether the mortality trends observed in the general population persist within the intensive care context.
Methods. Data from the DecubICUs study (NCT 03270345), a multinational, prospective, point-prevalence study with a 12-week follow-up for hospital mortality, were analyzed [1]. Only high-income economy countries were included (n = 31). Kaplan–Meier (KM) curves were plotted, and mortality differences were assessed using a mixed-effects logistic regression with age and age-adjusted SAPS-II as fixed effects and country as a random effect. Age categories considered were 18–39 years (reference category), 40–49 years, 50–59 years, 60–69 years, 70–79 years, and 80 + years.
Results. A total of 6,241 patients were included, of whom 3,856 were male (62%). KM curves indicated that life expectancy dropped for higher age categories (image 1). Higher odds ratios (ORs) for mortality were found in age groups starting at 50 years, compared to those aged 18–39 (see table). A stepwise increase in mortality ORs with advancing age was observed in the full and male cohort (image 2). Females in their 60s did not exhibit the same stepwise increase in OR (1.71, 1.02–2.89). When stratifying by sex, no sex-based differences in mortality were found, apart from a difference in survival estimates between males and females in their 60s (p = 0.031).

Mortality odds ratios (OR) and 95% confidence intervals (CI) of ICU patients—full cohort

Age category	OR	95%CI	p-value
18–39	Reference	-	-
40–49	1.29	0.90–1.86	0.161
50–59	1.83	1.34–2.50	< 0.001
60–69	2.34	1.75–3.14	< 0.001
70–79	3.50	2.62–4.67	< 0.001
80 and older	3.95	2.87–5.42	< 0.001

Conclusions. The consistent increase in mortality risk with age matches the trend seen in the general population. In contrast with the general life expectancy, no significant differences in mortality between the sexes were observed. Hypotheses on why females confer a mortality advantage in the general population, may require nuance in ICU patients, or potentially unknown factors might negate this effect. The observed anomaly in sexagenarian females requests further research. Although sex-based differences in treatment and outcomes have been previously reported, the specific finding that females in their 60s exhibit better outcomes is novel and might reflect a peculiarity of the dataset.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000505***.

Introduction. Early post-operative graft failure requiring ECMO can complicate heart transplantation.

Objectives. We sought to analyze the predictors and outcomes of extracorporeal membrane oxygenation (ECMO) support for early primary graft failure and determine its impact on mortality and complications in the first 30 days post-transplantation.

Methods. A retrospective review of all adults who underwent heart transplant in a single hospital between 2014 and 2024.

Results. Over a 10-year period, 25 (20.3%) of 123 patients who underwent heart transplantation in our hospital required ECMO support postoperatively. Those on postoperative ECMO were younger 47 vs 53 yr old, p 0.02, received more frequently preoperative amiodarone 40.9 vs 14.4% p 0.005, were more frequently transplanted emergently 52 vs 21%, were more frequently on ECMO preoperatively 52.4 vs 13.7%, and on vasopressors 46,7 vs 16,3%., more frequently had bilirubin > 2 mg/dl (37.5 vs 17.8% p 0.05) had longer extracorporeal circulation times 137 vs 107 min p 0.001 with similar ischemia times. Patients on postop ECMO support spent more days in ICU 17 vs 8,9 p 0,001, under mechanical ventilation 60 vs 9,15 h p 0,001 and were more frequently thrombopenic.

We found no differences regarding the type of donation (donation cardiac death DCD vs brain death DBD), donor's history of cardiac arrest,

type of cardioplegia (Del Nido vs Celsior), preoperative infection, donors under mechanical ventilation, donor's age or donor's days in ICU.
Mean duration of preoperative ECMo support was 5 ± 5.6 days (IQR 3.5–10.5), with mortality reaching 19% (vs 8.8%), and on postop ECMO 4 ± 2.5 days (IQR 3.5–6). Mortality in patients on postop ECMO reached 24% vs 7.1% in those without primary graft failure p 0.002. Overall only 18.2% of the patients had no rejection episodes in the first year, being it more frequent in postop ECMO patients (23 vs 0%, NS). Regarding hemodynamically comprising rejection episodes, more patients without postop ECMO support were free from rejection 45.9% vs 27.3%, NS.
On multiple logistic regression analysis, the use of amiodarone preoperatively, inotrope support, urgent priority or ECMo support preoperatively did not increase the mortality risk, while postoperative ECMO support was associated with a 5.1 OR (95% CI 1.047–25.51).
Conclusions. Primary graft dysfunction is a serious complication following heart transplant. Treatment with ECMO in the immediate postoperative period is associated with mortality, while in our patients, other known factors did not increase the risk of death.

Thrombocytopenia after CMV reactivation treatment

L. Dogan[1]; S. Demirel Kaya[2]; R. Zengin,[3]; ZT. Sarikaya[1]; B. Gucyetmez.[1]
[1]Anesthesiology and reanimation, Acıbadem Mehmet Ali Aydınlar University, School of Medicine, Istanbul, Turkey; [2]Intensive Care Unit, Acıbadem Altunizade Hospital, İstanbul, Turkey; [3]Infectious Disease and Clinical Microbiology, Acıbadem Altunizade Hospital, İstanbul, Turkey.
Correspondence: L. Dogan.
Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000509***.

Introduction. Cytomegalovirus (CMV) reactivation is a common complication in critically ill patients, particularly those in the intensive care unit (ICU) [1] [2]. While the implications of CMV reactivation have been extensively studied, the development of thrombocytopenia in this context remains less understood. Thrombocytopenia, characterized by decreased platelet count, is a frequent hematological abnormality in critically ill patients and can contribute to increased morbidity and mortality [3] [4]. This study aims to investigate the effect of antiviral treatment on ICU patients' thrombocyte levels and examine the impact of thrombocytopenia on patient outcomes.
Objectives. The primary objectives of this study were:

- To identify the clinical and laboratory factors associated with the development of thrombocytopenia in ICU patients treated for CMV reactivation.
- To determine the effect of thrombocytopenia on mortality in this patient population.

Methods. This study employed a data-based, observational, and cohort design. A retrospective review was conducted of all patients with CMV reactivation admitted to the Intensive Care Unit (ICU) between January 1, 2019, and March 1, 2025. The study population comprised patients with CMV reactivation who were treated with ganciclovir. CMV reactivation was defined as CMV DNA levels ≥ 4000 copies/mL in tracheal aspirate samples, with an upward trend and accompanied by clinical findings, and severe thrombocytopenia as < 50,000 platelets/μL. For analysis, the patient cohort was stratified into two groups: patients who did not develop thrombocytopenia and patients who developed thrombocytopenia.
Results. During the study period, 81 patients received treatment for CMV reactivation. The results indicated that patients who developed thrombocytopenia were older (p = 0.05) and presented with lower platelet levels at the initiation of therapy (p = 0.001). CMV reactivation in patients with severe thrombocytopenia was correlated with decreased platelet counts from the initiation of therapy (p = 0.001), and this trend persisted throughout the treatment course (p = 0.001). Furthermore, this group exhibited a significantly higher mortality rate (p = 0.023), and frequently presented with positive blood cultures (p < 0.001). Cox regression analysis revealed that platelet levels during CMV reactivation are a significant variable in the development of thrombocytopenia (p = 0.011).
Conclusions. CMV reactivation in critically ill patients is associated with the development of severe thrombocytopenia. Patients who developed severe thrombocytopenia had lower platelet levels at the initiation of therapy, the presence of positive blood culture as a co-infection, and a higher mortality rate. Lower platelet levels at the initiation of therapy are a significant risk factor for the subsequent development of severe thrombocytopenia.

From prediction to practice: a retrospective review of scoring systems in the management of patients with acute pancreatitis

AL. Kunjumon[1]; S. Vetcha[1]; D. Pandit[1]; L. Cooper[1]; G. Millen.[1]
[1]Critical Care, William Harvey Hospital, Ashford, United Kingdom.
Correspondence: A. Kunjumon.
Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000510***.

Introduction. Acute pancreatitis refers to the inflammation of the pancreas, characterized by varying degrees of autodigestion, edema, and necrosis (1). It is one of the most common gastrointestinal causes for admission to the intensive care unit (ICU), and is associated with significant morbidity and mortality. The development of organ failure remains the primary determinant of patient prognosis, with the severity and duration of organ failure playing a crucial role in outcomes. The Revised Atlanta Classification categorises the severity of acute pancreatitis into mild (no organ failure), moderately severe (transient organ failure that resolves within 48 h) and severe (persistent organ failure > 48 h) (2).
Specific scoring systems such as Glasgow Imrie score, and BISAP (Bedside Index for Severity of Acute Pancreatitis) have often been utilised to risk stratify patients with acute pancreatitis. (3,4). Glasgow Imrie score takes into account 8 variables and is calculated at 48 h of admission, whereas BISAP takes into account 5 variables and is usually measured on admission and a BISAP > 3 is associated with higher risk of complications (4).
By reviewing the Glasgow Imrie score, BISAP score, along with APACHE II and C-reactive protein (CRP) in patients admitted with acute pancreatitis in ICU, this study aimed to appraise the practice of using scoring systems and their usefulness in predicting persistent organ failure.
Methods. This retrospective review focused on patients admitted with acute pancreatitis to the Intensive Care Unit (ICU) of a District General Hospital between October 2022 and October 2024. The demographic data, aetiology of acute pancreatitis, incidence and severity of organ failure, length of stay in the Intensive Care Unit and hospital, as well as ICU mortality rates was noted. Patients were classified as having persistent organ failure if the organ failure lasted more than 48 h. APACHE II, Glasgow Imrie Score, BISAP score were calculated retrospectively and were compared between the two patients groups.
Results. A total of 30 patients were admitted with acute pancreatitis during the study period. The mean age of the cohort was 59 years, and

nearly three-quarters (73%) were male. Gallstones were the primary etiology for over half of the patients. Considering organ failure, 19 patients (63%) were classified as having persistent organ failure, while 11 patients (37%) with transient organ failure. There was a clinically and statistically significant difference in the length of stay between the patient groups. While patients with persistent organ failure had a median ICU stay of 15 days, it was 5 days in the transient organ failure group ($p < 0.001$). Similarly, the median total length of hospital stay was 25 days for patients with persistent organ failure and 12 days for those with transient organ failure ($p = 0.005$). The overall mortality was 9%.

Interestingly, when it came to differentiating or predicting persistent organ failure, the performance of the scoring systems was not statistically significant, possibly due to a small sample size. Glasgow Imrie score had the best discriminatory power with a value of 2.8 ± 1.7 in patients with persistent organ failure and 1.8 ± 1.6 in patients with transient organ failure and a p-value of 0.24. This was followed by APACHE II with a p value of 0.24. In comparison BISAP score showed poor discrimination which could be alluded to the low mean score on admission 1.7 ± 1.5. However, procalcitonin values were higher in persistent organ failure group in comparison to the transient group (6.4 versus 1.9), although there was no statistical significance.

Conclusions. Early identification of patients at risk of severe acute pancreatitis can help reduce morbidity and mortality, particularly given the differences in length of stay. While our study found no significant difference in the scoring systems' ability to predict persistent organ failure, the Glasgow Imrie score was the most promising and warrants further integration into clinical practice at the bedside. There is, however, a need for unique models to further enhance prognostic accuracy in this patient population.

Table 1 Outcomes in patients with acute pancreatitis

	All patients (n=30)	Persistent Organ failure (n = 19)	Transient Organ failure (n = 11)	p value
ICU Mortality	4 (9%)	3 (16%)	1 (9%)	1.00
ICU Length of stay	12 [5, 16]	15 [12, 23]	5[4,7]	**<0.001**
Hospital-length of stay	20 [12, 19]	25 [14, 49]	12 [7, 19]	**0.005**

Summary statistics are median [inter-quartile range] or number (percentage)

Table 2 Comparison of various scoring systems in acute pancreatitis

	All patients (n=30)	Persistent Organ failure (n = 19)	Transient Organ failure (n=11)	p value
Amylase	1486 [661, 2963]	1601 [661, 3087]	1465 [504, 2500]	0.64
CRP (admission)	19 [6, 79]	26 [4, 79]	13 [7, 239]	0.65
PCT	5.3 [1.1, 12.3]	6.4 [0.9, 17.4]	1.9 [1.4, 7.9]	0.33

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000512***.

Introduction. Early mobilisation (EM) of critically ill patients in intensive care units (ICUs) is recognised for its potential benefits in improving patient outcomes. There has been a paradigm shift towards incorporating EM as a standard practice in ICUs to mitigate the complications associated with immobility. The implementation of EM remains inconsistent globally, with limited evidence on its practice in South African ICUs. This study aims to address this gap by examining mobility practices and barriers to EM in a South African tertiary hospital setting.

Objectives. This study aimed to describe mobility practices and examine the facilitators, barriers and knowledge of staff regarding EM in ICUs at a tertiary hospital in South Africa.

Methods. An analytical cross-sectional observational study was conducted across four ICUs. Thirty patient folders were reviewed daily over five days to identify mobility opportunities. A self-designed review form, incorporating safety criteria, was used to assess the suitability of these opportunities. Additionally, 26 nurses and 16 physiotherapists completed self-administered questionnaires to assess their knowledge and perceived barriers to EM.

Results. The study involved 30 patients with a mean length of stay of 15 days. Of 107 potential mobility events, 77 were deemed safe for mobilisation, with in-bed activities being more common than out-of-bed activities. Staff demonstrated good knowledge of EM benefits but scored lower on safety criteria. Key barriers included staffing shortages, excessive sedation and the need for physician orders to mobilise patients.

Conclusions. This study highlights conservative mobility practices and significant barriers to EM in a tertiary hospital ICUs. Targeted educational interventions and organisational changes are necessary to enhance EM practices and improve patient outcomes.

Introduction. Accurate estimation of venous return is critical for assessing hemodynamic status in critically ill patients, as it directly influences venous return (VR) and cardiac output[1, 2]. VR depends on the pressure gradient between mean systemic filling pressure and right atrial pressure (RAP), making precise RAP measurement essential [2]. In clinical practice, central venous pressure (CVP) serves as a surrogate for RAP[3]; however, its accuracy is dependent on appropriate transducer levelling relative to an external anatomical reference[4, 5]. Despite its clinical significance, there is currently no consensus on the optimal external reference point for CVP measurement[4, 6], and incorrect levelling may result in clinically significant errors[7, 8]. This study investigates the accuracy of CVP measurements using three commonly utilized external reference points, comparing them to RAP values obtained via a solid-state catheter in the right atrium across three different body positions.
Objectives. To assess the agreement between CVP and RAP using three external CVP reference points, 5 cm below the sternal angle, one-third, and one-half of the anteroposterior chest diameter at the fourth intercostal space, across supine, semi-recumbent, and Trendelenburg positions in critically ill patients.
Methods. In this prospective observational study, 16 mechanically ventilated critically ill patients were included. RAP was measured using a solid-state catheter with its tip positioned in the mid-right atrium near the tricuspid valve. CVP was recorded via a central venous catheter placed in the superior vena cava or right atrium, with the pressure transducer sequentially zeroed at three anatomical landmarks: (1) one-half of the anteroposterior (AP) chest diameter in the fourth intercostal space (CVP-AP½), (2) one-third of the AP diameter in the fourth intercostal space (CVP-AP1\2), and (3) 5 cm below the sternal angle (CVP-StA) (Fig. 1) Measurements were obtained in supine, semi-recumbent (30°), and Trendelenburg (– 10°) positions (Fig. 1). Agreement between CVP and RAP was assessed using Bland–Altman analysis, limits of agreement (LoA) intraclass correlation coefficients (ICC), and Wilcoxon signed-rank tests.
Results. A total of 16 patients were included, yielding 144 paired RAP–CVP measurements across the three body positions. The differences between CVP and RAP are visualised using Bland–Altman plots (Fig. 2). Among the measurement methods, CVP-AP1\2 demonstrated the closest agreement with RAP across all positions. In the supine position, the CVP–RAP mean difference (M) was –0.56 mmHg (limits of agreement [LoA]: 0.40 to –1.52 mmHg; intraclass correlation coefficient [ICC]: 0.88). In the semi-recumbent position, M was –0.11 mmHg (LoA: 2.05 to –2.27 mmHg; ICC: 0.79), and in the Trendelenburg position, M was –0.88 mmHg (LoA: 0.52 to –2.27 mmHg; ICC: 0.90) (Table 1).
In contrast, CVP-AP½ tended to overestimate RAP, particularly in the supine position (M: 1.49 mmHg; LoA: 2.9 to –0.09 mmHg; ICC: 0.59) and the semi-recumbent position (M: 1.75 mmHg; LoA: 4.41 to –0.91 mmHg; ICC: 0.50). CVP-StA, using the sternal angle as a reference, showed the poorest agreement, especially in the semi-recumbent position (M: –2.83 mmHg; LoA: 1.3 to –7.9 mmHg; ICC: 0.18) (Table 1).
Spearman's correlation analysis revealed no significant association between the CVP–RAP differences (for CVP-AP1\2and CVP-AP1\2) and patient characteristics including BMI, height, AP diameter, weight, or LVEF, in any position. However, when using CVP-StA in the semi-recumbent position, AP diameter significantly influenced the CVP–RAP difference ($p = 0.044$).
Conclusions. Our results suggest that levelling the CVP pressure transducer at 1\2of the AP chest diameter in the fourth intercostal space will provide the most accurate estimation of RAP and minimizes variation in CVP readings across supine, semi-recumbent, and Trendelenburg positions. This approach also enhances consistency when comparing CVP measurements between individuals. Conversely, levelling the CVP transducer to 5 cm below the sternal angle should be avoided in clinical practice, as it introduces significant measurement variability and may lead to inaccurate CVP measurements in ICU and perioperative settings.

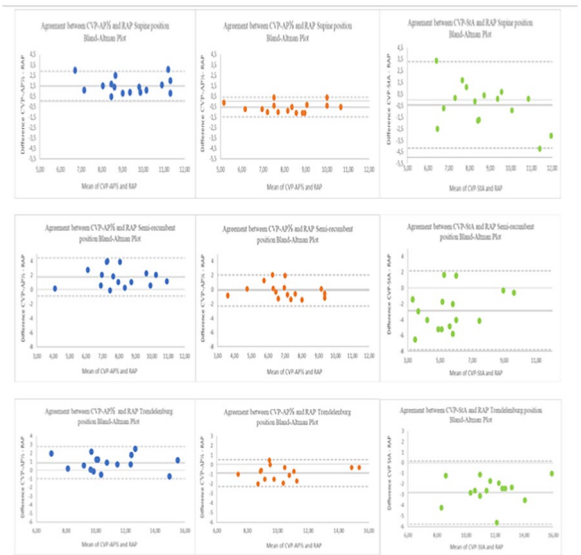

Fig. 2 (abstract 000513) Bland–Altman plots of difference between RAP and CVP (CVP-AP1\2, CVP-AP1\2and CVP-StA) in supine, semi-recumbent and Trendelenburg position.

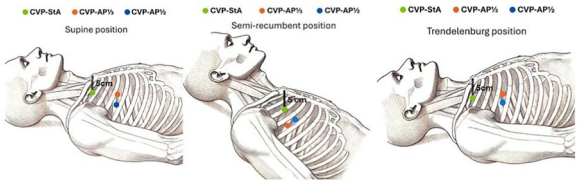

Fig. 1 (abstract 000513) The three CVP reference points described above. 5 cm below the sternal angle (CVP-StA), 1\2 of the AP diameter of the chest in the fourth intercostal space (CVP-AP½) and 1\2 of the AP diameter of the chest in the fourth intercostal space (CVP-AP1\2).

Table 2 Wilcoxon signed rank test is used to test the difference. For continuous variables, methods: mean (SD) is presented. For continuous variables difference: mean (95% CI, limits of agreement) / (SD) / [95% CI for the mean] is presented

Variable	Method RAP Mean (SD) n=16	Method CVP Mean (SD) n=16	Difference (Method RAP – Method CVP) Mean (95% CI Limits of Agreement) (SD) [95% CI for mean]	Systematic changes p-value	Intraclass Correlation Coefficient (ICC) Shrout-Fleiss reliability: random set

Introduction. Physiologically, fatty acids (FAs) are the primary source of energy in the adult heart, with glucose (G) contributing minimally. In advanced, but not early, stages of heart failure, the heart typically shifts towards higher glucose utilization and decreased FA oxidation. The energy metabolism profile of the heart in patients admitted with septic shock, with or without cardiac contractile impairment (i.e., Sepsis-Induced Myocardial Dysfunction, SIMD), is not well established. Most of the data come from preclinical studies, with the energy metabolism of the septic heart depicted as a FA/G bioenergetic "shutdown" accompanied by mitochondrial exhaustion.
Objectives. To compare adult patients admitted to the intensive and coronary care units for sepsis or acute heart failure (AHF), who were divided into two groups: i) septic shock with preserved left ventricular ejection fraction (LVEF) (≥ 45%) or de novo LVEF < 45% (or a ≥ 20% drop from a previous low LVEF documented within the last 2 years), and ii) AHF with de novo LVEF ≤ 40% (HFrEF). Patients could have been infused with vasoactive drugs or weaned off them no later than 8 h before functional imaging. The use of FA-rich drugs, stimulants that enhance energy tracer uptake (propofol, etomidate, insulin), or dextrose > 5%, was prohibited.
Methods. Recording and comparison of demographic and general characteristics; cardiac biomarkers (HS troponin T [Tpn-T], NT pro-BNP, Galectin-3 [Gal-3]); echocardiography; and quantification of heart energy metabolism using one session of PET imaging with three different tracers: glucose (FDG), palmitate, and acetate.
Time window for inclusion: 48 h from admission. Sepsis was defined according to the Sepsis-3 criteria, and AHF with HFrEF was defined according to the ACC guidelines.
Results. 19 out of 24 patients were recruited (12 with sepsis, 7 with AHF). Age: 67 [58–77]; sex: 63.2/36.8% (M/F). On admission, APACHE II scores were similar: 26 [21–35] in sepsis and 22 [20–29] in AHF. SOFA scores were slightly higher in sepsis: 8 [5–13] vs. 3 [1–9] in AHF (p = 0.0464). Biomarkers NT pro-BNP and Gal-3 were indiscriminately elevated, whereas Tpn-T levels were significantly higher in AHF (423 [74–4523] vs. 36 [19–57] ng/L in sepsis, p = 0.0091).
While myocardial external efficiencies (MEE) were slightly decreased in both groups, myocardial oxygen consumption (MVO2) and Work Metabolic Index (WMI) shifts were distinctive: i) increased MVO2 in sepsis (0.167 [0.116–0.218] vs. 0.092 [0.062–0.101] mL O2/min/g in AHF, p < 0.0001), ii) enhanced WMI in AHF (6.51 [4.51–8.77] vs. 2.64 [2.15–5.49] mmHg· mL/m^2, p = 0.0135). Myocardial FA uptake was lower in AHF: 0.1651 [0.085–0.224] vs. 0.2527 [0.182–0.284] µmol/min/g in sepsis (3 missing data points, p = 0.0599), and the esterified/oxidized FA ratio significantly increased with reduced LVEF (septic shock with de novo impaired LVEF: 33.4 [21.1–141.3]%—1 missing, AHF: 43.2 [39.3–187.9]%—2 missing, p = 0.0003 and < 0.0001 vs. septic shock without impaired LVEF). In parallel, myocardial glucose uptake was clearly

enhanced in septic shock with de novo impaired LVEF: 27.6 [17.6–37.7] vs. 1.28 [0.114–3.95] µmol/min/100g in septic shock without impaired LVEF, and 3.088 [1.33–12.06] µmol/min/100g in AHF ($p = 0.0303$ and 0.041, respectively). Moreover, glucose, but not FA, utilization by the heart was negatively correlated with contractile function ($R^2 = 0.679$, $n = 12$, $p = 0.0018$) only in septic patients.
Conclusions. Patients with sepsis-induced myocardial dysfunction exhibit a distinctive energy metabolism profile, characterized by a low work metabolic index, an elevated esterified/oxidized FA ratio, and an enhanced glucose utilization, all of which are linked to contractile impairment. ClinicalTrials.gov Identifier: NCT05202938.

Introduction. Malnutrition is a common and serious issue among critically ill children, often resulting in significant muscle mass loss due to increased protein catabolism, reduced protein synthesis, or both. As urea and creatinine are end-products of nitrogen metabolism, the urea-to-creatinine ratio (UCR) has been proposed as a potential biomarker of catabolic activity. However, evidence supporting its use in pediatric populations remains limited.
Objectives. This study aimed to evaluate the utility of UCR as a biomarker of sarcopenia in critically ill pediatric patients by examining its association with nutritional status, nutritional support, and clinical outcomes.
Methods. This is a retrospective, single-center observational study of critically ill patients aged < 18 years hospitalized for more than 72 h in an academic PICU from 2019 to 2024. Demographics, nutritional status, energy/protein intake, and UCR on PICU days 1–3-5–7-14–21, as well as outcome endpoints, were recorded.
Results. The study included 262 patients, boys 161 (61.5%), median age 5.3 (IQR 1.6–12.2), BMI z-score 0.06 (IQR-1.25–1.32). Enteral nutrition started within 48 h in > 90% of patients. Energy coverage was longitudinally increased, reaching 63% (recommended 70%) on Day 7 ($p = 0.005$). Independent factors (multiple linear regression analysis) for increased energy adequacy (according to Schofield equation) were the younger age ($p < 0.001$), undernutrition ($p < 0.001$), mechanical ventilation ($p < 0.001$), and complex comorbidities ($p = 0.002$). Younger age was the only independent predictor of achieving adequate protein intake (≥ 1.5 g/kg of ideal body weight per day) during the first 7 days of PICU stay ($p = 0.004$). The UCR showed a downward trend from Day 1 [44.5 (IQR 32.6–59.6)] to Day 5 [38.2 (IQR 25.9–54.7)], followed by an upward trend reaching Day 21 [45.8 (IQR 30.2–65.9)], suggesting ongoing catabolism in patients with prolonged PICU stay, although the changes were not statistically significant. Over time, no association was found between energy or protein adequacy and UCR. Furthermore, 28-day mortality, duration of mechanical ventilation, and PICU length of stay were not associated with nutritional status, energy intake, or UCR.
Conclusions. Nutritional status, anthropometric measurements, and nutritional support during PICU stay were not associated with UCR values or clinical outcomes. These findings do not support the use of the urea-to-creatinine ratio as a reliable biomarker of catabolism in critically ill children. Further prospective, multicenter studies are warranted to clarify the relationship between nutritional intake, UCR dynamics, and clinical outcomes in this population.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000517***.

Introduction. Acinetobacter baumannii infections emerge as a critical problem in Greece and countries around the Mediterranean due to increased resistance and lack of therapeutic alternatives. The in-hospital all cause mortality from Acinetobacter spp infections can reach up to 44%, overemphasizing the need for effective therapeutic solutions.
Objectives. The aim of this preliminary, ongoing study is to investigate the efficacy and safety of three antimicrobial combinations of colistimethate in patients with Pan Drug Resistant Acinetobacter baumannii. The primary objective was the sterilization of blood cultures and potential major side effects in 14 days.
Methods. 39 patients were included in this study (24 male, 15 female), with median age of 59, from January 2023 to December 2024.
12 patients suffered from traumatic brain injury, 10 were major trauma patients, 7 patients suffered from intracerebral and subarachnoid hemorrhage, 5 patients underwent abdominal surgery and 5 suffered from acute respiratory failure.
All 39 patients presented with PDR Acinetobacter baumannii blood stream infections during their hospitalization (Fig. 1). Antimicrobial synergy was tested in the microbiology lab and the combinations that were found to be in vitro effective were: colistimethate + rifampicin, colistimethate + daptomycin and colistimethate + tigecycline.
20 patients received colistimethate + rifampicin (Group 1).
11 patients received colistimethate + daptomycin (Group 2).
8 patients received colistimethate + tigecycline (Group 3).
Results. Group 1: 14 out of 20 patients presented with sterile blood cultures by the 14th day. The synergistic effect of colistimethate + rifampicin was effective in 70% of the patients.
Group 2: 6 out if 11 patients presented with sterile blood cultures by the 14th day.
The synergistic effect of colistimethate + daptomycin was effective in 54% of the patients.
Group 3: 3 out of 8 patients presented with sterile blood cultures by the 14th day. The synergistic effect of colistimethate + tigecycline was effective in 37% of the patients.
The incidence of **acute kidney injury** between the three groups were found similar [**Group 1**:5 out of 20 patients (25%), **Group 2**: 3 out of 11 patients (27%) and **Group 3**: 2 out of 8 patients (25%)]. Nevertheless in **Group 3**, 4 out of 8 patients (50%) suffered from coagulation disorders (thrombocytopenia, hypofibrinogenemia) in contrast with

none of the patients from Group 1 and 2. Last but not least, 2 out 20 patients (10%) from **Group 1** suffered from elevated liver enzymes(2 to threefold) and 1 out of 11 patients (9%) from **Group 2** suffered from elevated CPK.

Conclusions. The combination of colistimethate + rifampicin seems to be more effective and relatively safe in patients with PDR Acinetobacter baumannii. Nevertheless, novel therapeutic alternatives have thus become a necessity.

Introduction. Chest radiography is the standard practice to confirm correct positioning of central venous catheters (CVC). Advances in multimodal large language models (MLLMs) that merge vision and language understanding have sparked interest in their use for interpreting medical images.

Objectives. This study aimed to evaluate the reliability of three MLLMs in assessing CVC placement in ICU patients.

Methods. We retrospectively collected chest X-rays of ICU patients with newly inserted CVCs (July–December 2024). Each image was reviewed by four ICU physicians, one radiologist and three MLLMs (GPT 4.5, Claude 3.7 Sonnet, Gemini 2.5 Pro). They evaluated three parameters: CVC access route (jugular/subclavian), CVC position acceptability and pneumothorax presence. We used Fleiss' kappa for agreement among human reviewers and Cohen's kappa for pairwise comparisons. Image quality was evaluated using a point system based on X-ray properties. A score ≥ 2 indicated good image quality.

Results. We collected 94 unique X-rays (55 of good quality). Human reviewers demonstrated almost perfect agreement for CVC access route (kappa = 0.95,95%CI 0.89–1.00), moderate agreement for CVC position (kappa = 0.47,95%CI 0.41–0.54), and fair agreement for pneumothorax detection (kappa = 0.36,95%CI 0.30–0.42). Agreement between human experts' consensus and MLLMs was very poor (Table 1). Assessment distribution patterns are shown in Table 2. Image quality affected MLLM performance variably. Human expert agreement remained consistently high regardless of quality. All MLLMs exhibited systematic differences from human experts in CVC access route classification and two of them in position acceptability.

Table 1 (abstract 000518) Agreement between MLLMs and human consensus

	MLLM	Cohen's Kappa (95% CI)	Accuracy	Sensitivity	Specificity
CVC access route	ChatGPT	-0.14(-0.35,0.08)	46.8%	50.6%	18.2%
	Claude	-0.06(-0.2,0.07)	28.7%	25.3%	54.5%
	Gemini	0.02(-0.21,0.24)	56.4%	57.8%	45.5%
CVC position	ChatGPT	0.00(-0.3,0.3)	69.1%	100%	0%
	Claude	-0.01(-0.28,0.27)	64.9%	89.2%	10.3%
	Gemini	-0.16(-0.40,0.09)	52.1%	67.7%	17.2%
Pneumothorax	ChatGPT	-0.01(-1.00,1.00)	96.8%	0%	98.9%
	Claude	-0.03(-0.83,0.77)	93.6%	0%	95.7%
	Gemini	-0.01(-1.00, 1.00)	96.8%	0%	98.9%

Table 2 (abstract 000518) Assessment distribution across image quality groups

	Quality	Assessment	Human consensus	ChatGPT	Claude	Gemini
CVC access route	Good	Jugular	92.7%	54.5%	23.6%	58.2%
		Subclavian	7.3%	45.5%	76.4%	41.8%
	Poor	Jugular	82.1%	52.5%	32.5%	57.5%
		Subclavian	17.9%	47.5%	67.5%	42.5%
CVC position	Good	Acceptable	70.9%	100%	94.5%	78.2%
		Not acceptable	29.1%	0%	5.5%	21.8%
	Poor	Acceptable	66.7%	100%	82.5%	65%
		Not acceptable	33.3%	0%	17.5%	35%
Pneumothorax	Good	Present	0%	0%	3.6%	0%
		Absent	100%	100%	96.4%	100%
	Poor	Present	5.1%	2.5%	5%	2.5%
		Absent	94.9%	97.5%	95%	97.5%

Conclusions. This study demonstrates that current MLLMs perform poorly in evaluating CVC placement on chest radiographs. The negative kappa values for MLLMs-human agreement indicate performance worse than chance, raising significant concerns about their reliability.

Introduction. Hemodynamic monitoring is pivotal in the management of the critically ill unstable patient. Transpulmonary thermodilution (TPTD) by pulmonary arterial catheter and Pulse Contour Cardiac Output (PiCCO) are widely used for hemodynamic monitoring in the intensive care unit(1), but are invasive and time-consuming to set up. Transthoracic echocardiography (ECHO) is another modality that is increasingly being used for initial shock and CO assessment as it is non-invasive and easily accessible in most units. Technological advancement has enabled the automated ECHO measurement of CO (aCO), further expediting hemodynamic monitoring and management of critically ill patients. Previous studies have demonstrated reasonable agreement between manual ECHO measurement of CO (mCO) and PiCCO (pCO) (2–4), and between aCO and mCO measurements(5). In this study, we aim to assess the agreement between these three parameters.
Methods. We conducted a single-centre, prospective, observational study in a tertiary intensive care centre. Patients with arrhythmia were excluded. PCO measurements by TPTD (PiCCO) were first performed, followed by aCO and mCO measurements by a trained clinician who was blinded to the results of pCO. During the measurement period, all vasoactive agents were kept unchanged, and no additional fluid therapy were administered. The ECHO CO was measured as per established protocol. Results were analysed according to published methods of Bland–Altman limits of agreement and percentage error (PE)(6).
Results. We included 14 adult patients, with repeat measurements performed in the some of the patients provided a significant hemodynamic change had occurred, yielding 21 datasets. Mean CO for pCO, aCO and mCO were 6.94, 6.43 and 6.56L/min. Both aCO and mCO measurements have a small mean difference in comparison with PCO, but demonstrate wide 95% limits of agreement. PE for aCO and mCO as compared to pCO were 48.6% and 41.2%, respectively. There was, however, a small mean difference between aCO and mCO measurements (-0.13L/min PE 16.6%).

Table 1. (abstract 000519) Results analysis

Measurements	Mean difference (L/min)	Standard deviation (L/min)	95% Limits of agreement (L/min)	Percentage error (%)
Automated CO & PiCCO CO	-0.51	1.66	(-3.76, 2.74)	48.6
Automated CO & Manual CO	-0.13	0.55	(-1.21, 0.95)	16.6
Manual CO & PiCCO CO	-0.39	1.42	(-3.17, 2.39)	41.2

Conclusions. Both aCO and mCO provide close values overall to pCO, with mCO being the more accurate of the two. However, both demonstrate high 95% limits of agreement, and the PE of both are above Critchley's PE (6, 7) cutoff of 30%. The trending ability of aCO measurements needs to be further researched.

Frailty and fate: exploring outcomes after intensive care in patients aged more than 80 years

AL. Kunjumon[1]; MU. Farooq[1]; TN. Somasinghe[1]; G. Millen[1]; L. Cooper.[1]
[1]Critical Care, William Harvey Hospital, Ashford, United Kingdom.

Introduction. Frailty is a state of increased vulnerability resulting from a decline in reserve across multiple physiological systems, increasing susceptibility to adverse events and is an inevitable consequence of aging (1). Currently, the proportion of "very old intensive care patients" (VIPs) admitted to critical care is estimated at 15%, and this figure is expected to rise in the coming years (2). This change in demographic composition of critical care population presents multiple challenges—older patients with multiple chronic conditions who face higher risks of mortality and morbidity. Furthermore, studies such as VIP2 have demonstrated that frailty assessment using the clinical frailty scale is able to predict short-term mortality in elderly patients admitted to intensive care unit, and is similar to established scoring systems like APACHE and SOFA (3).
This study aimed to evaluate the association between the Clinical Frailty Scale (CFS) of elderly patients aged 80 years or more at admission with the level of dependence/frailty and mortality at 6 months and 12 months after discharge from intensive care unit.
Methods. This was a retrospective analysis of 'very old intensive care patient' admissions (aged ≥ 80 years) in the intensive care unit of a district general hospital. Admissions for both medical and surgical (emergency and elective) causes from January to December 2023 were included in the study. The Clinical Frailty Scale (CFS) using the Rockwood Scale was recorded at admission, with frailty defined as a Clinical Frailty Scale of ≥ 5. Outcome variables assessed included length of stay in the intensive care unit (ICU), mortality in the intensive care unit and at 6-months and 12 months as well as the Clinical Frailty Scale (CFS) at 6 months and 1 year.

Results
Among the total of 876 patients admitted to the intensive care unit in 2023, 120 individuals were aged ≥ 80 years and enrolled in the study. Retrospective data were obtained from electronic medical records. Of the 120 cases, 45 were medical and 75 surgical admissions, including 34 emergency surgeries. Based on the clinical frailty scale at admission, 68 patients were categorised as frail (CFS ≥ 5) and 52 as non-frail. Admission factors such as the nature and reason for admission, incidence of sepsis were similar between the groups.

The overall ICU mortality was 15% for the cohort which increased to 35% (42 patients) at the 12 months timepoint. Six-month mortality was significantly higher among patients identified as frail at admission (35%) compared to non-frail patients (19%). At 12 months, mortality further increased to 43% in the frail group and 25% in the non-frail group ($p = 0.04$). There was, however, no significant difference between frail and non-frail groups in the ICU length of stay which is possibly reflective of the advance decision-making and relatively the larger number of elective surgical admissions.
Of the 78 survivors at 12 months, Frailty scale was available for only 38 patients at all time points, i.e., at admission, 6 months and 12 months due to the retrospective nature of data collection. A significant decline in functional status was observed in all these patients following an intensive care admission, most notably in emergency surgical admissions. The incidence of frailty increased from 50% at admission to 68% at 6 months and further increased to 76% at 12 months, which is clinically and statistically significant ($p < 0.001$).
Conclusions. Frailty is an independent risk factor for poor outcomes in both short-term and long-term mortality and functional decline, in very old intensive care patients and particularly more in emergency surgical admissions. It is essential to consider frailty in the risk stratification especially in preassessment of surgical patients to support informed, shared decision-making with patients and their families. Larger sample size studies are required to further delineate the effect of frailty in the subgroups of surgical and medical admissions to intensive care.

Table 1 Comparison of admission factors between frail and non-frail patients

Variable	Category	Non-frail (N=52)	Frail (N=68)	P-value
Age	-	84 [82, 86]	84 [81, 86]	0.99

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000521***.

Introduction. Acute pancreatitis (AP) varies in severity, ranging from mild cases to critical conditions associated with high mortality and multiple organ dysfunction. Several prognostic scores have been developed to stratify the severity of AP, including BISAP, Ranson, Glasgow-Imrie, Balthazar, SOFA, and APACHE II, each with specific characteristics and criteria.
Objectives. To compare the discriminatory power of different scoring systems in predicting hospital mortality in patients with acute pancreatitis admitted to the intensive care unit (ICU).
Methods. This is a retrospective cohort study including patients hospitalised with acute pancreatitis and admitted to the ICU of a secondary care hospital between 2022 and 2024. Clinical characteristics of the patients were collected, and BISAP, Ranson, Glasgow-Imrie, Balthazar, SOFA, SAPS II, and APACHE II scores were calculated on ICU admission. The predictive power of each score was assessed through the analysis of the area under the receiver operating characteristic (AUROC) curve.
Results. A total of 71 patients were included, with a mean ± SD age of 62 ± 15 years; 58% (n = 41) were male. In our sample, 37% (n = 26) was attributed to lithiasis, 23% (n = 16) idiopathic, 20% (n = 14) alcoholic, 14% (n = 10) due to hypertriglyceridaemia, and 9% (n = 6) post-ERCP. Relatively to the prognostic scores, BISAP 2.4 ± 1.4 (mean ± SD), Ranson 1.8 ± 1.1 at 24h and 3 ± 1.6 at 48h, Glasgow-Imrie 3.6 ± 1.8, Balthazar 2.3 ± 2, SOFA 6.5 ± 3.8, SAPS II 39 ± 20, and APACHE II 17 ± 9. The discrimination value of each score is shown in Table 1.
ICU mortality was 27% (n = 19) and hospital mortality was 31% (n = 22).

Table 1- (abstract 000521) The AUROC curve and 95% confidence interval for each score in the prediction of hospital mortality

Score	AUROC curve	95% CI
BISAP	0,597	0,455 – 0.740
RANSON_24	0,603	0,459 – 0.747
RANSON_48	0,590	0,429 – 0.751
GLASGOW_IMRIE	0,651	0,510 – 0.793
BALTHAZAR	0,527	0,361 – 0.693
SOFA	0,765	0,649 – 0.881
SAPS II	0,806	0,679 – 0.934
APACHE II	0,846	0,734 – 0.957

Conclusions. In our population, ICU prognostic scores (SOFA at admission, SAPS II, and APACHE II) predicted hospital mortality more accurately than specific acute pancreatitis stratification scores such as BISAP, Ranson, Glasgow-Imrie, and Balthazar.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000522***.

Introduction. Acute pancreatitis (AP) occurs in varying degrees of severity, from mild to severe cases associated with high mortality and multiple organ failure. Early identification of risk factors for ICU mortality allows for a more targeted treatment strategy, better resource allocation and the possibility to improve patient outcomes.

Objectives. To identify independent risk factors at admission related with ICU mortality.

Methods. Retrospective cohort study of all patients hospitalised with acute pancreatitis and admitted to the ICU of a secondary care hospital between 2022 and 2024. Clinical data, comorbidities, laboratory results and severity scores were analysed. The primary endpoint was ICU mortality.

Results. A total of 71 patients were included in the study, with their characteristics outlined in Table 1. The ICU mortality rate was 27% (n = 19).

Table 1. (abstract 000522) Clinical and demographic characteristics of the 71 patients included in the study.

Characteristic	Total (n = 71)	Dead (n = 19)	Crude OR	P value
Age, mean ± SD	62 ± 15	70 ± 11	1.055	0.014
Male, n (%)	41 (58)	12 (63)	1.360	0.578
Frailty score, median (IQR)	1 (1–2)	2 (1–3)	1.675	0.028
Charlson, median (IQR)	3 (2–5)	4 (3–5)	1.091	0.432
BISAP score, mean ± SD	2.4 ± 1.4	2.8 ± 1	1.388	0.122
Ranson 24h, mean ± SD	1.8 ± 1.1	2.2 ± 1.1	1.680	0.042
Ranson 48h, mean ± SD	3 ± 1.6	3.4 ± 1.8	1.193	0.325
Glasgow-Imrie score, mean ± SD	3.6 ± 1.8	3.9 ± 1	1.126	0.416
Balthazar score, mean ± SD	2.3 ± 2	2.4 ± 2.1	1.022	0.884
SOFA score at admission, mean ± SD	6.5 ± 3.8	9.4 ± 3.2	1.432	< 0.001
SAPS II score, mean ± SD	39 ± 20	58 ± 20	1.094	< 0.001
APACHE II score, mean ± SD	17 ± 9	26 ± 6	1.252	< 0.001
Etiology, n (%)	26 (37)	4 (21)	0.364	0.108
Lithiasis	14 (20)	4 (21)	1.120	0.864
Alcohol	10 (14)	1 (5)	0.265	0.224
Hypertriglyceridemia	6 (9)	1 (5)	0.522	0.565
Post-ERCP	16 (23)	9 (47)	5.786	0.004
Idiopathic	1(1)	0(0)		
Medication				
Dysfunctions, n (%)	34 (48)	16 (84)	10.074	< 0.001
Neurologic	39 (55)	16 (84)	6.725	0.001
Cardiovascular	53 (75)	17 (90)	3.778	0.099
Respiratory	48 (68)	18 (95)	13.200	0.015
Renal	39 (55)	10 (53)	0.881	0.814
Hepatic	27 (38)	8 (42)	1.263	0.669
Coagulopathy				

When adjusted for age, Frailty score, idiopathic pancreatitis, and dysfunctions (neurologic, cardiovascular, respiratory, renal), the final model retains Frailty score and neurologic dysfunction with adjusted OR (95% CI) of 2.006 (1.063–3.785) and 12.637 (2.796–57.107).

Conclusions. In our population, older age, higher frailty score, higher Ranson score at 24 h, higher prognostic ICU scores, idiopathic pancreatitis, neurological, cardiovascular and renal dysfunction were associated with higher ICU mortality. In these patients nor progression of necrosis, infection, non-conservative treatment or antibiotic therapy were associated with this outcome.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000523***.

Introduction. Acute respiratory distress syndrome (ARDS) is classified based on oxygenation, and severe hypoxemia is associated with increased mortality. However, approximately one-third of mechanically ventilated patients diagnosed with ARDS have newly developed or exacerbated diffuse parenchymal lung diseases (DPLD)1.
Objectives. We conducted a post hoc analysis of a multicenter retrospective cohort study to evaluate whether the association between ARDS severity and in-hospital mortality differs depending on the diagnosis of DPLD.
Methods. We included mechanically ventilated patients diagnosed with moderate or severe ARDS based on the Berlin definition at 10 hospitals in Japan between December 2017 and December 2019. Patients were categorized as having severe (P/F ≤ 100) or moderate (P/F 101–200) ARDS according to the lowest P/F ratio within 48 h of mechanical ventilation. The primary outcome was in-hospital mortality. Based on expert diagnosis, patients were classified into three DPLD categories: classic ARDS, idiopathic pulmonary fibrosis (IPF), and non-IPF DPLD. We assessed the association between severity classification and in-hospital mortality across DPLD categories, and evaluated the interaction between ARDS severity and DPLD category.
Results. Among 274 patients, 167 were classified as having severe ARDS and 107 as moderate. In the severe ARDS group, 64.5% had classic ARDS, 10.3% had IPF, and 25.2% had non-IPF DPLD. In the moderate group, the proportions were 68.3%, 6.0%, and 25.7%, respectively. Among 183 patients with classic ARDS, in-hospital mortality was significantly higher in patients with severe ARDS compared to moderate ARDS (62.3% vs. 42.1%, P = 0.006). However, no significant difference in mortality between severe and moderate ARDS was observed in patients with non-IPF DPLD (70 patients; 40.7% vs. 34.9%, P = 0.80) and IPF (21 patients; 63.6% vs. 60%, P = 1.00). In patients with classic ARDS, severe cases had higher odds of in-hospital mortality compared to moderate cases (odds ratio [OR] 1.90, 95% confidence interval [CI] 1.03–3.50; interaction P = 0.04). In contrast, the association was not significant in IPF (OR 0.75, 95% CI 0.12–4.66; interaction P = 0.76) or non-IPF DPLD (OR 1.58, 95% CI 0.60–4.16; interaction P = 0.36).
Conclusions. Our findings highlight the importance of diagnosing the underlying cause of ARDS when interpreting P/F-based severity classification. Mechanically ventilated patients with IPF may have a high risk of mortality regardless of oxygenation status.

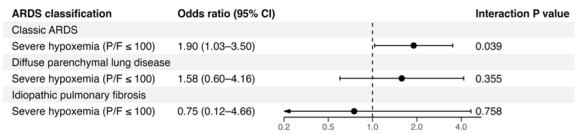

Figure (abstract 000523) Forest plot showing the odds ratio for in-hospital mortality in patients with severe hypoxemia (P/F ≤ 100). Abbreviation: ARDS, acute respiratory distress syndrome.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000524***.

Introduction. Surgical inflammation may impair recovery and delay oncological therapy in cancer patients. Propofol and dexmedetomidine have potential anti-inflammatory properties, but their clinical impact compared to inhalational agents remains unclear. This study investigated the effect of these anaesthetic techniques on perioperative inflammation and postoperative outcomes in oral cancer surgery.
Hypothesis: Combination of dexmedetomidine and propofol (TIVA), will work as anti-inflammatory agent and causes less perioperative inflammation when compared with inhalational agents. This perioperative inflammation is also associated with decreased postoperative analgesic requirement.
Objectives. This study aims to assess the impact of different modes of anaesthesia on perioperative inflammation and post-operative pain in patients undergoing oral cancer surgery. Due to scarcity of evidence concerning these perioperative phenomena and anesthesia modes, this study was planned. Primary outcome was to compare difference in change of TNF alpha at postoperative day 1 and day 3, in both the groups. Secondary outcomes was to compare changes in level of IL-6, IL l0 and IL13 in blood in both the groups at day 1 and day 3. Postoperative pain scores till 48 h, duration of hospital stay and day of return to intended oncological therapy (RIOT) in both the groups were also compared.
Methods. The study was conducted after approval from ethics committee and registration at clinical trial registry-India. Total 66 patients of American Society of Anaesthesiologists (ASA) physical status grade I to III, aged 25 to 65 years, with oral cancer, randomized into two groups. Preoperative biomarkers IL-6, IL-10, IL-13, and TNF-α were recorded. Patients in group A received TIVA with dexmedetomidine infusion(0.5mcg/kg/hr infusion) to maintain a Bi spectral index value 40–60 and group B received inhalational agents (Minimum alveolar concentration of 1.0) for maintenance. Rest all anaesthesia technique was similar as per the standard protocol. Biomarkers were again recorded on postoperative day 1 and day 3. Postoperative pain scores, total analgesic consumption in 48 h, day of discharge and day of RIOT were also noted. Quantitative variables are presented as median (IQR) or mean (SD). Chi-square test was applied for qualitative data. Unpaired Student's t test was applied for comparing quantitative data. The results were significant if P value was < 0.05.
Results. IL6, IL 10, TNF alpha and IL 13 were comparable on post-operative day 1 and day 3 in TIVA and inhalational agents group. Postoperative pain scores were also comparable in both the groups. Analgesic consumption at 24 h (p = 0.305) and 48 h (p = 0.147) was also comparable. Most of the patients were discharged by day 3 (57%) in both the groups. Day of discharge (p value = 0.783) and RIOT (p value = 0.235) were also comparable.
Conclusions. The study shows that TIVA and inhalational agents produce similar effects on perioperative immune markers (TNF alpha, IL 6, IL13 and IL 10) in oral cancer patients. No significant difference was observed in pro and anti-inflammatory markers, day of discharge or RIOT.

Relevance to patient care: This study suggests that anaesthetic technique does not influence immunosuppression, postoperative pain scores, analgesic requirements and patients recovery. Both anaesthesia technique had equivalent short term perioperative outcomes, suggesting that it may not influence early perioperative course in oral cancer surgery. Anaesthesia technique can be chosen based on patient profile, comorbidities, and surgical requirements.

Intermittent titration of positive end-expiratory pressure is beneficial during extended prone position in acute respiratory distress syndrome.

L. Sang[1]; Z. Lin[1]; Z. Zhao.[1]

[1]Critical Care Medicine, Guangzhou Medical University, Guang Zhou Shi, China.

Correspondence: Z. Zhao.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000526***.

Introduction. Extended prone position ventilation (PPV > 24 h), widely adopted during COVID-19, showed decreased mortality in moderate to severe acute respiratory distress syndrome (ARDS) [1–2]. However, it remains incompletely characterized for synergistic integration with lung-protective strategies.

Objectives. In a previous study, the feasibility of prolonged PPV with dynamic titration of positive end-expiratory pressure (PEEP) was demonstrated [3]. The present study aimed to compare physiological responses between conventional prone sessions (16 h with initial PEEP titration) and prolonged sessions (24-48 h with 6-hourly PEEP adjustments).

Methods. A single-center comparative physiology study (prospective vs. historical cohort) was conducted in our ICU. This ICU-based study enrolled moderate-severe ARDS patients ($PaO2/FiO2 \leq 150$ mmHg). The prospective cohort (n = 29) received dynamic PEEP tuning during 24-48 h prone positioning (DP-group). The historical controls (n = 16) underwent 16 h prone with PEEP titrated once during the supine position (FP-group). The PEEP was titrated based on ventilation homogeneity assessed by electrical impedance tomography.

Results. Both groups exhibited progressive PaO2/FiO2 elevation, reaching 236.9 ± 65.5 mmHg (DP-group) and 226.8 ± 89.5 (FP-group) at 16 h (both p = 0.01 *vs*. supine). However, only DP-group maintained improvement to 258.2 ± 77.3 mmHg at 48 h (p = 0.035 *vs*. 16 h). Earlier oxygenation enhancements emerged in DP-group (ΔPaO2/FiO2 at 2 h: 71.5 ± 58.6 *vs*. 27.9 ± 63.4 mmHg, P = 0.025). Dynamic PEEP significantly improved regional compliance balance (global ventilation heterogeneity 0.39 ± 0.07 *vs*. 0.49 ± 0.10, DP *vs*. FP-group, p < 0.001).

Conclusions. In moderate-to-severe ARDS patients, implementing a combination of dynamic PEEP titration and prolonged prone positioning (24–48 h) proves practical. This innovative strategy could augment the benefits of lung-protective ventilation.

From complications to confidence: mastering PICC line management in critical care through comprehensive guideline

S. Theodoridou[1]; F. Gkioulos[2]; J. Martin-Lazaro.[3]

[1]Intensive Care Unit, Royal London Hospital, London, United Kingdom; [2]Intensive care unit, King's College Hospital, London, United Kingdom; [3]Icu, Newham University Hospital, London, France.

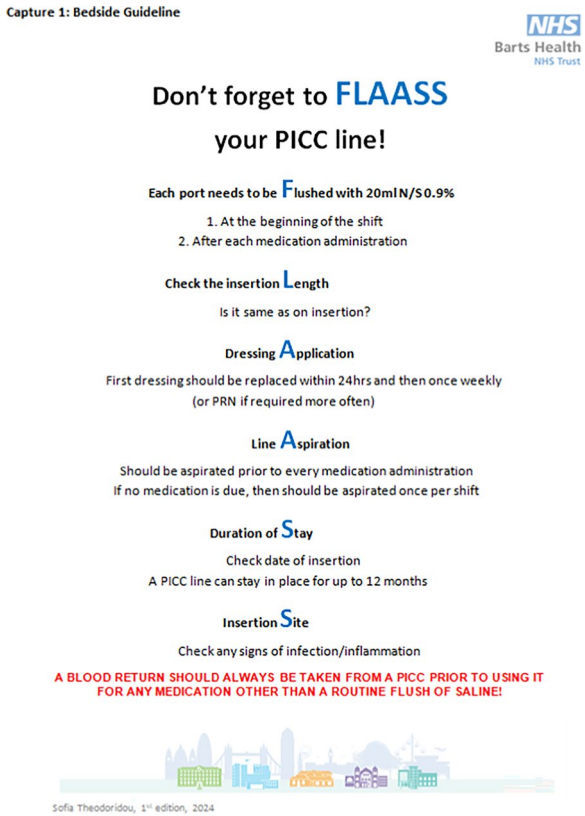
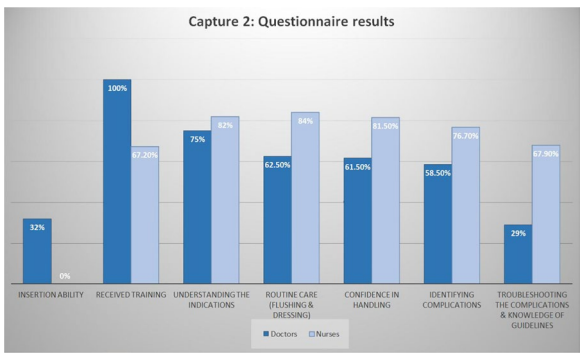
Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000527***.



Introduction. A Peripherally Inserted Central Catheter (PICC) is a long term central access device [1, 4] which is used for chemotherapy, long term antibiotic administration, parenteral nutrition and for blood sampling. It is a long hollow tube made of silicone or polyurethane [1], is inserted in the ante-cubital fossa under ultrasound guidance and terminates in proximity to the cavoatrial junction [1, 2]. In the ICU, it can also be used for the administration of centrally delivered medications [3]. However, long-term catheters require daily assessment in order to prevent and manage complications [5], such as thrombosis, obstruction and catheter-related bloodstream infections (CRBSIs) [2].

Objectives. A clinical audit was conducted in the Intensive Care Unit of a London university hospital following frequent complications with PICC lines. This quality improvement project aimed to assess the staff knowledge in managing these Central Venous Access Devices (CVADs) and to provide education and training to healthcare professionals to enhance their use.



Methods. Initially, we developed anonymous questionnaires for ICU doctors and nurses to assess their knowledge and confidence in handling PICC lines. Following this, we delivered presentations and bedside teaching for doctors, CCOT nurses, and ICU nurses. We also created a PICC line bedside guideline with the acronym "FLAASS" (Capture 1) to facilitate quick assessment of the patient's PICC line. This guideline was placed at every bed space to enable daily evaluations of the CVAD, helping to prevent complications or address them early.

Results. The initial questionnaire revealed that many staff members lacked confidence and some had not received proper training (Capture 2). Additionally, many, both nurses and doctors, were uncertain about how to manage complications (Capture 2). After regular teaching sessions and daily assessment of PICC lines using the provided guideline (capture 1), staff members became more confident and were able to educate each other. As a result, we observed that complications, such as obstructions, were addressed more quickly, allowing the PICC lines to remain in place for longer periods.

Conclusions. In conclusion, PICC line placement in the ICU should be considered when a long-term intravenous access is required. However, due to increased risk of CVADs associated complications, proper education and training of staff facilitates better outcomes, allowing the line to remain in situ for a prolonged duration.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000529***.

Introduction. Monitoring cardiac output (CO) is crucial for managing hemodynamics in patients with circulatory failure. The CADFlow system (Sensus Medical, China) is an innovative hands-free continuous auto-Doppler flow monitor that provides ongoing CO assessments by measuring the carotid velocity–time integral (cVTI) and calculating the cross-sectional area from the diameter of the carotid artery, assuming a 10% ratio of carotid to total CO. This study aimed to evaluate the accuracy, precision, and ability of CADFlow to track changes in cardiac index (CI) during fluid challenges (FC) in patients with circulatory failure, using transpulmonary thermodilution (TPTD) as a reference method.
Methods. This prospective bicentric study was conducted from October 2024 to January 2025. Adults experiencing circulatory failure (mean arterial pressure < 65 mmHg or requiring vasopressors) and needing a fluid challenge were enrolled if a PiCCO device was in place. CI was simultaneously measured by both CADFlow (CI-CAD) and TPTD (CI-TPTD) before and after administering a 500 mL infusion of Ringer's lactate. The intra- and inter-observer variability during probe placement, as well as the least detectable change (LSC) during continuous monitoring, were recorded to evaluate reproducibility. The agreement between the two methods was analyzed using Pearson's correlation and Bland–Altman plots, assessing bias, limits of agreement (LoA), and percentage error (PE). The ability to detect trends was examined using Pearson's correlation, Bland–Altman plots, four-quadrant plots, and polar plots. Receiver operating characteristic (ROC) curves were employed to assess the capacity of CI-CAD to detect CI-TPTD increases of $\geq$ 15%.
Results. A total of 40 patients with circulatory failure (93% with septic shock; median SOFA score of 8, APACHE II score of 19) were included in the study. Among these, 85% required invasive mechanical ventilation, 88% received norepinephrine, and the 28-day mortality rate was 30%. The intra- and inter-observer reproducibility of CI-CAD measurements was found to be excellent, with intraclass correlation coefficients (ICC) of 0.93 and 0.91, respectively. Continuous monitoring revealed a low LSC of 1.1% for CI-CAD. Among the 80 paired measurements, CI-CAD displayed a moderate correlation with CI-TPTD ($r = 0.67$, $p < 0.01$), showing a bias of 0.18 L/min/m^2 but wide limits of agreement (-1.50 to + 1.86 L/min/m^2, PE = 50%). In terms of ΔCI data, CADFlow demonstrated outstanding trending capability, showing a strong correlation between changes in ΔCI-CAD and ΔCI-TPTD (Pearson's $r = 0.91$, $p < 0.01$) and minimal bias in the Bland–Altman analysis (-0.07 L/min/m^2; LoA: -0.46 to + 0.61 L/min/m^2). Excluding a

central zone with a radius of 0.15 L/min/m^2 (5% of the mean CI-TPTD), four-quadrant plot analysis confirmed 95% concordance in trending direction, while polar plot analysis yielded a polar angle of -4.26° (with radial limits of ± 22.3°). For detecting ΔCI-TPTD increases of ≥ 15%, CADFlow achieved 96% sensitivity and 100% specificity, with an area under the curve (AUC) of 0.98. Subgroup analyses indicated reduced agreement in patients with low CI (< 3 L/min/m^2, PE = 66%), high norepinephrine equivalence (≥ 0.29 mcg/kg/min, PE = 54%), and carotid plaques (intima–media thickness ≥ 1.3 mm, PE = 66%). Nonetheless, trending performance remained robust across all subgroups (Pearson's r > 0.89 and concordance > 94% in the four-quadrant plot).
Conclusions. In patients with circulatory failure, CADFlow demonstrates excellent performance in tracking changes in cardiac index during fluid challenges. In contrast, static CI-CAD measurements exhibit moderate accuracy and precision compared to CI-TPTD. These findings suggest that while CADFlow may not be a direct replacement for TPTD, it provides significant value in functional hemodynamic monitoring by reliably tracking dynamic changes in CI.

Introduction. Self-extubation is a common complication in intubated patients in the intensive care unit (ICU) and is associated with a high rate of weaning failure. The aim of this study was to identify predictors of weaning failure following self-extubation and to evaluate the prognosis of these patients.
Methods. Data were extracted from the French ICU database, OutcomeRea™. The objective of the study was to identify factors associated with weaning failure, defined as reintubation or death within 48 h of self-extubation. The association between weaning failure after self-extubation and mortality, ICU stay duration, and the occurrence of nosocomial pneumonia was also assessed.
Results. During the study period between November 1996 and May 2022, 12,917 patients were intubated in the ICU. Of these, 701 patients experienced self-extubation without therapeutic limitations before extubation, and 276 (39.4%) of these patients experienced weaning failure. In an adjusted analysis, an increase in the non-neurological SOFA score the day before self-extubation (OR, 1.15 [1.01; 1.31], p = 0.04), the length of invasive ventilation before self-extubation (3–7 days, OR, 1.32 [0.81; 2.14]; > 7 days, OR, 1.84 [1.04; 3.25]; p < 0.01), and enteral nutrition on the day of self-extubation (OR, 2.23 [1.54; 3.22], p < 0.01) were found to be associated with a higher risk of weaning failure. After adjusting for confounders, reintubation within 48 h following self-extubation was associated with increased 28-day mortality (HR = 3.03 [1.79; 5.12]; p < 0.01) and 90-day mortality (HR = 2.86 [1.86; 4.4]; p < 0.01), an increased risk of nosocomial pneumonia (sdHR, 18.28 [7.70; 43.42]; p < 0.01), and a 13-day increase in ICU length of stay (p < 0.01).
Conclusions. Enteral nutrition on the day of self-extubation, prolonged invasive mechanical ventilation prior to extubation, and a high non-neurological SOFA score were all associated with weaning failure following self-extubation. Self-extubation failure was also associated with an increased risk of mortality, nosocomial pneumonia, and extended ICU length of stay.

Investigating the clinical outcomes of continuous infusion of sedative agents in critically ill patients with invasive mechanical ventilation in Taiwan

CC. Wu[1]; HT. Chien[2]; SH. Lu[1]; YJ. Tseng[1]; SC. Ku[3]; FJ. Lin.[1]
[1]Pharmacy, NTUH (National Taiwan University Hospital), Taipei, Taiwan; [2]Graduate Institute of Clinical Pharmacy, National Taiwan University, Taipei, Taiwan; [3]Department of internal medicine, National Taiwan University Hospital, No. 7, Zhongshan South Road, Taipei, Taiwan.
Correspondence: C.C. Wu.
Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000531***.

Introduction. Optimal sedation strategies are essential for mechanically ventilated ICU patients. Current guidelines favor non-benzodiazepine (non-BZD) sedatives, such as dexmedetomidine (DEX) and propofol (PPF), over benzodiazepines (BZDs). However, real-world data in Taiwan remain scarce.
Objectives. To evaluate the clinical and economic impact of non-BZD versus BZD continuous sedation in ICU patients requiring invasive mechanical ventilation.
Methods. This retrospective cohort study used data from the National Taiwan University Hospital Integrated Medical Database (2011–2019). Adults receiving mechanical ventilation and continuous sedation within 48 h of intubation were included. Propensity score matching (1:1) was performed. Primary outcomes included ICU length of stay (LOS), time to extubation, mortality, and hospitalization costs. Subgroup analyses compared DEX and PPF to BZDs.
Results. Among 2,454 eligible patients, 625 matched pairs were analyzed (Fig. 1). Compared with BZDs, non-BZDs significantly reduced ICU LOS (9.71 vs. 11.78 days, p < 0.0001), time to extubation (4.33 vs. 6.50 days, p = 0.0051), and hospitalization costs (629,319 vs. 781,014 NTD, p < 0.0001), without affecting 90-day mortality (38.7% vs. 40.0%, p = 0.6442)(Table 1). DEX showed the greatest reduction in ICU LOS (8.89 vs. 12.65 days, p = 0.0037) and time to extubation (3.35 vs. 6.50 days, p = 0.0011), while PPF mainly provided cost savings (611,654 vs. 733,036 NTD, p = 0.0016).

Table 1: (abstract 000531) Clinical outcome in patients using non-BZD and BZD

	Non-BZD (n = 625)	BZD (n = 625)	HR	P value
Mortality				
90-day mortality	242 (38.72%)	250 (40.00%)	0.948 (0.756–1.189)	0.6442
Hospital mortality	202 (32.32%)	210 (33.60%)	0.942 (0.742–1.196)	0.6264
ICU mortality	164 (26.24%)	170 (27.20%)	0.947 (0.728–1.233)	0.6872
Length of stay				
Hospital LOS (days)	24.87 (13.36–49.82)	24.31 (13.43–51.37)		0.5810
ICU LOS (days)	9.71 (4.87-1.758)	11.78 (5.96–20.40)		**< 0.0001***
Time to extubation (days)	4.33 (1.75–10.03)	6.50 (2.81–11.90)		**0.0051***
Tracheostomy rate (%)	82 (12.65%)	91 (14.04%)	0.871 (0.618–1.228)	0.4320
Hospitalization expenditure (NTD)	629,319 (375,328–1,052,284)	781,014 (436,672–1,414,415)		**< 0.0001***

BZD: benzodiazepine, HR: hazard ratio, LOS: length of stay, NTD: new Taiwan dollars, *p < 0.05.

Conclusions. Non-BZD sedatives, especially DEX, were associated with shorter ICU stays, faster extubation, and reduced costs without increasing mortality. These findings support the preferential use of non-BZDs for ICU sedation in Taiwan.

Intensive Care Medicine Experimental, ***2025***;13(1): ***000532***.

Introduction. The healthcare sector, particularly Intensive Care Units (ICUs), is among the leading contributors to CO_2 emissions. These emissions significantly impact global climate change and affect future generations' health. Revising and innovating multiple aspects of the care pathway, such as the rational use of pharmaceuticals, represents a critical step toward energy efficiency and greater sustainability.
The "PARACETAMOL CHALLENGE" project, inspired by a study conducted in the Netherlands and informed by the experiences of other European hospitals, constitutes a critical and structured analysis of paracetamol (acetaminophen) usage within our hospital one of the most frequently prescribed and administered drugs in therapeutic protocols. A Dutch study found that 1 g of paracetamol produces 310–628 g of CO2, while a tablet generates just 38 g (1)(2).
Objectives. This study seeks to optimize paracetamol use in hospitalized patients by assessing its risks and benefits, improving clinical appropriateness, and reducing environmental impact. The goal is to raise awareness, enhance team skills, and develop a care bundle for better patient management.
Methods. A team of nurses, doctors, and pharmacists led the project in three phases: data collection, analysis, and knowledge assessment. Two nurses gathered data from the EMR of patients in intensive care, cardiothoracic, and abdominal units, focusing on the route of paracetamol administration and whether patients could have taken oral paracetamol instead of intravenous (IV), provided they were able to eat. In Phase 1 (Nov 4–17, 2024), data on paracetamol use and patient feeding status were collected.
Phase 2 involved analyzing the data and sharing the results with the team to foster better communication between nurses and prescribing doctors about when patients could safely switch to oral paracetamol.
A poster and survey were distributed to evaluate awareness of the Paracetamol Challenge. A webinar was also planned to address the environmental impact of paracetamol use.
Results. Data collected over two weeks in November revealed that 1,123 paracetamol IV units were administered, with 55.48% (623) potentially avoidable and 44.42% (500) clinically appropriate. IV administration resulted in 392,344 g of CO2, compared to just 23,674 g for oral administration. The cost of IV bottles was €255.43, while oral administration would have cost only €18.64. (3).
Alongside, the environmental impact analysis revealed that oral administration of paracetamol resulted in approximately 24,000 g of CO_2 emissions during the select period, whereas IV ones accounted for approximately 400,000 g.
When extrapolated on an annual basis, the adoption of oral administration could substantially reduce the CO_2 footprint, yielding a savings of over 10,000,000 g of CO_2.
Adherence in the ICU was higher, with 67.68% of administrations deemed appropriate, while cardiothoracic and abdominal departments had 24.48% and 29.17% appropriate, respectively.
Overall, the webinar garnered 65 responses, with nursing staff accounting for 66% of participants.

Conclusions. Projected over a year, the study highlights significant environmental and economic savings. By promoting sustainable practices in healthcare, it can reduce CO2 emissions and operating costs. The "Paracetamol Challenge" aims to foster a multidisciplinary team that empowers nurses to assess the route of administration, while encouraging collaboration and respect for the environment.

Period considered	IV cost	Tablet cost	Total savings
2 weeks	255,43 €	18,64€	236,75€
1 year (projection)	7152,04 €	523,04€	6629 €

Expenditure results: comparison between IV form and tablet (PO).

Period	EV (g)	PO (g)	Total CO_2 Footprint (g)
2 weeks	391,244	23,674	367,570
1 year	10,954,832	662,872	10,291,960

Analysis

- **2 Weeks:** During this short period, the EV emissions stood at 391,244 grams, while passenger or other emissions were 23,674 grams, contributing to a total CO_2 footprint of 367,570 grams.
- **1 Year:** Over the course of a year, EV emissions increased significantly to 10,954,832 grams, and PO emissions reached 662,872 grams, resulting in a total CO_2 footprint of 10,291,960 grams.

Co2 Footprint results: comparison between IV form and tablet (PO)—(2 weeks vs 1 year projection)

Diagnostic accuracy of dynamic ultrasound indices versus bioreactance—noninvasive cardiac output monitoring for fluid responsiveness in shock

P. Hanci.[1]
[1]Intensive Care, Trakya University Faculty of Medicine, Edirne, Turkey.
Correspondence: P. Hanci.
Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000533***.

Introduction. Measurements taken using a bioreactance-based, non-invasive hemodynamic monitoring method have shown that the increase in stroke volume index (ΔSVI) resulting from the passive

leg raising (PLR) manoeuvre can serve as a reliable and reproducible dynamic index for predicting volume responsiveness.
Objectives. The primary aim of this study was to assess the reliability of ultrasound-based fluid responsiveness parameters in comparison to bioreactance-based monitoring measurements for determining the fluid responsiveness of patients in shock.
Methods. The study included intubated, sedated, and mechanically ventilated patients aged 18–90 with shock admitted to the medical intensive care unit from March 2023 to April 2025. The vena cava inferior (VCI) distensibility index, left ventricular out-flow tract (LVOT) velocity time integral (VTI), cardiac index (CI), respiratory phasic variability of LVOT-VTI, corrected carotid flow time (cCFT), and respiratory phasic variability of the maximum carotid flow value were measured and recorded by an experienced sonographer. The pulse pressure variation (PPV) of the patients was obtained through invasive arterial monitoring. Afterwards, the Starling® monitor was connected to the patients, and CI was measured. PLR manoeuvre was performed, and ΔSVI was recorded. Fluid responsiveness was determined based on the ΔSVI.
Results. A total of 39 patients were included in the study. The median age was 70 years [60–77], and 51.3% (n = 20) of the patients were male. The median APACHE II score was 29.5 [22.7–33.2], APACHE PMR was 67.2% [47.8–83.0], and the SOFA score was 12 [11–13]. The distribution of shock types, according to the monitor's measurements, was as follows: distributive shock in 26 patients (66.7%), hypovolemic shock in 9 patients (23.1%), cardiogenic shock in 2 patients (5.1%), and obstructive shock in 2 patients (5.1%). Volume responsiveness, as determined by ΔSVI with PLR using the monitor, was present in 53.8% (n = 21) of patients. (Table 1) A strong correlation was observed between CI measurements obtained using LVOT-VTI and the monitor, with a Spearman's rank correlation coefficient of 0.835 (p < 0.001). However, no significant correlation was found between CI and the cCFT, with a Spearman's rank correlation coefficient of 0.156 (p = 0.395). The sensitivity and specificity values for predicting volume responsiveness were highest for PPV, with a sensitivity of 94.4% and a specificity of 70.5%. LVOT-VTI variability also demonstrated high sensitivity (85.0%) but slightly lower specificity (66.6%). Kappa measures of agreement were 0.538 for PPV and 0.463 for LVOT-VTI variability (p = 0.01 and p = 0.003, respectively). Cronbach's alpha indicated the highest internal consistency for PPV (0.728), followed by LVOT-VTI variability (0.656), CF variability (0.568), and VCI distensibility (0.559). (Table-2) LVOT-VTI variability and PPV demonstrated the highest predictive ability for volume responsiveness, with area under the curve (AUC) values of 0.847 (95% CI: 0.726–0.968, p < 0.001) and 0.832 (95% CI: 0.679–0.985, p = 0.001), respectively. CF variability showed moderate correlation (r = 0.36, p = 0.03) with an AUC of 0.754 (95% CI: 0.587–0.921, p = 0.01), while VCI distensibility demonstrated a weaker correlation (r = 0.21, p = 0.20) with a lower AUC of 0.676 (95% CI: 0.495–0.857, p = 0.06). (Table 3) (Fig. 1) ICU mortality was 48.7% (n = 19), and the standardized mortality ratio (SMR) was calculated as 72.4%. Median ICU length of stay (LOS) was 14 days [IQR: 7–26], and median hospital LOS was 29 days [IQR: 7–45].
Conclusions. This study's findings suggest that LVOT-VTI variability is a reliable dynamic indicator for predicting volume responsiveness in critically ill patients, showing superior diagnostic performance compared to VCI distensibility and CF variability.

Introduction. The adult sepsis event (ASE) definition, developed by the U.S. Centers for Disease Control and Prevention (CDC), is an electronic surveillance tool intended to enable consistent sepsis monitoring across various hospital settings. ASE is based on the electronic Sequential Organ Failure Assessment (eSOFA) criteria, which utilize structured electronic health record data to retrospectively detect sepsis for surveillance purposes. Although the eSOFA criteria were developed to be applicable across multiple clinical environments, validation studies to date have focused primarily on inpatient populations. This study aims to apply the eSOFA criteria in the emergency department (ED) setting and evaluate their diagnostic performance compared with the Sepsis-3 SOFA criteria in patients with suspected infection.
Objectives. To assess the diagnostic performance of the ASE-based eSOFA criteria compared to Sepsis-3 SOFA definitions in emergency department patients with suspected infection, and to evaluate the clinical utility of incorporating isolated serum lactate elevation into the eSOFA framework.
Methods. A retrospective review was conducted on patients aged 19 years or older who presented to the emergency departments of three medical institutions from September 1 to September 30, 2023, with suspected infections. Blood cultures were drawn for all enrolled patients (n = 698). Patients were classified according to Sepsis-3

criteria if their SOFA score increased by ≥ 2 points from baseline. eSOFA classifications required concurrent organ dysfunction within two days before or after blood culture collection, defined by criteria such as new vasopressor initiation, new invasive mechanical ventilation, renal or liver function deterioration, thrombocytopenia, or lactate ≥ 2.0 mmol/L. An expanded eSOFA definition included patients with isolated lactate ≥ 2.0 mmol/L. Statistical analyses included calculation of sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), and the area under the ROC curve (AUROC).

Results. Among 698 patients, 456 (65.3%) met Sepsis-3 criteria, 251 (35.9%) met ASE-defined eSOFA, and 340 (48.7%) met expanded eSOFA criteria. Patients fulfilling both SOFA and eSOFA showed the highest mortality (19.8%). Mortality was 19.5% in eSOFA-positive patients, 17.4% in expanded eSOFA-positive patients, and 13.3% in SOFA-positive patients. ASE-defined eSOFA had a sensitivity of 52.0%, specificity of 94.2%, PPV of 94.4%, and AUROC of 0.730. Expanded eSOFA improved sensitivity to 64.3% but reduced specificity to 80.6%, with AUROC 0.720. Mortality increased stepwise with the number of dysfunctional organs across all criteria. Inclusion of lactate alone identified additional high-risk patients missed by SOFA.

Conclusions. Our study shows that eSOFA moderately agrees with Sepsis-3 SOFA in identifying sepsis in the emergency department. Although it identifies fewer patients, those selected by eSOFA have similar or higher mortality, indicating effective detection of high-risk cases. Adding lactate ≥ 2.0 mmol/L increases sensitivity but lowers specificity, requiring careful consideration. eSOFA can be a useful adjunct tool, with lactate use tailored to local resources and patient needs.

Comparison of adult sepsis event (ASE)-defined eSOFA and SOFA (≥ 2) criteria with and without isolate lactate elevation

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000535***.

Introduction. Veno-arterial extracorporeal membrane oxygenation (VA-ECMO) is a life-support therapy that may be used to treat patients with a refractory cardiogenic shock (RCS) [1]. Usually, ECMO implementation is performed under general anesthesia (GA) and requires mechanical ventilation. Unfortunately, complications of mechanical ventilation are well known, such as lung trauma or ventilator-associated pneumonia (VAP) [2,3]. In addition, GA can worsen hemodynamic outcomes in patients that already encounter hemodynamic instability. Awake ECMO implementation is an alternative strategy that may lead to better clinical outcomes [4]. As it is an invasive procedure performed while the patient is still conscious, there are concerns about the psychological disorders and quality of life (QoL) after intensive care unit (ICU) stay. In fact, testimonies show that this technique could leave long-term traumatic memories [5].

The aim of this study was to assess the impact of Awake ECMO procedure on QoL after surviving an intensive care unit (ICU) stay.

Methods. This retrospective cohort study was conducted between the 1st of January, 2020 the 31st of December, 2024 in a single-center cardiac surgery ICU. Consecutive patients over 18 years old who required an ECMO implementation for RCS were included. Data concerning comorbidities, anesthesia strategy during ECMO implementation, ICU stay and outcomes after ICU discharge were collected. Two groups were defined according to anesthesia strategy during ECMO implementation: GA group and Awake group. Data on QoL and psychological disorder after ICU stay were assessed in a face-to-face or telephonic post-ICU consultation, with the Hospital Anxiety and Depression (HAD) scale [6], the Post Traumatic Stress Disorder Checklist for Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (PCL-5) [7] and the Short Form-12 Items (SF-12), split in Physical Component Score (PCS) and Mental Component Score (MCS)[8].

The study was approved by a local Ethics Committee (IRBN532025/CHUSTE).

Results. During study period, 206 patients underwent VA-ECMO (Fig. 1). A total of 45 patients were included. Among the 23 survivors, 13 (57%) were included in the GA group and 10 (43%) in the Awake group. 17 patients (10 in the GA group and 7 in the Awake group) were included in the final analysis after 6 patients were lost to follow-up. The PCS in the Awake group was significantly higher than in the AG group (mean absolute difference = 11.26; p = 0.05). There was no significant difference for other psychological or QoL outcomes. Mortality was similar between the two groups (OR = 1.35; 95% CI [0.41; 4.46]; p = 0.63). There was more VAP in the GA group (p = 0.01).

Conclusions. Awake VA-ECMO implementation did not impact psychological status after ICU stay compared to the GA procedure. Regarding the complications that could be caused by GA, Awake ECMO technique represents a good alternative for RCS therapy.

Introduction. Accurate microbiological documentation seems central for managing severe pneumonia. While the FilmArray® Pneumonia + panel (FA-PP) offers rapid pathogen identification, its effectiveness during antibiotic treatment and in predicting clinical outcomes remains unclear.
Methods. We conducted a prospective observational study across four ICUs from April 2022 to June 2024, including patients with ventilator-associated pneumonia (VAP) or ventilated hospital-acquired pneumonia (vHAP). Bacterial loads were monitored on days 0, 1, 3, 7 and 10 and 3 days after stopping antibiotics, using endotracheal aspirates (ETAs) analyzed by FA-PP and standard cultures. The main objective was to assess the correlation between quantitative changes in FA-PP results and clinical success. Quantitative changes over time were analyzed using mixed ordinal logistic regression.
Results. Of the 93 patients enrolled, 60.2% (n = 56) achieved clinical success, while the ICU mortality rate was 25.8% (n = 24). Although FA-PP and culture quantification results declined over time ($p < 0.0001$), neither method consistently correlated with clinical success (non-significant for both). At diagnosis, FA-PP showed excellent diagnostic performance compared to culture, with a sensitivity of 94% [95% CI: 87–97] and a specificity of 98% [95% CI: 97–98]. Quantitative concordance improved with higher DNA copies, from 22.9% at the culture threshold at 10^4 DNA copies/ml in FA-PP to 100% at $\geq 10^7$ DNA copies/ml. Diagnostic performance remained stable during antibiotic treatment with 94% sensitivity and 95% specificity in follow-up ETAs.
Conclusions. FA-PP provides rapid and accurate diagnostics but does not predict clinical outcomes during treatment, indicating limited utility for repeated testing in patient management.

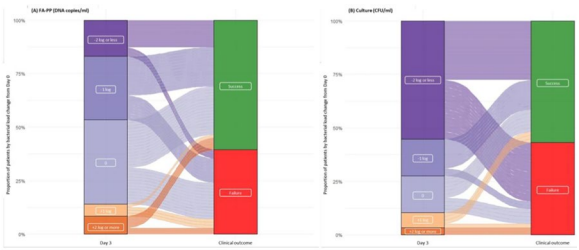

Fig 1 (abstract 000537) Waterfall plot of the greatest change in bacterial load from diagnosis (Day 0) to Day 3 in ICU patients with vHAP/VAP, and their corresponding clinical outcome. (A) Changes in DNA copies/ml quantified by FA-PP in 71 patients. (B) Changes in CFU/ml quantified by conventional culture in 58 patients. Data are derived from Table 2**A.**

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000539***.

Introduction. Acute respiratory distress syndrome (ARDS) represents a significant burden on critical care, accounting for 10.4% of global ICU admissions and substantial mortality (1). Its clinical, radiological, pathological, and biological heterogeneity poses substantial challenges in patient management, including difficulties in treatment selection and patient stratification for clinical trials (2). Identifying reproducible, clinically relevant, and physiologically distinct subphenotypes in ARDS may support personalized strategies in critical care. Previously, we trained a clustering model using a Chilean cohort of patients with ARDS and identified two physiological subphenotypes: Efficient and Restrictive, which differ in clinical characteristics and outcomes.
Objectives. To externally validate the previously described ARDS physiological subphenotypes in an independent patient cohort.
Methods. The original model was trained using Gaussian Mixture Modeling (GMM) in a Chilean cohort of 224 ARDS patients diagnosed according to the Berlin criteria. We externally validated this model by applying the trained GMM to predict subphenotypes in an Amsterdam University Medical Center cohort of 494 COVID-19 ARDS patients. Data preprocessing included data cleaning, harmonization, normalization, encoding, and imputation, following the original modeling pipeline. Physiological variables from the first day of mechanical ventilation were analyzed, and clinical characteristics along with 28-day mortality were compared between the predicted subphenotypes.
Results. The external validation identified two distinct subphenotypes: Efficient (n = 153) and Restrictive (n = 341). Compared to the Efficient subphenotype, the Restrictive subphenotype exhibited a more mechanically restrictive pattern (driving pressure 15.9 vs. 10.7 cmH2O, p < 0.001), less efficient ventilation (Vd/Vt ratio 0.70 vs. 0.60, p < 0.001), and worse oxygenation (PaO2/FiO2 ratio 135.7 vs. 157.8, p < 0.001) (Table 1). The Restrictive subphenotype also had significantly higher 28-day mortality compared to the Efficient group (30.5% vs. 20.9%; p = 0.036), consistent with previous findings from the Chilean cohort (Fig. 1). Notably, this mortality difference was independent of the PaO2/FiO2 ratio, and therefore cannot be fully explained by traditional severity alone.

Table 1 Comparison of key physiological variables and mortality between predicted ARDS subphenotypes.

Variable	Efficient (n = 153)	Restrictive (n = 341)	p-value
Driving pressure (cmH_2O)	10.7 (9.3–12.7)	15.9 (13.8–18.0)	< 0.001
VD/VT ratio	0.595 (0.553–0.656)	0.696 (0.644–0.742)	< 0.001
Mechanical power (J/min)	14.1 (11.5–17.8)	18.8 (15.3–23.3)	< 0.001
PaO_2/FiO_2 ratio (mmHg)	157.8 (122.5–195.0)	135.7 (98.6–165.7)	< 0.001
28-day mortality (n, %)	32 (20.9%)	104 (30.5%)	0.036

Conclusions. The ARDS physiological subphenotypes identified using a clustering model trained in a Latin American population were successfully validated in an independent European cohort. The consistent physiological and outcome profiles across populations confirm the robustness and potential clinical utility of these subphenotypes for ARDS stratification and, possibly, personalized critical care management.

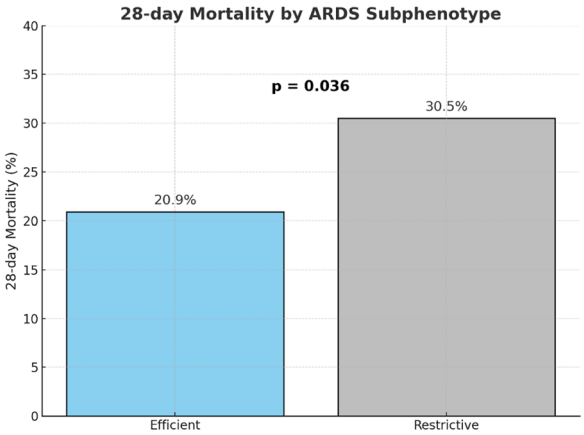

Fig 1 (abstract 000539) Comparison of 28-day mortality between predicted subphenotypes. The Restrictive group showed significantly higher mortality than the Efficient group (30.5% vs. 20.9%, p = 0.036)

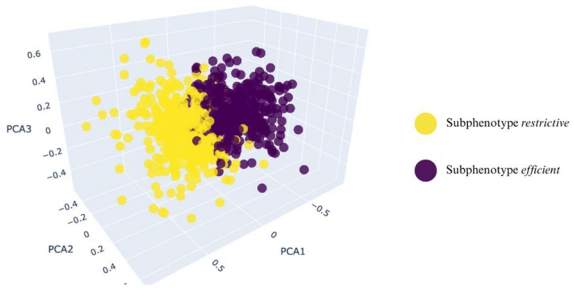

Fig 2(abstract 000539) Projection of patients onto the first three principal components, showing distinct clusters predicted by the trained GMM model

Introduction. Strenuous respiratory effort has been proposed as a second hit in severe acute lung injury, introducing the concepts

of "patient self-inflicted lung injury" (P-SILI) and underassistance myotrauma. The cardiorespiratory physiological effects of non-invasive respiratory support therapies such as continuous positive airway pressure (CPAP) and high-flow nasal cannula (HFNC) remains elusive.
Objectives. Here we investigated the effects of CPAP and HFNC on respiratory effort, expiratory muscle load, lung edema, right ventricular ejection, systemic inflammation, and lung & respiratory muscles injury in experimental P-SILI.
Methods. Lung injury was induced in Sprague Dawley rats through surfactant depletion (saline lavage), followed by three hours of unsupported (2L/min, positive control) or supported ventilation (CPAP 6 cmH2O, HFNC 4L/min, and protective mechanical ventilation [MV, negative control] groups), all of them with FIO2 1. Subjects were sequentially assessed through conventional ICU monitoring, arterial blood gases, esophageal manometry, surface electromyography (sEMG) on rectum abdominis muscle, lung and diaphragm ultrasound, and transthoracic echocardiography. Multiplex analysis and H&E histopathological assessment were carried out to study systemic inflammatory response, and damage on lungs, diaphragm, and intercostal muscles, respectively.
Results. Compared against the positive control group, all respiratory support therapies improved oxygenation at the end of the study, but only the CPAP and MV groups resulted in lower: 1) PaCO2, 2) respiratory effort (ΔPes) and work of breathing; 3) sEMG expiratory muscle activation; 4) ultrasound diaphragm excursion; and 5) pulmonary artery respiratory variability. Furthermore, intragroup analysis showed that CPAP also reduced respiratory rate and lung edema in the long run. In contrast, HFNC group increased the diaphragm excursion and lactate over time. Mortality occurred in unassisted (3/10) and HFNC groups (2/11). Only MV resulted in lower plasma chemokine growth-regulated protein alpha (GRO-alpha) than the unsupported group, without differences in any other cytokine. In morphological assessment, all respiratory support therapies prevented lungs (inflammation, vascular, airway and alveolar epithelial injury), diaphragm, and intercostal muscles injury (muscles inflammation, nuclei misposition, fragmentation, and necrosis) compared to the unassisted group, with MV showing the highest injury protection and HFNC, the lowest.
Conclusions. CPAP is more effective than HFNC in reducing respiratory effort, work of breathing, expiratory muscle activation, and cyclical vascular on–off flow, in experimental P-SILI. However, both therapies are helpful in preventing tissue injury and improving oxygenation. Interestingly, underassistance myotrauma also occurs in accessory respiratory muscles, not just the diaphragm.

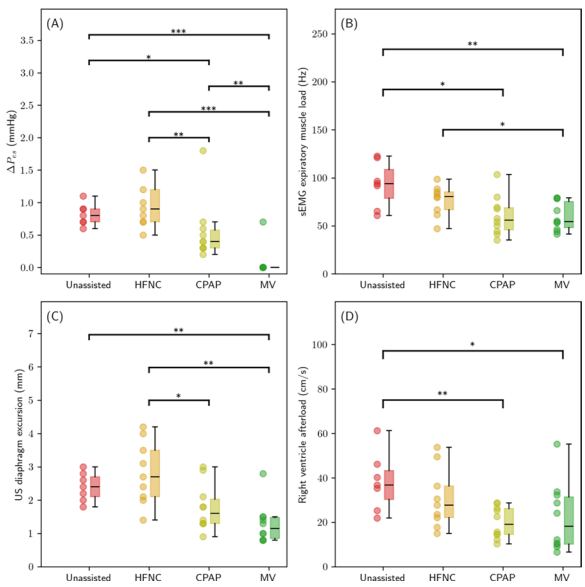

Fig. 1 (abstract 000540) Intergroup comparisons at the end of the study of the following parameters: respiratory effort (A), expiratory muscle activation (B), diaphragm excursion (C), and pulmonary artery respiratory variability (D). ΔPes = swing of esophageal pressure; sEMG = surface electromyography; US = ultrasound. * p value < 0.05; ** p value < 0.01; *** p value < 0.001

Diaphragmatic thickening velocity and weaning outcome: a pilot study

AA. Menis[1]; V. Tsolaki[1]; ME. Papadonta[1]; V. Vazgiourakis[1]; M. Konstantinos[1]; E. Zakynthinos[1]; D. Makris.[1]

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000542***.

Introduction. Diaphragmatic dysfunction has been implicated with weaning failure. The velocity of diaphragmatic contraction (Dcv) has been evaluated using multiple modalities to predict the weaning outcome. However, the velocity of diaphragmatic thickening (Dtv) has not. Dtv is calculated as the ratio of diaphragmatic thickening to inspiratory time.
Objectives. Our hypothesis is that Dtv could differentiate weaning success from weaning failure and have better correlations with esophageal pressure and esophageal pressure–time product than Tfdi.
Methods. Fifty-six patients were enrolled in the study. Inclusion criteria were readiness for weaning from mechanical ventilation, as assessed by the treating physician according to published criteria, and first weaning attempt. Weaning failure was defined as a spontaneous breathing trial failure and/or need for reintubation and mechanical ventilation at 48 h. During an unassisted SBT we performed diaphragmatic sonography, peak-inspiratory thickness (Dtpi) and end-expiratory thickness (DTee), and simultaneous measurements of esophageal pressure swings (ΔPes). Diaphragmatic thickening velocity (DTv) was calculated as [peak inspiratory thickness(Dtpi) – end expiratory thickness (DTee)]/inspiratory time. Diaphragmatic thickening fraction was also calculated [(Dtpi – Dtee)/ Dtee]. The ultrasound operators were blinded to the outcome of weaning and the pressure measurements. The treating physicians were blinded to the ultrasound and pressure measurements.
Results. Twenty-eight patients succeeded weaning. Patients succeeding weaning displayed higher values of DTv [0.36 cm/sec (± 0.15) vs 0.25 cm/sec (± 0.13), p = 0.004)] and ΔPes [9.19 cmH2O (7.14–11.98) vs 5.66 cmH2O (4.45–10.38), p = 0.026]. Tfdi had no difference between weaning success and failure (p = 0.224). DTv correlated with ΔPes (rho = 0.30, p = 0.035) (Fig. 1.) while Tfdi did not (p = 0.317). There

were no differences in sex, age, APACHE II or reason of intubation. Successfully weaned patients were ventilated for fewer days than failure patients (8.5 (4–14.5) vs 14 (11–18), p = 0.019).
Conclusions. The main finding of this study is that DTv differed between weaning success and failure. Moreover, it was correlated, albeit weakly, with ΔPes. Our reasoning behind the fact that DTv has a better performance than Tfdi in assessing breathing effort, is that DTv does not assess the thickness per se of the muscle but rather, the velocity of its thickening. As the muscle contracts, it thickens and consequently it shortens. The velocity of shortening has been correlated with the produced work and inversely correlated with the opposed load. Thus, DTv has an improved correlation with weaning and breathing effort when compared with Tfdi.

Relationship between diaphragmatic thickening velocity and esophageal pressure

Prediction of the Severity Level of Extravascular Lung Water Index in Septic Shock Patients

Q. Nguyen[1]; HHQ. Nguyen.[2]
[1]ICU A9, Bach-mai Hospital, Hanoi, Vietnam; [2]ICU A9, Bach Mai Hospital, Hanoi, Vietnam.

Intensive Care Medicine Experimental, 2025;**13(1)**: 000543.

Introduction. In septic shock, increased pulmonary vascular permeability can lead to acute lung injury and ARDS, affecting fluid resuscitation, optimal hemodynamics, and tissue perfusion, which ultimately increases mortality and complications. The extravascular lung water index (EVLWI) in the PICCO hemodynamic monitoring system can be used to evaluate pulmonary permeability.
Objectives. We conducted a study to assess the EVLWI for predicting the severity level in septic shock treatment.
Methods. Patients with septic shock, defined according to Sepsis-3 criteria (hypotension requiring vasopressor support, lactate > 4 mmol/L), aged over 18 years, were included and monitored using the PICCO system to measure EVLWI. Exclusion criteria included patients with heart shunts, valvular heart disease, or those who had undergone lung resection. EVLWI measurements were taken at the time of PICCO placement, and at 24 h, 48 h, and 72 h. Results were compared between the survivor and non-survivor groups.
Results. A total of 31 patients were included in the study, of which 16/30 (51.6%) were survivors, and 15/30 (48.4%) were non-survivors. Causes of septic shock included pneumosepsis (45.2%), abdominal sepsis (22.5%), urosepsis (12.9%), biliary sepsis (12.9%), and unknown origin sepsis (6.5%). At the time of admission, EVLWI did not show significant differences between the two groups, with the survivor group having an average of 13.94 ± 6.55 and the non-survivor group 11.67 ± 4.48. However, after 72 h of treatment, EVLWI significantly decreased in the survivor group (10.81 ± 3.35, p < 0.05) compared to the non-survivor group (14.07 ± 7.03). At 72 h, patients with an EVLWI value between 0–10 had a lower mortality rate of 35.2%, compared to those with an EVLWI > 10, who had a mortality rate of 64.2%. The cut-off value for EVLWI > 10.5 ml/kg at 72 h showed a mortality prediction for septic shock with a sensitivity of 60% and specificity of 69%.
Conclusions. In septic shock patients, the EVLWI index showed statistically significant differences between survivors and non-survivors at 72 h. An EVLWI value greater than 10.5 ml/kg at 72 h is a reliable predictor of mortality with a sensitivity of 60% and specificity of 69%.

Impact of levosimendan on outcome as adjunct to standard therapy in ARDS patients supported with VV-ECMO—a retrospective observational study

F. Kraft[1]; JG. Prokop[1]; P. Opfermann.[1]
[1]Medical University of Vienna, Department of Anaesthesia, Intensive Care Medicine and Pain Medici, Medical University of Vienna, Vienna, Austria.
Correspondence: J.G. Prokop.
Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000545***.

Introduction. Acute respiratory distress syndrome (ARDS) is associated with high mortality. In severe cases, venovenous extracorporeal membrane oxygenation (VV-ECMO) is employed when conventional therapies fail. [1,2] Right ventricular injury (RVI) can further worsen prognosis, even under ECMO support. [3,4] Levosimendan, a calcium sensitizer with inotropic and vasodilatory properties, may enhance right ventricular function and reduce pulmonary artery pressure without increasing myocardial oxygen consumption.[5,6] However, its impact on clinical outcomes in ARDS patients supported with VV-ECMO remains unclear.[6].
Objectives. The primary objective was to assess whether the administration of levosimendan is independently associated with improved ICU and 90-day survival in ARDS patients treated with VV-ECMO. Secondary objectives included evaluation of catecholamine-free days (CFD) and ventilator-free days (VFD) within 28 days of ECMO initiation.
Methods. We conducted a retrospective observational study including adult patients with ARDS treated with VV-ECMO (> 24 h) between January 2014 and October 2024. Patients who received levosimendan as an adjunct to standard care to prevent right ventricular dysfunction were allocated to the treatment group; all others served as controls. Patients bridged to lung transplantation were excluded. CFD and VFD were compared using the Mann–Whitney U test. We performed a multiple logistic regression for ICU and 90-day mortality adjusted for SAPS II, SOFA score at ECMO initiation, BMI, sex, and duration of mechanical ventilation prior to ECMO.
Results. A total of 169 patients (mean age 52 ± 13 years; 69% male) were included, of whom 62 received levosimendan. COVID-19 was the underlying cause of ARDS in 51%. Baseline SAPS II (38 [33–43] vs. 38 [32–47]) and SOFA scores (8 [7–9] vs. 8 [7–10]) were comparable between groups. ICU mortality was 50% in the levosimendan group and 46% in controls; 90-day mortality was 52% vs. 48%, respectively. Levosimendan was not significantly associated with ICU mortality (OR 1.33; 95% CI 0.65–2.73; p = 0.44) or 90-day mortality (OR 1.33; 95% CI 0.66–2.56; p = 0.46). Kaplan–Meier analysis of 90-day survival showed no significant difference. Median CFD (6 [0–17] vs. 7 [0–18]; p = 0.49) and VFD (0 [0–0] vs. 0 [0–1]; p = 0.49) did not differ significantly. Utilization of adjunctive therapies prior to ECMO—prone positioning (82% vs. 80%), inhaled nitric oxide (58% vs. 58%), and neuromuscular blockade (52% vs. 42%)—was similar in both groups.
Conclusions. In this retrospective cohort of patients with severe ARDS requiring VV-ECMO, levosimendan administered as an adjunct to standard care was not associated with improved ICU or 90-day survival. Furthermore, no differences were observed in catecholamine-free or ventilator-free days.

Combined diaphragmatic and rectus femoris ultrasound for predicting weaning outcomes in mechanically ventilated ICU patients: a prospective observational study abstract

F. Chongyan[1]; J. YUH[1]; M. Limei[1]; F. Hui[1]; Z. Jianjun.[1]
[1]Department of Emergency and Critical Care Medicine, Second Affiliated Hospital, Soochow University, Su Zhou Shi, China.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000546***.

Introduction. ICU patients frequently experience rapid loss of muscle mass and function during hospitalization, leading to weaning difficulties[1]. Ultrasound has become a promising bedside tool for real-time muscle function assessment due to its practicality[2, 3]. This study aimed to systematically characterize temporal changes in diaphragm and peripheral muscles (rectus femoris) in mechanically ventilated patients using ultrasound monitoring, analyze their correlations, and explore their association with mechanical ventilation weaning success.
Methods. This prospective observational study enrolled mechanically ventilated patients from a tertiary hospital ICU. Ultrasound measurements of rectus femoris thickness (RFT), rectus femoris cross-sectional area (RFCSA), and diaphragmatic thickening fraction (DTF) were recorded on days 1, 3, 5, 7, and at extubation day. Day 1 RFT and RFCSA served as baseline to calculate variation rates at subsequent timepoints. Correlations between muscle parameters and weaning outcomes were analyzed. The predictive performance of single and combined indicators was evaluated.
Results. 73 patients were included (median age 73 years, range 28–91; 30.43% female). Rectus femoris ultrasound parameters showed significant positive correlations with DTF at all timepoints ($r > 0.50$, $P < 0.05$). The failed weaning group exhibited: significantly higher RFT variation rates (day 3: 13.55% ± 11.78% vs. 9.02% ± 7.67%; day 5: 18.28% ± 14.43% vs. 11.32% ± 7.05%; day 7: 26.40% ± 14.88% vs. 12.38% ± 6.70%; extubation day: 28.30% ± 15.88% vs. 13.56% ± 7.10%; $P < 0.05$). Significantly higher RFCSA variation rates (day 3: 13.38% ± 10.46% vs. 6.91% ± 9.31%; day 5: 19.16% ± 14.80% vs. 10.48% ± 6.46%; day 7: 24.29% ± 12.52% vs. 12.33% ± 5.06%; extubation day: 26.31% ± 14.72% vs. 14.36% ± 6.01%; $P < 0.05$). Significantly lower DTF at all timepoints (day 1: 18.68% ± 4.63% vs. 27.88% ± 6.24%; day 3: 17.72% ± 3.69 vs. 27.82% ± 5.99%; day 5: 16.19% ± 5.25% vs. 27.14% ± 6.55%; day 7: 15.84% ± 5.99% vs. 25.26% ± 5.91%; extubation day: 14.34% ± 6.01% vs. 29.31% ± 6.13%; $P < 0.05$). ROC analysis revealed optimal predictive performance for RFCSA variation rate ($AUC = 0.869$, $P < 0.05$) and DTF ($AUC = 0.892$, $P < 0.05$) at extubation day. Combined use improved AUC to 0.926 ($P < 0.05$).

Conclusions. Ultrasound assessment of the rectus femoris reflects diaphragmatic function and expands respiratory muscle monitoring strategies. Rectus femoris thickness and cross-sectional area changes, when combined with diaphragmatic ultrasound, enhance the reliability of predicting weaning outcomes, providing stronger clinical evidence for extubation decisions.

Introduction. Cerebral hemodynamics assessed by transcranial color Doppler (TCCD) ultrasonography is frequently altered in critically ill patients experiencing circulatory shock, showing impaired cerebral autoregulation [1], decreased estimated cerebral perfusion pressure (eCPP) [2] and increased pulsatility index (PI) [3]. While a recent study investigated individualized hemodynamic management guided by TCCD-PI in patients with sepsis-induced encephalopathy [4], the effect of a second-line vasopressors on TCCD ultrasonography has poorly been explored in patients with refractory shock.
Objectives. To assess the changes in TCCD before and after the introduction of a second-line vasopressor in critically ill patients with refractory shock.
Methods. This was a single-center prospective ongoing registry, conducted at the ICU of the HUB (Brussels, Belgium). We included adults with refractory shock undergoing second-line vasopressors, admitted between May 2024 and February 2025, with a complete TCCD at all the timepoints; TCCD was used to assess mean flow velocity (MFV), PI, resistivity index (RI), and eCPP [calculated as = mean arterial pressure (MAP) x (end diastolic velocity (EDV)/MFV) + 14] [4] in the proximal portion of the right middle cerebral artery right before (T0) and at 6 and 24 h after the initiation of the vasopressor.
Results. We enrolled 13 patients, 5 treated with vasopressin and 8 with angiotensin-II; 84.6% were males and mean age was 62 ± 16 years. A significantly higher number of patients with eCPP > 60 mmHg was observed in the angiotensin-II group (p = 0.014) at 6 h (Table 1). Repeated measures Linear Mixed Model analysis showed a significant main effect of time on both norepinephrine dose (p < 0.001) and angiotensin-II dose (p < 0.001) (Fig. 1). No other significant differences in other TCCD-derived parameters were observed (Fig. 2). Possible confounders (sodium, PaCO2 and temperature) were also assessed, and showed no significant main effect for time or group.

Table 1 (abstract 000547) Clinical presentation and outcomes in the two groups.

	Vasopressin (5 patients)	Angiotensin-II (8 patients)	*p-value**
Type of shock: [1]			0.39
Septic	2 (40)	5 (62.5)	
Cardiogenic	1 (20)	0 (0)	
Septic + cardiogenic	0 (0)	1 (12.5)	
Other vasoplegic	2 (40)	2 (25)	
T0-APACHE II [2]	23.6 ± 11.4	27.7 ± 6.1	0.82
T0-SOFA Score [2]	13.2 ± 4.4	12.6 ± 4.2	0.94
T0-eCPP > 60 mmHg [1]	2 (40)	3 (37.5)	0.93
6h-eCPP > 60 mmHg [1]	0 (0)	6 (75)	*0.014*
24h-eCPP > 60 mmHg [1]	1 (20)	2 (33.3)	0.62
T0-PI < 1.1 [1]	1 (20)	3 (37.5)	0.5
6h-PI < 1.1 [1]	1 (25)	6 (75)	0.098
24h-PI < 1.1 [1]	1 (20)	2 (33.3)	0.62
T0-RI < 0.75 [1]	3 (60)	5 (62.5)	0.93
6h-RI < 0.75 [1]	3 (75)	8 (100)	0.14
24h-RI < 0.75 [1]	3 (60)	5 (83.3)	0.39

1- n. (%).
2- Mean ± S.D.
*- Significant if p < 0.05.

Conclusions. With the limits of our small sample, the administration of angiotensin-II was associated with a higher eCPP in critically ill patients with refractory shock and requiring a second-line vasopressor.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000548***.

Introduction. Patients hospitalized in ICU, require pulmonary physiotherapy (PPh), aiming to enhance the patient's functional capacity and to improve respiratory independence. In our center this normally consists of intrapulmonary percussive ventilation (IPV). Sudden fluctuations in pulmonary ventilation and pulmonary perfusion may cause changes in PCO2 values. Sudden decreases in PCO2 can cause impaired coronary flow and decreased cerebral perfusion.

Objectives. A pilot study to compare transcutaneous CO2 (tCO2) values to values in arterial blood gas (aCO2) and end tidal CO2 (ETCO2) before and after PPh. To study the effect on CO2 during PPh in mechanically ventilated patients using continuous TCO2 measurement, fluctuations which normally go unmeasured.

Methods. Using the SENTEC continuous CO2 measurement, it is possible to measure CO2 transcutaneously during IPV sessions. Comparison with PCO2 from the arterial blood gas (aCO2) and measured end tidal CO2 (ETCO2) took place both pre- and post-PPh. All patients studied were sedated and on IPPV (intermittent positive pressure ventilation) without spontaneous breathing. Measurements took place 15 min pre-PPh, immediately post-PPh and 15 min after PPh. CO2 was measured transcutaneously during the whole PPh procedure (tCO2). All measured values are given in mmHg.

Results. 15 patients with differing reasons for admission were included, all on IPPV. One patient was excluded because he demonstrated spontaneous breathing during PPh. In the remaining 14 (8 male, mean age 67,6 years) mean FiO2 was 0.41, mean PEEP was 8. Looking at all values before and after the PPh sessions together, mean aCO2 was 40.1 (SD = 6.81), mean tCO2 was 42.4 (8.24) and mean ETCO2 was 30.4 (7.10). TCO2 was more strongly correlated to aCO2 ($r = 0.928$, $p < 0.001$) than ETCO2 ($r = 0.724$, $p < 0.001$). Mean difference between aCO2 and tCO2 was 2.3 (3.17); for aCO2 and ETCO2 this was 9.73 (5.18), ($p < 0.001$). During PPh, mean difference from baseline (at initiation of PPh) to maximum value measured tCO2 during PPh was 5.28 (5.61) ($p = 0.002$), with a range from 0.00 to maximum 22.2. Mean baseline to minimum measured tCO2 during PPh was 4.46 (3.05) ($p < 0.001$) with a range from 0.00 to 8.7. Mean difference from baseline to end value, at cessation of PPh, was 2.33 (3.94), from 4.7 higher to 8.7 lower. The mean range (highest to lowest during PPh) was 9.74 (5.85), minimum 5.00, to a maximum of 28.6.

Conclusions. The correlation between aCO2 and tCO2 is very robust, stronger than with ETCO2. TCO2 measurement proved feasible during PPh and significant changes in TCO2 were measured during PPh, reflecting significant changes in PCO2, which can have particular importance in patients vulnerable to changes in CO2, such as those with neurotrauma or acute brain injury. TCO2 measurement, because of its immediacy, may have added value in steering PPh and other manoeuvres, such as ventilation after intubation, in these patient populations.

Correspondence: F.W. Hiemstra.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000549***.

Introduction. Circadian rhythms are severely disrupted in patients in the intensive care unit (ICU), which has been associated with poor clinical outcomes[1,2]. Feeding is one of the most important regulators of the circadian clock. A potential contributor to the circadian disruption in the critically ill is therefore the fact that enteral nutrition during ICU stay is worldwide administered 24 h a day. Rhythmic feeding-fasting cycles may provide a potent synchronizing cue for the circadian clock, suggesting that optimalization of feeding-fasting cycles in the ICU might strengthen or restore circadian rhythms[3].

Objectives. The CIRCLES study aims to investigate the impact of cyclic daytime enteral nutrition versus continuous enteral nutrition on circadian rhythms in critically ill patients.

Methods. This investigator-initiated non-blinded randomized controlled trial was conducted in a tertiary care ICU. Patients with an expected ICU stay > 48 h who are receiving or intended to receive enteral nutrition were eligible for inclusion. Patients were randomized to receive either continuous enteral feeding (standard of care) or cyclic enteral feeding during daytime hours (between 8 AM to 8 PM). Similar nutritional targets were prescribed in both groups, and standard of care protocols regarding glucose regulation and treatment of glucose intolerance were followed. Primary outcomes were amplitude of 24-h rhythms in core body temperature, mean blood pressure and heart rate (variability) as determined with cosinor analysis on day 3–4 after the initiation of enteral nutrition. Secondary study outcomes include average glucose levels, insulin requirements, caloric intake and gastric residual volumes. The primary and secondary outcomes were compared between the two study groups using a Student's t-test, or a Mann–Whitney U-test for non-normally distributed data. Data are presented as means with standard deviations, or as medians with interquartile ranges when the data are not normally distributed.

Results. A total of 85 patients were included in the study, of whom 62 completed follow-up until study day 3—4. Baseline characteristics of the included patients are presented in Table 1. The amplitude of 24-h rhythms in core body temperature, heart rate, mean arterial pressure, and heart rate variability—measured by SDNN and RMSSD—was consistently higher in the cyclic feeding group compared to the continuous feeding group, although these differences did not reach statistical significance (Fig. 1). Daily caloric intake per kilogram body weight was comparable between groups, with patients in the continuous feeding group receiving 20.38 ± 5.20 kcal/kg/day and those in the cyclic group 18.25 ± 6.39 kcal/kg/day (p = 0.12). Mean gastric residual volume per measurement was significantly elevated in the cyclic group (88.47 [68.64—107.75] mL) compared to the continuous group (58.21 [26.02—96.75], p < 0.05) Time-weighted average blood glucose levels were marginally but significantly higher in patients receiving cyclic feeding (9.28 ± 1.59 mmol/L) than in those receiving continuous feeding (8.57 ± 0.96 mmol/L, p < 0.05). No significant difference was observed in daily insulin administration, with average doses of 19.26 [0.00–63.38] units/day in the continuous group versus 15.60 [0.00–50.70] units/day in the cyclic group (p = 0.89).
Conclusions. Amplitudes of 24-h rhythms in vital signs were numerically higher on study day 3 to 4 in patients randomized to the cyclic daytime feeding group compared to the continuous feeding group, although these differences were not statistically significant. Cyclic feeding during daytime hours was safe and feasible. Further research is required to support its use as a possible intervention to strengthen circadian rhythms in the ICU, and to determine whether circadian rhythm enhancement translates into improved clinical outcomes.

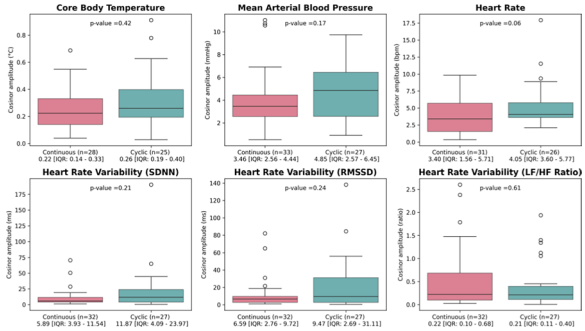

Fig 1 (abstract 000549) Cosinor amplitudes of vital signs on study day 3 to 4. Data are presented as median and interquartile range, and groups are compared with a Mann–Whitney U test.

Complementing capillary refill: splenic Doppler for dynamic perfusion monitoring in septic shock

S. Beltramino[1]; D. Carbone[1]; MF. Coñequir[1]; GM. Gaudenzi Acuña[1]; A. Manchado Bruno[1]; JM. Rojas Salgado.[1]

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000550***.

Introduction. Septic shock is still associated with high mortality. As part of the treatment, early resuscitation is often guided by clinical parameters such as capillary refill time (CRT), but its reliability is limited by interobserver variability and clinical factors such as vasopressor use or edema. While splenic Doppler ultrasound has shown utility in detecting occult hemorrhagic shock, its role in septic shock remains unexplored. This study evaluates splenic perfusion using Doppler ultrasound, specifically the splenic velocity–time integral (s-VTI), as a complementary tool for visceral perfusion assessment.
Methods. This is a preliminary report of a prospective observational study including adult patients with septic shock. Splenic Doppler measurements (Fig. 1), including s-VTI and splenic resistance index (s-RI), were performed using a sector probe at ICU admission (0 h), 3 h, 6 h, and every 24 h thereafter until shock resolution (defined as 24 h without vasopressors), death, or day 7. CRT was assessed on the distal phalanx of the index or great toe after 10 s of compression. We also include 30 healthy controls for splenic Doppler measurements and then we defined a cut off s-VTI < 22 cm to detect splenic hypoperfusion, based on the 10th percentile.
Results. We include 13 patients, with a median age of 69 years. The median value of SOFA was 12. 23,08% had reduced ejection fraction, 46,15% were on mechanical ventilation, and 53,85% needed renal replacement therapy. At admission, septic patients exhibited significantly lower s-VTI than controls (17.2 vs. 31 cm; p < 0.001). Among survivors, s-VTI increased by 107.9%, reaching normalization at shock resolution (31.75 cm; p < 0.001). Non-survivors maintained persistently low values (15.5 and 16.7 cm) (Fig. 2). s-RI showed limited clinical value, with minor changes after resuscitation (0.68 baseline vs. 0.60 final) but remained elevated compared to controls (0.49; p < 0.001) (Fig. 3).
CRT was prolonged in 85% at admission and normalized in 91% of survivors. In those with both abnormal CRT and s-VTI, s-VTI recovered first in 4 patients, CRT in 1, and both simultaneously in 4. Recovery occurred at 38 h for s-VTI vs. 43 h for CRT. At the final observation point, the correlation between s-VTI and CRT was moderate (ρ = -0.63; p = 0.02), while that between s-RI and CRT was weak (ρ = -0.12; p = 0.69).
Conclusions. Improvement in splenic perfusion, as assessed by s-VTI was associated with clinical outcome and recovery from septic shock,

detecting visceral perfusion changes as early as, or even earlier than, CRT. s-RI lacked clinical utility in this setting. The moderate correlation between s-VTI and CRT may reflect the heterogeneity of perfusion and vasoplegia in septic shock. This finding could provide new insights into the evaluation of different hemodynamic phases. The combination of s-VTI and CRT in a protocol for guided resuscitation may be useful in the management of septic shock, by helping to restore perfusion and minimize potential harm.

Trauma code protocol in a tertiary center in Cantabria (Spain)

M. López Sánchez[1]; MA. Ballesteros Sanz[1]; MC. Fariñas Alvarez[2]; M. Andrés Gómez[3]; MI. Rubio Lopez.[1]
[1]Intensive Care Unit, Marqués de Valdecilla University Hospital, Santander, Spain; [2]Quality Service, Marqués de Valdecilla University Hospital, Santander, Spain; [3]Emergency Service, Marqués de Valdecilla University Hospital, Santander, Spain.

Intensive Care Medicine Experimental*, *2025*;13(1)**: ***000551.

Introduction. Trauma is a major cause of morbidity and mortality. Actually, Trauma Code Protocol (TCP) has become standard of care at most tertiary care centers, but it can lead high rates of overtriage. Cantabria, in the north of Spain, has a population of 593.386 inhabitants. From April 1, 2022 we have implemented TCP in our hospital.
Objectives. To describe epidemiology, severity scores, and mortality in trauma patients with activated TCP or not.
Methods. This retrospective and descriptive single-center study was performed between January 1, 2024 to December 31, 2024. The study participants were trauma patients admitted to a Trauma Intensive Care Unit (ICU) in a tertiary center in Cantabria (Spain). The Trauma Code was classified as Yellow (12 criteria) and Red (6 criteria) based on ATS criteria. It was activated by the on-call intensivist, with a call from the Out-of-Hospital Emergencies or Emergency Service.
Epidemiological data, Injury Severity Score (ISS), and RTS (Revised Trauma Score) were collected in TCP patients and non-TCP.
Results. A total of 221 trauma patients were admitted to the ICU (34,9% of total admissions). Number of TCP activations were 520. A total of 121 TCP (63 Red and 58 Yellow) were admitted to the ICU (54,7% of trauma patients and 42,5% of all activations). Main source of Yellow TCP was Emergency Service (75,8%). These patients had an average age of 57,2 years (19–81), 20,6% were women, with an average ISS of 22,6 (9–75), RTS 6,2 (5,58–7,84), use of mechanical ventilation in 15,5%, and a mortality rate of 1,7% (1 patient). Main source of Red TCP was Out-of-Hospital Emergencies "061" (84,1%). These patients had an average age of 48,8 years (17–87), 14,2% were women, with an average ISS of 24,3 (1–75), RTS 6,4 (1,02–7,84), use of mechanical ventilation in 52,3%, and a mortality rate of 7,9%(5 patients). Overall mortality in TCP was 4,9%.
TCP was not activated (non-TCP) in 100 patients with an average age of 57 years (17–89), an average ISS of 23,2 (1–75), RTS 7 (6,084–7,84), use of mechanical ventilation in 36%, and a mortality rate of 12% (12 patients).
Conclusions. Mortality was lower in TCP than in non-TCP. Although mortality in Yellow TCP was lower than in Red TCP, both were low. In TCP and non-TCP similar ISS and RTS scores were collected.

Intensive Care Medicine Experimental*, *2025*;13(1)**: ***000552.

Introduction. The patient autonomy, as a prevailing tenet of medical ethics [1], and the notable escalation in the utilization of life-sustaining therapies [2] have raised the issue of withholding or withdrawing treatments in end-of-life care. However, the financial costs and workforce burden of potentially inappropriate therapies (PITs) persist as a significant burden, particularly in countries where ambiguities surrounding the withdrawal or withholding of such therapies remain, including Turkey.
Objectives. To ascertain the incidence as well as the financial and workforce costs of PITs.
Methods. The study was conducted between 12/01/2024 and 03/28/2025, following ethics committee approval (date:11/19/2024, IRB no.2785). The hypothetical decision for PITs was based on at least one of four criteria, in addition to a baseline criterion outlined in Table 1. Financial and workforce costs were calculated by comparing expenses from the date of the PITs decision to discharge, against the total hospitalization cost.

Table 1 (abstract 000552) Identification of PITs.

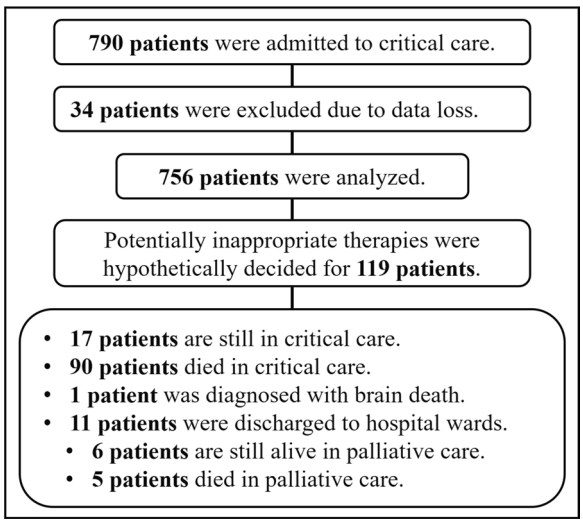
A	**The patient's attending physician has determined that the treatment is no longer in the patient's best interest [3,4]**
B.1	The treatments only prolong the dying process instead of achieving the intended therapeutic goals [5–8]
B.2	No reasonable expectation that the patient will recover sufficiently to survive outside the acute care setting [9,10]
B.3	Presence of severe irreversible neurological damage or persistent vegetative state [5–8,10]
B.4	Death is considered unavoidable for the patient [8]

Results. A total of 756 patients were analyzed and 119 were identified as receiving PITs (Fig. 1) with an incidence of 15.7%. The financial burden of these patients amounted to €442,291.87, constituting 25.0% of the total cost (Fig. 2). The total number of hospitalization days was 8,858, while it was 3,319 days after the PITs decision, with a proportion of 37.5%. The PITs depicted in Table 2.

Table 2 (abstract 000552) Workforce cost of PITs.

Potentially inappropriate therapies			
	Day(s)/ count(s)/ session(s)		***Count(s)/unit(s)***
Mechanical ventilation	1991	Blood sampling	310
Cardiopulmonary resuscitation	132	Urine sampling	140
Continuous renal replacement therapy	64	Tracheal aspirate sampling	177
Paracentesis	6	Tissue sampling	45
Vasopressor therapy	889	X-ray	237
Central venous catheterization	105	Magnetic resonance imaging	12
Conventional hemodialysis	12	Computed tomography	64
Thoracentesis	1	Ultrasonography	5
Percutaneous endoscopic gastrostomy	10	Decubitus debridement	6
Gastroscopy/ Colonoscopy	3	Tracheostomy	2
Percutaneous biliary drainage	1	Ventricular shunt surgery	1
Amputation	1	Blood product transfusion	200

Conclusions. An approach is recommended for the decision of withholding or withdrawing the PITs, with the involvement of patients and families to safeguard patients' best interests while ensuring the efficient allocation of health resources.



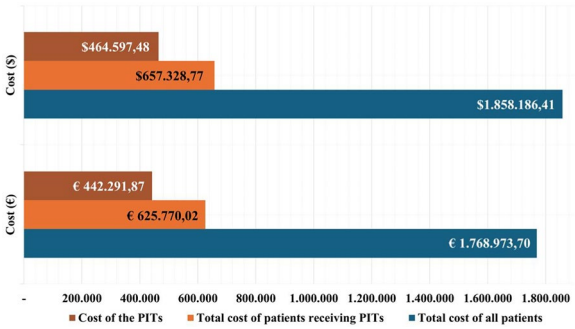


Fig 1 (abstract 000552) Flowchart of the study

The conversion of the euro and the dollar was based on the average exchange rates from the Central Bank of the Republic of Turkey during the period under study (1 € = 37,70 ₺, 1 $ = 35,89 ₺).Abbreviations: PITs, potentially inappropriate therapies.
Fig. 2. Cost analysis of the patients.

Introduction. The heart transplant patient is susceptible to infection due to immunosuppression. There is a need to clarify microbiological

patterns in the preservation fluid and explore their relationship with early infection events in the recipient patient.
Objectives. The objective of this study is to analyze the early infection of the graft and its relationship with the infection of the preservation fluid.
Methods. This is a retrospective study that analyzes the data of 86 donors with their respective recipients from December 2019 to May 2024. Clinical data, all available cultures of preservation fluids, pre-transplant donor cultures and recipient cultures during the postoperative period in the intensive care unit were analyzed.
The heart was stored in a bag immersed in Custodiol® preservation liquid and surrounded by ice to maintain a temperature of 4ºC during cold ischemia time for transport. Two samples of preservation fluid were sent for culture.
Results. The prevalence of positive cultures of preservation fluid was 55.8% (48/86). The frequencies of microorganisms isolated in the preservation fluid are shown in table and Fig. 1. 8.3% (4/48) of the preservation fluid samples were polymicrobial, and 13 (27%) were positive for at least one high-risk pathogen. The most common single-agent isolated pathogens were Staphylococcus epidermidis (44%), Staphylococcus aureus methicillin-sensitive (19%) and propionibacterium acnes (19%). No multidrug-resistant pathogens were found in our series. We did not find in our series infections of the receptor related to the preservation fluid infection.
Conclusions. Despite the high incidence of positive cultures of the preservation fluid, the rate of related infection is 0. In other studies with a higher volume of patients, the average of related infections is around 1%. This makes us, as many authors recommend, consider the profitability of stopping the cultures of preservation fluid in our center.

Introduction. To compare in-hospital mortality estimated by the STABLE scale (Stratification Risk Analysis in Bridging Patients to Lung Transplant on ECMO) (1) in patients admitted to the Intensive Care Unit (ICU) receiving extracorporeal membrane oxygenation (ECMO) support as a bridge to lung transplantation (BLT).
Methods. Retrospective study (2021–2024) including patients admitted to ICU who received ECMO support as BLT in a tertiary hospital with a lung transplant volume > 50/year. ICU stay was defined as the sum of pre and post-lung transplant days, and real in-hospital mortality as death between the first hospitalization day to hospital discharge. Predicted in-hospital mortality was estimated by the STABLE scale, with data obtained from the electronic medical record. Categorical variables: % (absolute value) and quantitative variables: mean ± ds (normal distribution) or medians (IQR25-IQR75; non-normal distribution). Normality: Shapiro–Wilk test. Area under the curve (AUC) of real and predicted mortalities.
Results. We included 15 patients with ECMO support as BLT. Mean age 59 ± 9 years, 60% (n = 9) male. Main lung disease: diffuse interstitial lung disease (non-pulmonary fibrosis type) 53.3% (n = 8). At the time of hospital admission, 42.9% (n = 6) were undergoing pre-transplant evaluation and 35.7% (n = 5) were on the transplant waiting list, with LAS (Lung Allocation Score) values of 88 (81–90) points. Prior to transplantation or death, 13.3% (n = 2) received renal replacement therapy for acute renal failure; 7.1% (n = 1) had Br values > 1.2 mg/dl and 40% (n = 6) required mechanical ventilation (MV). After ECMO commencement, half of the patients with MV were extubated (n = 3). Median ECMO runs 4 (2–4) days. MV days until transplantation or death: 4.5 (2–22). Days on the waiting list until transplantation or death: 25 (12.5–53.5). ICU stay 27 (8–42) days.
Real in-hospital mortality: 33.3% (n = 5). STABLE scale 6.20 ± 4.2 points, predicted STABLE scale mortality 11.8% (5.7;13.9). AUC ROC of STABLE scale 0.78 (IC95 0.51;1.00); AUC ROC of estimated mortality 0.79 (IC95 0.53;1.00).
Conclusions. In our study, the probability of death estimated by the STABLE scale correlates adequately with real mortality. However, due to the low statistical power of the study, it is not possible to define a cut-off for the STABLE score above which there is a better correlation with actual mortality.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000555***.

Introduction. Nasal colonization by methicillin-resistant Staphylococcus aureus (MRSA) in critically ill patients triggers contact precautions and decolonization protocols, aiming to prevent transmission and infection. Failure of decolonization may occur, however little is known regarding the associated factors.
Objectives. To identify clinical factors associated with failure of MRSA decolonization in a cohort of ICU patients undergoing a standardized decolonization protocol.
Methods. We conducted a retrospective study of 71 ICU patients admitted from May 2022 to October 2024 with a positive screening swab for MRSA upon admission. Eight patients who were unable to complete the decolonization protocol or follow-up testing were excluded, resulting in a final sample of 63 patients. All included patients underwent decolonization with intranasal mupirocin and chlorhexidine gluconate baths for 5 days. Follow-up swabs were collected at 48 h, day 7, and day 14. Decolonization was deemed

successful if all three follow-up swabs were negative. In cases of persistent positivity, a second 5-day course of mupirocin and chlorhexidine was administered. Persistent positivity after two cycles was considered a decolonization failure. To explore potential predictors of failure, we assessed the association between decolonization outcome and clinical variables, including age, sex, diabetes mellitus (DM), immunosuppression, malignancy, chronic kidney disease (CKD), dialysis, presence of medical devices, recent hospitalizations, and recent antibiotic use (within the previous 3 months). Chi-square tests and binary logistic regression were used for statistical analysis.

Results. The overall decolonization success rate was 71.4%, with 45 out of 63 patients achieving documented MRSA eradication. Among all variables, only DM showed a statistically significant association with decolonization failure (chi^2 = 4.71; p = 0.030) and logistic regression confirmed a strong trend toward significance for DM (OR = 3.59; p = 0.06). No significant association was found for age, gender, CKD, dialysis, immunosuppression, malignancy, medical devices, hospitalizations or recent antibiotic use.

Conclusions. DM appears to be associated with a higher risk of MRSA decolonization failure in critically ill patients. These findings suggest that in diabetic patients, strict adherence to the decolonization protocol is particularly important. Timely and complete follow-up with control swabs may be especially valuable in this subgroup, helping to confirm eradication and avoid false assumptions of success.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000557***.

Introduction. End-of-life care (EOLC) is a fundamental aspect of intensive care medicine, requiring clinical expertise, ethical decision-making, and emotional resilience from healthcare professionals. Understanding how ICU professionals perceive and experience EOLC is essential to improving support systems and training programs.

Objectives. To evaluate the perceptions, experiences, and emotional impact of EOLC among ICU physicians and nurses, identifying potential disparities and areas for improvement in institutional support.

Methods. A cross-sectional survey was conducted among ICU staff (physicians and nurses) at Hospital Universitario 12 de Octubre between January and February 2025. The survey, adapted from Riegel et al1, included Likert-scale questions (1 = strongly disagree, 6 = strongly agree) assessing knowledge, attitudes, and personal experiences related to EOLC. Descriptive statistics (mean ± standard deviation) were used to summarize responses, and Mann–Whitney U tests were performed to compare differences between physicians and nurses.

Results. A total of 58 ICU professionals participated (43,33% physicians, 56,66% nurses). Physicians reported significantly higher training in communication with families (3.25 ± 1.42 vs. 1.31 ± 0.73, p < 0.001) and symptom management (3.38 ± 1.55 vs. 1.84 ± 1.24, p < 0.001). They were also more likely to rely on scientific literature in EOLC decisions (4.08 ± 1.31 vs. 3.03 ± 1.65, p = 0.016) and had received more postgraduate education in EOLC (3.38 ± 1.74 vs. 2.41 ± 2.04, p = 0.019) (Table 1). Nurses scored higher related to the perception that EOLC becomes a nurse-led practice once the decision to withdraw care has been made (5,09 ± 1,146 vs. 3,54 ± 1,285, p < 0.001). Both groups showed similar perceptions in the domains of organizational culture and palliative care resources and values, indicating a shared understanding of institutional support and the availability of resources for end-of-life care (Tables 2 and 3).

Conclusions. The findings suggest that while ICU physicians receive more formal training in end-of-life care (EOLC) and base their decisions more on scientific evidence, nurses perceive themselves as playing a central role once care withdrawal decisions have been made. This divergence in training and perceived responsibilities may influence how EOLC is approached within multidisciplinary teams. Despite these differences, both groups share a common perception of institutional support and available resources, which could serve as a foundation for further improvements. Addressing these gaps through targeted educational programs and fostering a more structured, collaborative approach to EOLC could enhance the quality of care and support provided to both patients and healthcare professionals.

Table 1 Knowledge of end-of-life care among ICU professionals

Knowledge of End-of-Life Care among ICU Professionals	Mean (± SD)	Physicians (Mean ± SD)	Nurses (Mean ± SD)	Mann-Whitney U Test p-value
I have received in-service education that assists me to support and communicate with families of dying patients	2,14 ± 1,432	3,25 ± 1,422	1,31 ± 0,738	p <0,001
I have received in-service education that assists me to provide care and manage patient symptoms at the end-of-life	2,52 ± 1,592	3,38 ± 1,555	1,84 ± 1,247	p <0,001
I draw on evidence from the literature to provide end-of-life care to patients and their families	3,50 ± 1,57	4,08 ± 1,316	3,03 ± 1,656	p = 0,016
My postgraduate education included end-of-life care content relevant to the critical care context.	2,83 ± 1,93	3,38 ± 1,74	2,41 ± 2,046	p = 0,019

Intensive Care Medicine Experimental*, *2025*;13(1)**: ***000559.

Introduction. Extended inflammatory parameters (EIP) are markers assessed during total blood count analysis. There is limited evidence regarding use of EIP in chronic conditions [1], malnutrition [2], and sepsis in the intensive care unit (ICU) [3]. Inflammatory parameters often add to clinical assessment. The introduction of new, easily accessible inflammatory markers in ICU settings could improve decision-making.
Objectives. This study assesses EIP in ICU patients during antimicrobial treatment, and their correlations with routine inflammatory parameters.
Methods. This retrospective study was approved by the bioethical committee and included patients with confirmed bacterial infection receiving antimicrobials in the ICU. Patient demographics, mortality during antimicrobial treatment, and overall ICU mortality were recorded. Patients' laboratory results were obtained from the day before starting microbial treatment (D0), for up to 5 days of therapy (D1-D5). EIP included neutrophil reactivity intensity (NEUT-RI), and neutrophil granularity intensity (NEUT-GI).
Results. The study included 88 antibiotic therapies in the ICU. The average age was 54.9 years and 35,2% of patients were female. Factors associated with mortality during microbial treatment were higher NEUT-RI at D1 (71.1 vs 60.8, $p = 0.01$), and higher procalcitonin (PCT) at D5 (15.94 vs 3.8 ng/mL, $p = 0.017$). Factors associated with overall ICU mortality were lower NEUT-GI at D0 (153.1 vs 156.6, $p = 0.006$), higher PCT at D2 ($p = 0.012$), D3 ($p = 0.042$), D4 ($p = 0.023$), D5 ($p = 0.005$), and the higher neutrophil–lymphocyte ratio at D0 ($p = 0.016$), D2 ($p = 0.008$), D3 ($p = 0.007$), D4 ($p < 0.001$), D5 ($p = 0.003$). NEUT-RI had significant ($p < 0.05$) moderate correlation with CRP at D0 ($r = 0.59$), D2 ($r = 0.44$), D3 ($r = 0.52$), D4 ($r = 0.49$), and D5 ($r = 0.42$). NEUT-GI had significant negative weak correlation with PCT at D2 (r =—0.29), and D3 (r =—0.24). NEUT-RI and NEUT-GI had significant weak correlation at D0 ($r = 0.37$) and D1 ($r = 0.29$).
Conclusions. In this study, early EIP assessment predicted ICU outcomes. Higher NEUT-RI at the beginning of antimicrobial treatment was associated with worse outcomes. Higher NEUT-GI values before antimicrobial treatment were related to better overall ICU survival. The moderate correlation between NEUT-RI and CRP calls for further research in fields where CRP showed benefits in monitoring inflammation. The weak correlation between NEUT-RI and NEUT-GI only during the first two days suggests different cellular mechanisms affecting the parameters and needs further investigation. The use of EIP in ICU settings requires additional studies.

Introduction. Despite inconclusive findings from major trials [1], current guidelines [2] on septic shock recommend vasopressin as a potential adjunct to first-line therapy with norepinephrine. However, the optimal timing for introducing a second vasopressor agent remains uncertain [3].
Objectives. To assess the association between vasopressor strategy (norepinephrine monotherapy vs multiple vasopressor combination) and ICU mortality in patients requiring hemodynamic support.
Methods. Data from the seven ICU databases from the US and Europe (n = 349,993 patients)—AmsterdamUMCdb[4], eICU-CRD[5], HiRID[6], MIMIC-III, MIMIC-IV[7], NWICU[8], SICdb[9]—were harmonized and cleaned. Routinely collected information on demographics, comorbidities, physiological variables, lab results, and treatment parameters were extracted for the first 24 h of vasopressor administration.
Multivariable logistic regression was used to assess the association between vasopressor strategy and ICU mortality, adjusting for age, sex, weight, admission type, use of corticosteroid, renal replacement therapy and mechanical ventilation, APACHE II and SOFA scores, comorbidities, septic shock, fluid intake and urine output in the first 24h. Adjusted absolute risks of ICU mortality were predicted at every maximum rate of concurrent vasopressor in norepinephrine-equivalent dose [10], in 0.1 µg/kg/min increments for each strategy. Sensitivity analysis in patients with sepsis was conducted.
Results. Among 31,728 included patients, the median age was 66 years [IQR 55–75], with a predominance of male patients (61.1%). The median SOFA score was 4 [IQR 1–7], median vasopressor maximal rate during the first 24 h was 0.14 µg/kg/min norepinephrine equivalents [IQR 0.07–0.29]. The cohort comprised 27,922 patients receiving norepinephrine monotherapy and 3,806 patients receiving multiple vasopressors (vasopressin, epinephrine, or phenylephrine in addition to norepinephrine), with ICU mortality rates of 14.8% (4,120/27,922) and 35.4% (1,349/3,806), respectively.
Norepinephrine monotherapy was associated with significantly lower ICU mortality compared to multiple vasopressors at doses below 0.3 µg/kg/min (predicted ICU mortality risk at 0.3 µg/kg/min: 18.9% [95% confidence interval (CI): 16.9–21.0%] vs. 24.1% [95% CI: 21.1–27.3%]) (Fig. 1). Conversely, at maximal doses of 2.2 µg/kg/min and above, multiple vasopressor combinations were associated with improved outcomes (predicted ICU mortality risk at 2.2 µg/kg/min: 46.7% [95% CI: 40–53.5%] vs 59.3% [95% CI: 53.6–64.7%]). Subpopulation analysis

of sepsis patients confirmed the results (**Fig. 2**). Subgroup analysis revealed that at 0.3 µg/kg/min, norepinephrine plus vasopressin was associated with higher mortality (25.2% [95% CI: 21.6–29.3%]) compared to norepinephrine monotherapy (18.7% [95% CI: 16.7–20.8%]), while norepinephrine plus phenylephrine showed no significant difference (22.7% [95% CI: 19–26.7%]) (**Fig. 3**).

Conclusions. Our findings suggest a dose-dependent relationship between vasopressor strategy and ICU mortality. Compared to therapy with multiple vasopressors, norepinephrine monotherapy was associated with lower mortality at doses below 0.3 µg/kg/min but higher mortality at doses above 2.2 µg/kg/min. These results may inform clinical decision-making on vasopressor escalation.

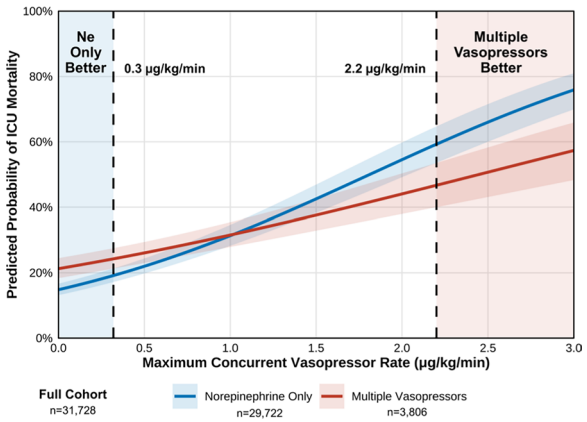

Fig 1 (abstract 000560) Adjusted risk of in-ICU mortality at different maximum rates of vasopressors for single or multiple vasopressors strategy. Ne: norepinephrine.
Maximum rate of vasopressors is shown in µg/kg/min of norepinephrine-equivalent dose, computed from the first 24 h from start of vasopressors. Multiple vasopressors include every combination of two or more vasopressors at the same time.
Thresholds 1 and 2 correspond, respectively, to the first dose where confidence intervals overlap and the first dose where confidence intervals separate.
Prediction is adjusted for age, sex, weight, admission type, use of RRT, mechanical ventilation, APACHE II and SOFA scores, diagnosis of hypertension, congestive heart failure, cardiac arrhythmia, renal failure, liver disease, chronic pulmonary disease, or metastatic cancer, sepsis, corticosteroid use, fluid intake, and urine output in the first 24h.

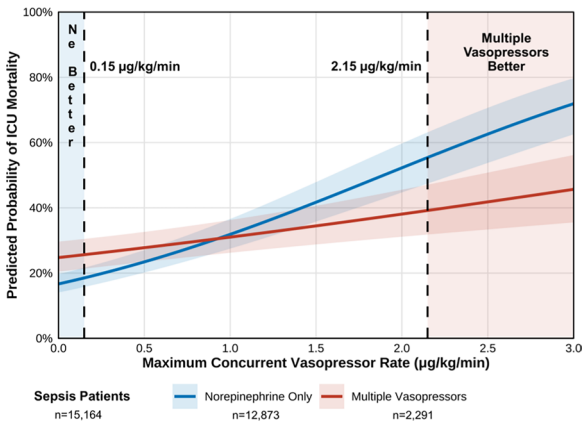

Fig 2 (abstract 000560) Adjusted risk of in-ICU mortality at different maximum rates of vasopressors for single or multiple vasopressors strategy in the subpopulation with sepsis.
Ne: norepinephrine only.
Maximum rate of vasopressors is shown in µg/kg/min of norepinephrine-equivalent dose, computed from the first 24 h from start of vasopressors. Multiple vasopressors include every combination of two or more vasopressors at the same time.
Thresholds 1 and 2 correspond, respectively, to the first dose where confidence intervals overlap and the first dose where confidence intervals separate.
Prediction is adjusted for age, sex, weight, admission type, use of RRT, mechanical ventilation, APACHE II and SOFA scores, diagnosis of hypertension, congestive heart failure, cardiac arrhythmia, renal failure, liver disease, chronic pulmonary disease, or metastatic cancer, corticosteroid use, fluid intake, and urine output in the first 24 h.

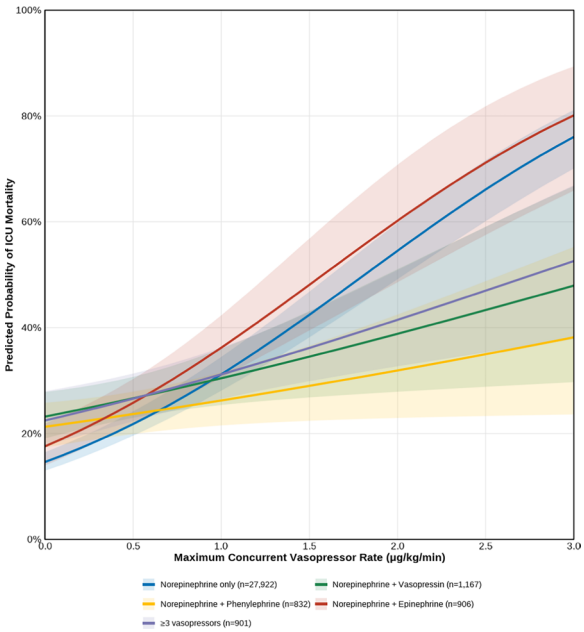

Fig 3 (abstract 000560) Adjusted risk of in-ICU mortality at different maximum rates of vasopressors for single or multiple vasopressors strategy, including every different combination.
Maximum rate of vasopressors is shown in µg/kg/min of norepinephrine-equivalent dose, computed from the first 24 h from start of vasopressors.
Prediction is adjusted for age, sex, weight, admission type, use of RRT, mechanical ventilation, APACHE II and SOFA scores, diagnosis of hypertension, congestive heart failure, cardiac arrhythmia, renal failure, liver disease, chronic pulmonary disease, or metastatic cancer, sepsis, corticosteroid use, fluid intake, and urine output in the first 24h.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000563***.

Introduction. Family engagement is a cornerstone of pediatric intensive care unit (PICU) care, yet limited qualitative data in pediatrics captures caregivers' real-time experiences. Family Care Journals (FCJs) were introduced as a communication and reflection tool, enabling families to document their journey and voice concerns. Thematic analysis of open-ended caregiver comments provides deeper insight into the family experience beyond structured survey responses.
Objectives. After completing the quantitative phase of the study, we proceeded with the qualitative phase, aiming to identify recurring themes in caregivers' feedback following the implementation of FCJs in the PICU. Our goal was to understand the key drivers of satisfaction and pinpoint areas for improvement in care delivery.
Methods. From 2016 to 2020, 366 caregivers of critically ill children completed a 12-item questionnaire at PICU discharge. Open-ended comments (n = 172; 147 English, 25 Spanish) were analyzed using an inductive thematic approach. Responses were categorized into positive and negative sentiments and grouped into thematic domains based on content patterns. During the study period, the unit transitioned from the original PICU space to a new, state-of-the-art 57-bed PICU spanning three floors.
Results. Positive themes (68.1%) were dominated by expressions of gratitude (54.1%), especially toward compassionate nursing care, staff professionalism, and inclusion in decision-making. Communication satisfaction was the second most frequent positive theme (13.4%). Negative comments (31.9%) highlighted areas for improvement in communication (15.1%), mainly due to interdisciplinary inconsistencies and language barriers (2.9%). Environmental concerns (11.6%) were predominantly associated with the previous PICU space, which lacked adequate accommodations for families. After moving to the new 57-bed facility, comments reflected improved satisfaction with space, comfort, and amenities. Delays in care (5.2%) were attributed to systemic hospital bed availability issues. These thematic insights aligned with quantitative findings.
Conclusions. Thematic analysis revealed that emotional support, clear communication, and physical comfort are central to positive family experiences in the PICU. FCJs served as a valuable avenue for caregivers to express concerns and appreciation and for care teams to identify actionable improvements. The move to a modern, larger PICU enhanced environmental satisfaction and further supported family centered care. These insights support the continued use of FCJs and inform strategies for ongoing quality improvement in critical care settings.

Introduction. The landscape of critical care is evolving. Advances in treatment and supportive care, along with the evolving technology supporting surgical interventions, like robotics, have made possible the achievement of outstanding results. The contemporary evaluation of the prognosis of critically ill surgical patients is paramount to promoting individualized care. This study aims to assess and compare the outcomes of elective and urgent surgical patients admitted to the Intensive Care Unit, both short-term (first 30 days) and long-term (until two years).
Methods. Post hoc analysis of the CIMbA LT study, a retrospective, multicentre, observational study conducted on Portuguese multipurpose Intensive Care Units over four years. Surgical patients were segregated for further analysis. We compared differences between patients admitted after elective or urgent surgery.
Results. We included 13,748 surgical adult patients admitted to an Intensive Care Unit during the study period. Roughly one-third of our population was submitted to elective and two-thirds to urgent surgery. Patients submitted to an urgent procedure had higher severity and in-hospital mortality (24.6% versus 8.2%, $p < 0.001$), whilst among those who survived until hospital discharge, scheduled surgery patients had higher long-term mortality (28.9% versus 25.0%, odds ratio 1.21, 95% CI 1.11–1.32). This difference in the long-term risk was statistically significant in the younger population. All surgical critically ill patients had a markedly increased risk of 1-year mortality, compared to the general population, even after being discharged alive from the Hospital: urgent surgical procedure, odds ratio 10.8 (95% CI 9.0–12.9); elective surgery odds ratio 14.6 (95% CI 11.3–18.8).
Conclusions. Surgical patients submitted to urgent and elective procedures have different trajectory patterns after Intensive Care Unit admission and should have a personalized approach. Urgent surgery patients have high short-term mortality, whilst elective surgical patients showed higher long-term mortality risk, particularly noticeable in younger cohorts. All surgical patients admitted to the Intensive Care Unit had a very high first year risk of mortality.

Risk of mortality associated with older age and sepsis for surgical patients, elective (panel A) and urgent (panel B), at the ICU, Hospital

and after 2 years (continuous line—odds ratio; dashed lines—95% CI). ICU—Intensive Care Unit.

Survival curves according to the age group: survival in the first 30 days after admission (panel A) and from the 31st day until two years, addressing only patients who survived the first 30 days after surgery (panel B). Age group: adult: 18–50 years; senior: ≥ 50–65; old: ≥ 65–80; very old: ≥ 80.

Introduction. Malignant hypertension (MH), a life-threatening condition characterized by rapidly progressive blood pressure elevation with acute target organ damage, remains a critical challenge in the intensive care unit (ICU). MH primarily affects the microvasculature and causes ischemia, leading to brain hemorrhages, renal failure, retinal damage, and cardiac dysfunction. The mechanisms driving organ-specific vulnerability remain poorly understood. Experimental models are essential to decipher the complex interplay between genetic background (innate susceptibility) and vascular injury and to develop targeted interventions. We hypothesized that inflammation may modulate susceptibility to MH-induced injury.
Objectives. To investigate the mechanisms underlying MH-induced microvascular damage, explicitly focusing on the role of inflammation.
Methods. Three-month-old 129S1/SvImJ (129/Sv) and C57BL/6 J male mice received angiotensin II (AngII) (600 ng/kg/min) or saline (NaCl 0,9%) for 28 days (D28) via osmotic minipumps. Target-organ damage was assessed using standardized methods: cognitive testing (Morris Water Maze), blood–brain barrier (BBB) permeability (3 kDa TMR-dextran tracer), immunostaining (GFAP, IBA1, CD206), cerebral microbleeds, renal ultrastructure (electron microscopy), urinary albumin/creatinine ratio (UACR), echocardiography (LVMass), electrocardiography (QRS duration), and retinal vascular analysis. Brain microvessels were isolated for bulk RNA sequencing. A subgroup of 129/Sv mice received low-dose LPS (0.25 mg/kg/week) to explore the role of inflammation.
Results. Despite comparable AngII-induced hypertension between strains, only 129/Sv mice developed characteristic features of MH on D28. These mice suffered from systemic disease. Retinal analyses revealed blood–retinal barrier disruption and dextran extravasation in hypertensive 129/Sv mice. Renal evaluation showed severe podocyte foot process effacement and a more than 25-fold increase in urinary albumin/creatinine ratio (UACR), while electron microscopy confirmed glomerular injury. Cardiac echography and electrocardiogram demonstrated left ventricular hypertrophy (LVH) and prolonged QRS duration, reflecting structural and electrical remodeling. In the brain, 129/Sv mice exhibited marked cognitive impairment in the Morris Water Maze, increased BBB permeability, and cerebral microbleeds, indicating significant neurovascular damage. Immunostaining revealed astrocyte activation. In contrast, C57BL/6J mice did not develop organ-specific damage, highlighting the strain-specific vulnerability to hypertensive injury.
Given that neurological deterioration is a significant concern for intensivists, we focused on brain susceptibility to better understand the mechanisms driving cerebral involvement in MH. We performed

bulk-RNA sequencing of brain microvessels to identify pathways involved in MH microvascular damages. In 129/Sv mice treated with AngII, we observed down-regulation of specific inflammatory pathways (interferon type I pathway) compared to the C57BL/6J strain, potentially contributing to their vulnerability to MH-induced damage. These results were supported by increased brain tissue-resident and perivascular macrophage activation (IBA1 and CD206 immunostaining), heart, and kidney (complement pathway) in C57BL/6J mice after AngII treatment compared to the hypertensive 129/Sv strain.
To confirm this hypothesis, in which low-grade inflammation could exert protective effects, we induced low-grade inflammation via intraperitoneal lipopolysaccharide (LPS) injections weekly (0.25 mg/kg) in 129/Sv mice with AngII administration. The hypertensive 129/Sv mice with LPS had significantly lower BBB permeability and lower UACR than the same hypertensive strain without LPS and did not develop LVH (Figure).
Conclusions. We developed a robust and original murine model of malignant hypertension that recapitulates severe human end-organ damage (1). This model reveals the critical interplay between genetic background and inflammation in shaping susceptibility to hypertensive injury. Our findings suggest that low-grade inflammation may exert protective effects in MH and support immunomodulatory strategies to prevent organ damage in hypertensive emergencies. These results offer a translational platform to explore precision medicine approaches in the ICU.

BBB : blood-brain barrier ; IVSd : interventricular septum in diastole ; LVH : left ventricular hypertrophy; LVIDd : left ventricular internal diameter end diastole ; LVMass-index : left ventricular mass index ; LVPWd : left ventricular posterior wall in diastole ; UACR : urinary albumin/creatinine ratio

The hypertensive 129/Sv mice with LPS had significantly lower BBB permeability and lower UACR than the same hypertensive strain without LPS and did not develop LVH

Introduction. Sepsis is one of the leading causes of critical care admissions worldwide. Sepsis guidelines recommend timely fluid resuscitation and antibiotic administration. However, most research focuses on patients with community acquired sepsis, and it is unclear how well these guidelines apply to inpatients who develop sepsis (or nosocomial sepsis).
Objectives. We conducted a systematic review to assess quality of care in hospitalized adults who develop sepsis. The outcomes of interest included mortality, ICU stay length, hospital length of stay, and survival to hospital discharge.
Methods. We searched MEDLINE, EMBASE, and Scopus (from January 2001–December 2024) for randomized controlled trials and cohort studies that included hospitalized adults (age > 18) who developed nosocomial sepsis. Two reviewers independently screened citations in two stages: titles/abstracts and full text. Disagreements were resolved through discussion or third-party adjudication. Studies were assessed using the Modified Cochrane 2.0 or Newcastle–Ottawa Risk of Bias tools. We initially planned to perform meta-analysis, however due to clinical and methodological heterogeneity, we summarize findings narratively.
Results. Of 6,258 citations, we included 12 studies. The studies included six retrospective cohort studies, five prospective cohort studies, and one quality improvement study. From the included studies, four main themes emerged: (1) early antibiotics and fluid resuscitation improved outcomes, (2) inpatients experience delayed initial resuscitation compared to those with community acquired sepsis who present to the emergency department, (3) routine assessment of physiologic markers such as serum lactate levels lead to more timely resuscitation, and (4) integration of allied healthcare personnel quality improvement projects reduces resuscitation times.
Conclusions. This study highlights the need for more research specifically focused on the care of sepsis in hospitalized patients. Further randomized controlled trials and quality improvement initiatives are essential to ensure quick recognition and implementation of sepsis management strategies in hospitalized patients, as recommended by the Surviving Sepsis Campaign. Our analysis shows that nursing-led quality improvement initiatives can improve sepsis management and reduce delays in treatment, underscoring the need for coordinated efforts across care teams.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000570***.

Introduction. Post-extubation dysphagia (PED) recovery time varies among survivors of critical illness. While factors associated with PED occurrence have been identified, those related to recovery duration remain unclear. Identifying which factors are most strongly associated with delayed swallowing recovery could help stratify patients and refine early intervention strategies. Moreover, prolonged dysphagia may extend hospital stay, increasing healthcare burden.
Objectives. To evaluate the association between recovery time from post-extubation dysphagia and clinical and nutritional factors, and its impact on hospital stay.
Methods. This study presents preliminary data from an ongoing prospective study (June 2024–February 2025) conducted at a public tertiary hospital in Argentina. It includes patients aged ≥ 18 years who required mechanical ventilation (MV) for ≥ 48 h. Swallowing function recovery (GUSS-ICU = 10) and recovery time (> 5 vs. ≤ 5 days) were analyzed in relation to clinical and nutritional factors, including age, sex, APACHE II score, malnutrition at ICU admission, ICU-acquired weakness (ICUAW), MV duration, and ICU stay. Chi-square and Mann–Whitney U tests were used for comparisons. Relative risk (RR) with 95% confidence intervals (95% CI) assessed associations. Kaplan–Meier

analysis evaluated the effect of swallowing recovery time on hospital stay (Log-Rank test).
Results. A total of 52 patients were included (mean age: 37 ± 16 years, 65.4% male). Mean APACHE II score: 19 ± 6. Malnutrition at ICU admission: 65.4%. Median MV duration: 7 days (P25-P75: 4–8). Median ICU stay: 11 days (P25-P75: 8–13). Swallowing recovery time ranged from 1 to 24 days (median: 5, P25-P75: 3–7). Patients were categorized as delayed recovery (> 5 days, n = 20) or faster recovery (≤ 5 days, n = 32). Delayed recovery was significantly associated with MV > 7 days (RR = 2.83; 95% CI: 1.42–5.64; p = 0.002; OR = 6.50; 95% CI: 1.84–22.92) and ICU stay > 11 days (RR = 3.00; 95% CI: 1.28–7.05; p = 0.004; OR = 5.73; 95% CI: 1.65–19.94). No significant associations were found with APACHE II, age, sex, malnutrition, or ICUAW. Patients with delayed recovery had longer hospital stays (p = 0.014). Kaplan–Meier analysis confirmed a significant effect of recovery time on hospital stay (Log-Rank: $\chi^2 = 44.143$, p < 0.001), with a mean stay of 9.3 ± 1.0 vs. 3.0 ± 0.2 days.
Conclusions. Prolonged mechanical ventilation (> 7 days) is associated with delayed recovery from post-extubation dysphagia (> 5 days), leading to longer hospital stays. These findings emphasize the need for early interventions to mitigate the impact of prolonged MV on swallowing recovery and hospital stay.

Introduction. Lack of awareness, guidelines and specialized staff/resources hinders post-mechanical ventilation dysphagia (PMVD) management, leading to suboptimal care. An interdisciplinary program enables timely identification, monitoring and intervention.
OBJECTIVES. To describe the ongoing development of a dysphagia management program providing continuous, standardized care through an interdisciplinary approach for patients weaned from MV.
Methods. The program, implemented in a tertiary public hospital in Argentina, covered care from ICU to post-hospital discharge. Phase 1 included establishing an interdisciplinary team (speech-language pathology [SLP], nutrition, physiotherapy and head and neck surgery), conducting a survey to assess ICU healthcare professionals' knowledge/perceptions and ongoing research on PMVD frequency, evolution and associated factors, using the Gugging Swallowing Screen-ICU and bedside and/or instrumental tests when needed. Phase 2 included training sessions and the formal presentation of institutional guidelines with standardized tools, alarm sign checklists, and management algorithms. Research remains ongoing, with new studies being developed. Future phases (3 and 4) will focus on rehabilitation, evaluating training improvements and ensuring sustainability through expanded research and surveillance.
Results. The dysphagia management program was successfully implemented in Phases 1 and 2. The interdisciplinary team and the application of guidelines facilitated early identification and interventions, enhancing communication and improving collaborative action. Preliminary findings indicate that most patients presented PMVD upon weaning and nearly half had dysphagia at ICU discharge. By hospital discharge, only a few patients still had dysphagia and the outpatient follow-up system ensured continuity of care for at-risk patients. A survey assessing healthcare professionals' knowledge/perceptions showed variability in responses among professional groups and differences in perception based on experience, which were addressed through targeted training. The feasibility of the program's initial phases was demonstrated: preliminary data from ongoing research showed that the proposed tools could be used successfully with the institution's available resources.
Conclusions. The PMVD management program demonstrated the feasibility and improving outcomes of addressing PMVD through an interdisciplinary team. This enabled early identification, assessment and tailored interventions across the patient care continuum, from weaning to post-discharge. Preliminary findings confirmed that the strategies were feasible and aligned with the institution's resources. Standardized guidelines streamlined care, while future rehabilitation programs and a planned surveillance system will ensure the program's sustainability and improvement. This model could be applied to other institutions for effective dysphagia management from ICU to post-discharge care.

000573 Comparative impact analysis of cardiac intensivist involvement on CABG surgery outcomes in Southern Philippines Medical Center—Heart Institute: a retrospective cohort study (2014–2024).

AC. Castañeto.[1]

Correspondence: A.C. Castañeto.
Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000573***.

Introduction. Coronary artery disease remains a leading cause of mortality worldwide, with coronary artery bypass graft (CABG) as a key intervention. Numerous international studies, predominantly from high-income countries, suggest improved postoperative outcomes with intensivist involvement. However, these findings may not be generalizable to low- and middle-income countries (LMICs) due to differences in healthcare infrastructure and resources. In the Philippines, local data on the impact of cardiac intensivists remain limited. Evaluating its effect in a local, resource-constrained context is essential to inform clinical and policy decisions.
Objectives. To determine the impact of integrating a cardiac intensivist on postoperative outcomes of CABG patients at Southern Philippines Medical Center (SPMC)—Heart Institute from 2014 to 2024. Specifically, it examines patient profiles and compares outcomes: mortality, ICU and hospital length of stay, mechanical ventilation time, blood transfusion volume, ICU readmission and complications—before and after the integration of a cardiac intensivist.
Methods. This retrospective cohort study analyzed CABG patients at SPMC-Heart Institute over two periods: pre-integration (July 2014 – June 2019, n = 150) and post-integration (July 2019 – June 2024, n = 118) with a cardiac intensivist. Primary outcomes were mortality, ICU length of stay, blood transfusion volume and mechanical ventilation duration. Secondary outcomes included postoperative hospital stay, ICU readmission, and complications. Statistical analysis was conducted using Mann–Whitney U and Chi-square tests.
Results. The post-integration group showed significant reductions in SICU stay (3.8 vs. 5.6 days, 95% CI: 3.33 – 4.27 vs. 4.73 – 6.47; p = 0.013), mechanical ventilation duration (9.2 vs. 29.0 h, 95% CI: 7.46 – 11.0 vs. 20.7 – 37.3; p = 0.008), and blood transfusion volume (2.3 vs 4.7 units, 95% CI: 1.68 – 2.92 vs. 3.76 – 5.64; p = 0.04). In-hospital mortality (3.4% vs. 8.7%; p = 0.125), postoperative hospital stay (11 vs. 14 days; p = 0.187), SICU readmissions (3.4% vs. 8.2%; p = 0.378), and complications, including AKI requiring dialysis (5.9% vs. 13.3%; p = 0.153) showed non-significant reductions.
Conclusions. The integration of a cardiac intensivist into CABG management significantly reduced ICU stay, ventilation duration, and transfusion needs. Although reductions in mortality and complications were not statistically significant, the trend suggests potential benefits. These outcomes are consistent with those reported in high-income

countries and underscore the value of cardiac intensivist involvement, particularly in resource-limited settings. Further multicenter studies in the Philippines are recommended to validate these results and evaluate long-term outcomes.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000574***.

Introduction. Patients undergoing high-risk cardiac surgery with cardiopulmonary bypass (CPB) are particularly susceptible to significant perioperative complications. Serum lactate (LCT), the conventional biomarker for tissue hypoperfusion, is limited by its delayed response. In contrast, gastric reactance (XL), derived from continuous gastric impedance monitoring, is a minimally invasive, real-time metric that captures early and patient-specific indicators of splanchnic ischemia.

Objectives. To compare the performance of XL and LCT as indicators of tissue hypoperfusion in high-risk cardiac surgery patients, focusing on perioperative events (pre-CPB, during CPB, post-CPB, first 4 h postoperatively).
Methods. This prospective observational study enrolled adult patients classified as high-risk based on any of the following criteria: Society of Thoracic Surgeons (STS) score ≥ 6%, EuroSCORE II ≥ 6%, left ventricular ejection fraction (LVEF) < 45%, tricuspid annular plane systolic excursion (TAPSE) < 17 mm, or lateral tricuspid annular systolic velocity < 0.1 m/s measured via tissue Doppler imaging. All patients underwent elective cardiac surgery—either valve replacement, coronary artery bypass grafting (CABG), or combined procedures—using CPB.
XL was continuously recorded using a feeding tube embedded with impedance sensors. Serum lactate (LCT) was measured at perioperative events. Postoperative complications—defined as excessive bleeding, cardiogenic shock, or vasoplegic syndrome—were used as clinical endpoints. The minimum value of XL (XL_Min) and the maximum LCT level (LCT_Max) per event were analyzed using receiver operating characteristic (ROC) curves.
Results. Among the 37 patients enrolled in the study, the 72-h mortality rate was 11% (4/37), while the 30-day mortality rate reached 30% (11/37). Major perioperative complications occurred in 62% of the cohort (23/37). During the Post-CPB event (see Table 1 and Fig. 1), XL_Min demonstrated the strongest predictive performance (AUC = 0.73, 95% CI [0.56, 0.89]; positive predictive value [PPV] = 0.88, 95% CI [0.80, 1.00]; negative predictive value [NPV] = 0.60, 95% CI [0.48, 0.79]), followed by the maximum lactate concentration (LCT_Max), which also showed notable performance (AUC = 0.65, 95% CI [0.46, 0.83]; PPV = 0.78, 95% CI [0.69, 1.00]; NPV = 0.53, 95% CI [0.43, 0.83]).
Conclusions. XL_Min outperformed LCT_Max in predicting major perioperative complications in this cohort of high-risk cardiac surgery patients. XL provided earlier and more patient-specific indications of tissue hypoperfusion, with higher predictive accuracy than LCT_Max. These findings support the potential role of XL as a real-time, noninvasive biomarker for guiding hemodynamic management and improving perioperative monitoring in this vulnerable population.

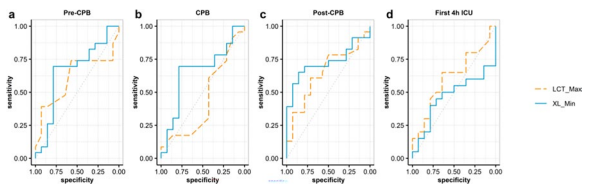

Fig 2 (abstract 000574) ROC curves comparison between Minimum XL (XL_Min) and maximum Lactate (LCT_Max) during **(a)** pre-CPB, **(b)** CPB, **(c)** post-CPB, and **(d)** first 4h in Intensive Care Unit (ICU). Cardiac pulmonary bypass (CPB).

Application of loading dose warfarin in pregnant women with pulmonary embolism—a prospective, randomized, double-blind trial

W. Huang[1]; H. Yan[2]; Y. Lu.[3]
[1]Department of Intensive Care Medicine, Shanghai Xuhui Central Hospital, Zhongshan-Xuhui Hospital, Fudan University, Shanghai, China; [2]Department of Pharmacy, Yangpu Hospital, School of Medicine, Tongji University, Shanghai, China; [3]Department of Epidemiology, Fudan University School of Public Health, Shanghai, China.
Correspondence: W. Huang.
Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000576***.

Introduction. Warfarin is the preferred oral anticoagulant for pulmonary embolism in pregnant women. A number of factors could influence the therapeutic dose of warfarin and there is individual variability, making it challenging to determine the appropriate initial and maintenance dose. Warfarin is usually used in a fixed loading dose regimen, which may increase the risk of bleeding or prolong the time to reach standard dose. Pharmacogenomic studies have shown that genotype-based pharmacogenetic models can accurately and effectively guide individual loading dosages, which could significantly reducing the risk of excessive anticoagulation.
Objectives. The aim of the study is to compare the efficacy and safety of loading dose versus maintenance dose of warfarin therapy in pregnant women with pulmonary embolism (PE) under the guidance of clinical pharmacogenetic information.
Methods. A total of 64 pregnant women with PE were recruited from September 2023 to August 2024. The patients were randomly divided into the experimental group and the control group using a random-number table according to the ratio of 1:1. Patients in the experimental group (pharmacogenetic-guided loading dose group) received a regimen combining the initial 1 to 3 days loading dose with the International Warfarin Pharmacogenetics Consortium (IWPC) dose prediction model. Patients in the control group (pharmacogenetic-guided maintenance dose group) only received a regimen guided by the IWPC dose prediction model for the initial 1 to 3 days. Starting from day 4,

the warfarin dose was adjusted according to the international normalized ratio (INR). The primary outcome was first time to therapeutic INR (2.0–3.0) in pregnant women with PE.
Results. The study found that the median time to first reach the therapeutic INR was 5.5 days in the experimental group compared to 7 days in the control group (p = 0.002). The median time within therapeutic range (TTR) was 97.24% in the experimental group compared to 95.50% in the control group (p = 0.001). The difference in adverse events showed no statistical significance between the two groups (P > 0.05).
Conclusions. Pharmacogenetics-guided loading dose to initiate warfarin therapy was superior to pharmacogenetic-guided maintenance dose. And there appears to be no increased risk of drug-related bleeding. The study could provide ideas for the precise treatment of warfarin in pregnant women with PE.

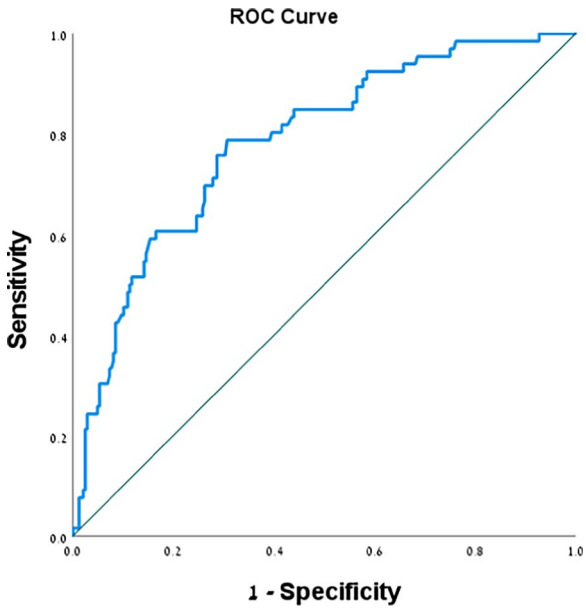
Neutrophil gelatinase-associated lipocalin (NGAL) for the assessment of persistent renal dysfunction after acute kidney injury



Y. Shacham[1]; S. Banai.[1]
[1]Cardiology, Tel Aviv Sourasky Medical Center—Ichilov, Tel Aviv-Yafo, Israel.
Correspondence: Y. Shacham.

Introduction. Renal injury is a significant complication in ST-segment elevation myocardial infarction (STEMI) and is associated with poor outcomes. The recently introduced term acute kidney disease (AKD) describes persistent renal dysfunction lasting 7–90 days post-acute kidney injury (AKI). Neutrophil gelatinase-associated lipocalin (NGAL), a biomarker for tubular injury, has shown promise in predicting AKI.

Objectives. The study aimed to evaluate NGAL's diagnostic utility for predicting AKD in STEMI patients.
Intensive Care Medicine Experimental, 2025;13(1): 000577.
Methods. This prospective observational study included 312 patients admitted with STEMI. NGAL levels were measured within 2 h of admission. AKI and AKD were defined using KDIGO criteria, and patients with chronic inflammation or end-stage renal disease were excluded. Receiver operating characteristic (ROC) analysis was performed to evaluate NGAL's predictive value for AKD and its optimal value for prediction.
Results. Overall, 64 patients developed AKI (21%), with 30 (47%) progressing to AKD. Patients with AKD had higher admission NGAL levels (median 165 ng/ml) compared to those with resolved AKI (112 ng/ml) or no AKI (88 ng/ml, p < 0.001,Fig. 1). NGAL had a good predictive ability for AKD (area under the ROC of 0.784), with a threshold of > 150 ng/ml having 65% sensitivity and 77% specificity for correct prediction (Fig. 2). Multivariate analysis confirmed NGAL > 150 ng/ml as an independent predictor of AKD (OR 6.42, 95% CI 3.15–13.09, p < 0.001).
Conclusions. Elevated NGAL levels are independently associated with AKD development in STEMI patients. These findings suggest NGAL could be a valuable biomarker for early risk stratification, supporting timely interventions to mitigate persistent renal injury. Further research is warranted to confirm its clinical utility.

NGAL levels in patients with no AKI, resolved AKI and AKD

Association between permissive azotemia and prognostic outcomes in sepsis-associated acute kidney injury: development of a blood urea nitrogen trajectory model

B. Geng[1]; H. Hongbin[1]; S. Tong[1]; Z. Zeng.[1]
[1]Department of Critical Care Medicine, Nanfang Hospital, Guang Zhou Shi, China.
Correspondence: B. Geng.
Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000578***.

Introduction. Sepsis-associated acute kidney injury (SA-AKI) constitutes a critical complication in ICU populations, independently linked to progressive chronic kidney disease and mortality. While preclinical models suggest renal protective effects of permissive azotemia[1], clinical translation remains unvalidated. This study aims to explore the clinical potential protective effects and feasibility of permissive azotemia.
Objectives. To characterize blood urea nitrogen (BUN) trajectory patterns and evaluate their clinical correlations with renal recovery and mortality in SA-AKI patients, thereby investigating the clinical feasibility of permissive azotemia strategies.
Methods. This retrospective cohort study utilized the Medical Information Mart for Intensive Care IV (MIMIC-IV) database to identify SA-AKI patients meeting KDIGO and Sepsis-3 criteria. Group-based

trajectory modeling was applied to delineate BUN evolution patterns in patients receiving renal replacement therapy (RRT patients) and not receiving RRT (non-RRT patients) [2]. Our primary outcome was 7-day renal function recovery. Secondary outcomes were ICU mortality, 28-day mortality and 90-day mortality. We used multivariable logistic regression and Cox proportional hazards models to assess associations between trajectory classes and clinical outcomes.

Results. Four distinct trajectory classes emerged in both RRT (n = 683) and non-RRT (n = 4,370) cohorts (Fig. 1). In RRT patients: Class 1 (rapidly declining high BUN, 28.4%) demonstrated reference outcomes; Class 2 (persistent mild azotemia, 17.9%) and Class 3 (persistent moderate azotemia, 35.7%) showed superior early renal recovery (OR 1.88 [1.02–3.49] and 1.74 [1.04–2.92], respectively) with comparable mortality; Class 4 (persistent severe azotemia, 18.0%) exhibited elevated 28-day (HR 1.66 [1.02–2.69]) and 90-day mortality (HR 1.65 [1.06–2.56]). Non-RRT patients maintaining normal/mild azotemia (Classes 1–3) demonstrated optimal outcomes, while Class 4 (moderate azotemia, 18.5%) showed increased ICU mortality (OR 2.25 [1.43–1.81]) and 28-day mortality risk (OR 1.59 [1.09–2.34]).

Conclusions. This trajectory analysis reveals four BUN evolution patterns with differential prognostic implications in SA-AKI. Moderate azotemia maintenance in RRT patients correlated with enhanced renal recovery (adjusted OR 1.74) without mortality penalty, whereas severe azotemia conferred mortality risks despite potential recovery benefits. Non-RRT patients exhibited optimal outcomes with physiological-to-mild BUN levels. These findings suggest tailored RRT management based on azotemia strategies may optimize SA-AKI outcomes.

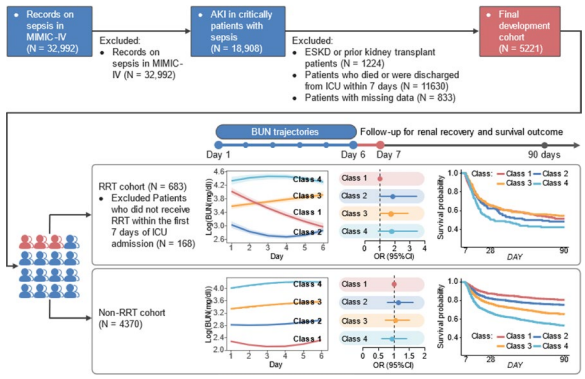

Fig 1 (abstract 000578) BUN trajectories associated with renal recovery and survival outcomes in SA-AKI patients

Introduction. Artificial intelligence techniques such as machine learning and deep learning are widely used in healthcare for predicting diseases and identifying risk factors. Thrombocytopenia is the most prevalent coagulation disorder in ICU patients.

Objectives. This study aims to employ machine learning techniques to identify if linezolide, compared to vancomycin or teicoplanin, is associated with higher frequency of thrombocytopenia in septic patients when initiating empirical antibiotic therapy.

Methods. We conducted a retrospective study on all patients admitted to the five medical and surgical ICUs in a large tertiary teaching hospital between 2018 and 2024. Every patient with equal or more than 18-year old, and thrombocytopenia at least five days after start of intravenous linezoide, vancomycin or teicoplanin was included. Twenty one clinical and laboratory risk factors were evaluated for predicting thrombocytopenia according to the previous studies and an expert panel. Different prediction algorithms, including Logistic Regression, Gradient Boosting, and Random Forest algorithms, were developed based on the supposed risk factors. The algorithm's performance was evaluated using accuracy, precision, recall, F1-score, and support metrics.

Results. The total number of patients admitted during the study period was 18,752, from which 872 patients received one of the target medications. Eligible patients during the study period were 512, whereas 186 patients experienced thrombocytopenia. Random Forest model performed best in identifying the effective factors, with an accuracy of 81.6%, a sensitivity of 72.7%, and a specificity of 79.8%. Key predictors included ICU admission platelet count, glomerular filtration rate at the time of start of the antibiotics, ICU diagnosis, APACHE II, duration of antibiotic therapy, age, length of stay in ICU before start of antibiotics, hemoglobin level at the ICU admission, septic shock and length of stay before ICU in hospital (Fig. 1).

Conclusions. In comparison to vancomycin and teicoplanin, linezolide is not associated with more frequent thrombocytopenia in septic ICU patients. Platelet count at the time of ICU admission and kidney function at the time of sepsis are more important determinant of risk of thrombocytopenia in these patients.

Risk factors for thrombocytopenia in septic ICU patients after receiving linezolide, vancomycin or teicoplanin.

The impact of ICU nurses' well-being on family satisfaction: preliminary results from a mixed-methods study

E. Guerra[1]; I. Marin[2]; M. Danielis.[3]
[1]Anaesthesia and Intensive Care, ULSS 6 EUGANEA, Padova, Italy; [2]Chief Nurse Office, ULSS 6 EUGANEA, Padova, Italy; [3]Department of Cardiac, Thoracic, Vascular Sciences and Public Health, University of Padua, Padova, Italy.
Correspondence: M. Danielis.
Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000582***.

Introduction. The well-being of ICU nurses is crucial, particularly given high burnout and turnover rates. While their exposure to ethical and existential challenges remains understudied, family satisfaction is a key quality measure in healthcare. The relationship between these two phenomena has yet to be explored.
Objectives. To investigate the relationship between ICU nurses' well-being and family satisfaction.
Methods. We employed a mixed-methods convergent parallel design, following the Good Reporting of A Mixed Methods Study (GRAMMS) guideline. Nurses' well-being was assessed using the brief form of the Nursing Questionnaire of Organizational Health (QISO), covering workplace comfort, stress, safety, work tolerability, openness to innovation, and psychophysical distress. Family satisfaction was measured using the Family Satisfaction-ICU (FS-ICU) tool, which evaluates satisfaction with care (16 items) and decision making (10 items) on a 5-point Likert scale. Participants included ICU nurses with $\geq$ 1 year of experience and family members of patients hospitalized for $\geq$ 72 h in four hospitals in northeast Italy. A focus group comprising ICU nurses, physicians, and nurse assistants explored perceptions, which were thematically analyzed using Atlas®. The study was approved by the Territorial Ethics Committee of the Central-Eastern Veneto Area (CET) with the approval code CET-ACEV: 6024/U6/24.
Results. The study included 52 nurses and 26 family members. The average QISO score was 2.53 out of 4, while the total FS-ICU average was 4.21 out of 5. Among nurses, 88% (n = 46) reported moderate well-being, 8% (n = 4) high well-being, and 4% (n = 2) low well-being. The lowest mean value of perceived well-being (2.22 out of 4) was related to job satisfaction. For family members, 69% (n = 18) reported high satisfaction, 27% (n = 7) moderate satisfaction, and 4% (n = 1) low satisfaction. Average scores were 4.27/5 for care received and 4.05/5 for the decision-making process. Qualitative analysis revealed the theme "Elements of organizational culture as determinants of family satisfaction", with four categories identified: internal communication and level of interprofessional collaboration, leadership style in work organization, quality of care provided, and barriers and facilitators in the relationship with family members. The integrated results reveal how effective communication between teams and family members, along with clear health and organizational objectives, enhances nurses' organizational well-being, which in turn impacts family satisfaction in the ICU (Fig. 1).
Conclusions. This study highlights the significant link between ICU nurses' well-being and family satisfaction, emphasizing the importance of prioritizing staff well-being to improve overall ICU outcomes.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000583***.

Introduction. Active respiratory mechanics (Ea, elastance, Ra, resistance) has not been measured during weaning of mechanically ventilated patients. They relationship with passive values (Ep,Rp) its related with the reserve available of load compensation.
Objectives. Our objective is to analyze these variables during a spontaneous breathing test (SBT).
Methods. In a multidisciplinary ICU, ventilated patients at least for 48 h, ready to weaning were studied. Airways pressure and flow were recorded, Ep and Rp were obtained on volume assist–control with constant flow. Active measurement (Ea, Ra) with the ventilator on pressure support ventilation without assistance (PS0PEEP0), were calculated

with occlusion pressure (Pocc) after an expiratory pause and the preceding inspiratory volume and flow.
Results. Forty-five patients were studied, after 8 ± 12 days on mechanical ventilation for different reason. Thirty-five patients were successful extubated, during SBT changed inspiratory flow and respiratory rate 0,58 ± 0,15 vs 0,80 ± 0,17 l/s (p < 0,001) and 21 ± 5 vs 19 ± 3 bpm (p = 0,02).
Active elastance was 50 ± 33% higher than passive elastance [40 ± 13 (15–85) vs 23 ± 9 cmH2O/l (p < 0,001)] and were related with respiratory effort (Pocc) r:0,5 (p < 0,001). The active resistance mean was 9 ± 4 vs 16 ± 6 cmH2O/l·s-1 (p < 0,001), 52 ± 41% lower than Rp. Did not relate with different inspiratory flow -0,1 (p = 0,3), and the correlation with Pocc was 0,3 (p = 0,02).
In 39 patients with 2–3 valid registers, Ea showed a variability of 36 ± 36% (1–161%). This was not related with the mean active elastance or respiratory effort. The Ra variability was 66 ± 40%, related with the resistance mean value r:-0,4 (p = 0,005) and did not relate with active elastance variability.
The weaning outcome (f, failure vs s, success) were not related with the respiratory mechanics measured in passive or active condition (Ep,f 23 ± 9 vs 23 ± 9; Rp,f 13 ± 5 vs 17 ± 6; Ea,f 42 ± 18 vs 39 ± 12.; Ra,f 9 ± 6 vs Ra,s 9 ± 4). The degree of change from passive to active, was not related with the weaning evolution.
Conclusions. Active respiratory mechanics can be measured during weaning of ventilated patients. These values are significantly influenced by respiratory muscle activity. In the group of patients studied, results showed too high variability and we couldnot evaluate the meaning in the weaning outcome.

Descriptive analysis of ventilation-associated pneumonia (VAP) in our intensive care unit (ICU). Role of oropharyngeal decontamination (OPD) and selective digestive decontamination (SDD) program in improving our tasas.

S. Mariño Guerreiro[1]; C. Gómez Gordo[1]; A. Martinez Cabezas[2]; AM. Alberola Herrero[2]; J. Pelaez Velez[2]; ME. Yuste Ossorio.[3]

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000584***.

Introduction. Ventilator-Associated Pneumonia (VAP) is defined as an infection of the lung parenchyma that occurs in patients undergoing invasive mechanical ventilation (IMV) and therefore requires tracheal intubation (a risk factor) for a period of more than 48 h. It is one of the main infections associated with healthcare, with high associated morbidity and mortality, as well as an increase in ICU length of stay and costs. The Pneumonia Zero project was launched in 2011 and will be updated in 2022, adding new measures to the package of recommendations. These measures include selective digestive and oropharyngeal decontamination, which we include in our ICU (Annex 1). The goal was to reduce the national average incidence of VAP to fewer than 7 episodes per 1,000 days of mechanical ventilation.
Objectives. To describe the evolution of VAP rates since the implementation of the package of preventive measures, considering the adaptation we did in 2022 with the incorporation of OPD and SDD, search and elimination of reservoirs and "waterless ICUs".
Methods. Patients admitted to our ICU since 2011 to 2024 during the annual ENVIN cut. Only included patients admitted for more than 24 h. Between 18 and 22 UCI beds. Followed until ICU's discharge. Statistical parameter: incidence density (ID) VAP episodes/1000 days of mechanical ventilation days. Data from National Nosocomial Infections Surveillance (ENVIN).
Results. The incidence rate has clearly decreased since the implementation of the package of measures in 2011, when the DI was 14,02. We observed a clear and immediate improvement in subsequent years. In 2017, data were not collected due to a hospital merger between the two hospitals in Granada, and in 2018, we suffered the consequences of the lack of adherence to the Pneumonia Zero protocol we had previously implemented in our unit. In 2019, normality began to return, and in 2022, the measures described above were added. Since then, our VAP rates have remained controlled and below the proposed national target (Annex 2).
Conclusions. It is clear that preventive measures to prevent VAP applied to our patients have a positive effect on controlling the number of patients suffering from this healthcare-associated infection. In this sense, they are also capable of reducing mortality, as well as hospital stays and costs. For all these reasons, we must continue along these lines.

Annex 2 (abstract 000584) Incidende density

Annex 1: Mandatory preventive measures

1	Proper training and education in airway management
2	Strict hand hygiene before handling the airway
3	Oral hygiene using chlorhexidine (0.12%–0.2%)
4	Control and maintenance of cuff pressure (> 20 cm H_2O)
5	Avoid, whenever possible, the supine position at 0°
6	Promote procedures that safely reduce the need for or duration of intubation
7	Avoid scheduled changes of tubing, humidifiers, and tracheal tubes
8	Continuous aspiration of subglottic secretions
9	Selective digestive decontamination (complete or oropharyngeal)
10	Systemic antibiotics (two days) during intubation in patients with decreased level of consciousness

Towards silent ICUs and smart alarms—requirement engineering for the interaction with SDC networks

M. Prendke[1]; A. Chaoui[1]; L. Mosch[1]; F. Balzer[1]; AS. Poncette[1]; AR. Flint.[1]
[1]Institute of Medical Informatics, Charité – Universitätsmedizin Berlin, Berlin, Germany.
Correspondence: M. Prendke.
Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000585***.

Introduction. The new IEEE 11073 Service-oriented Device Connectivity (SDC) standard family [1,2] enables the wireless connection and interoperability of medical devices in the ICU and the harmonization of multimodal data, including high-frequency data, alarms and medication. The implementation of the standard by the medical-device industry puts the long-awaited silent ICU patient room within reach [3]. With data transfer and remote device control available by SDC in real time and across devices from different manufacturers, the seamless inclusion of data-driven algorithms into the ICU environment is feasible [1,4], e.g., clinical decision support systems, high level smart alarms or alarm profile recommendations. To achieve this integration and leverage SDC to improve patient care, the interaction of non-SDC devices, IT systems and stakeholders with the SDC network needs to satisfy a multitude of requirements. What are they and are they included in the SDC standard?
Objectives. To elicit, analyze, plan, and check the requirements of external communication and interaction with an SDC network of medical devices.
Methods. Requirement engineering was performed according to best practice guidelines [5] by one data scientist and two physicians with research experience in medical informatics employing Natural language, Unified Modelling Language and Informal modelling. As requirement dimensions Function, Quality, Scenarios, Stakeholders and Structure of external communication and interaction with the SDC network were considered [5]. Requirements were developed in three steps: 1) requirements elicitation by introspection and archeology; 2) requirement analysis and planning by domain-driven development, informal modelling and vision; and 3) requirements checking by peer review [5].
Results. Functional, qualitative, and structural requirements for the interaction with the SDC network are shown in Table 1. Figure 1 illustrates stakeholders and use cases, revealing real-time data processing as a central use case. As visualized in the Data Flow Model, the currently published SDC standard [1] does not address the interaction requirements, while IHE [4] defines Gateways, considers interoperability, but defines only the FHIR and HL7 v2 Gateways as bidirectional (Fig. 2). Both ignore the importance of enabling high-frequency and real-time interactions.

Table 1: (abstract 000585) Functional, qualitative and structural requirements of the connected SDC- and non-SDC-network of medical devices

Function	Quality	Structure
Patient allocation: Matching data to patients Alignment: Time synchronization of data across devices Human-readability: Data understandable by humans Machine-readability: Data usable by algorithms	Data security: Protection against unauthorized data and device access Compact data format: Data format that allows real-time high-frequency data transfer Interoperability: Seamless SDC and non-SDC device and system interaction	Bandwidth: Rate of transfer suitable for real-time high-frequency data Bidirectional communication: Allow data transfer from and to SDC network Low latency: Allow real-time data transfer

Conclusions. Most of the necessary requirements are currently not included in the SDC standard [1], and only partially included in the IHE SDC supplement [4]. Real-time, bidirectional and high-frequency data transfer is essential for meaningful interactions with the SDC network. Our results are limited by the subjectivity of requirement engineering techniques. Further research is needed to verify, expand, and prioritize the requirements by including all stakeholders; and investigate suitable data standards for the interaction with the SDC network. An improved and extended SDC standard that considers the requirements of the interaction with non-SDC devices and systems is needed to create a unified, interoperable device architecture with harmonized data and not promote more proprietary systems. Only then can SDC deliver on its promises—such as the Silent ICU or the integration of algorithms—and thereby improve patient care and patient safety.

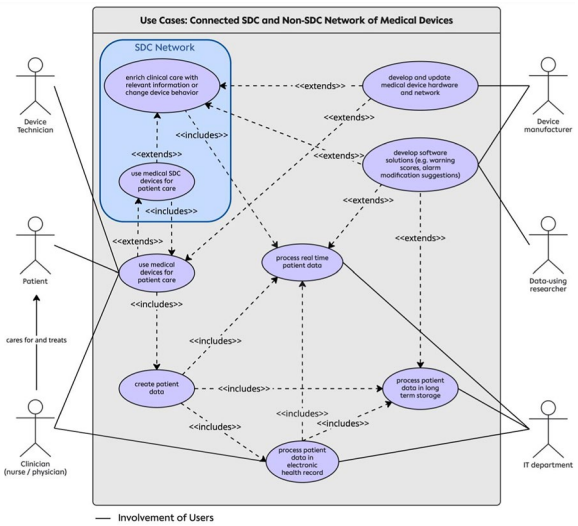

Fig 1 (abstract 000585) Scenario use cases of the connected SDC- and non-SDC-network of medical devices with stakeholders as users

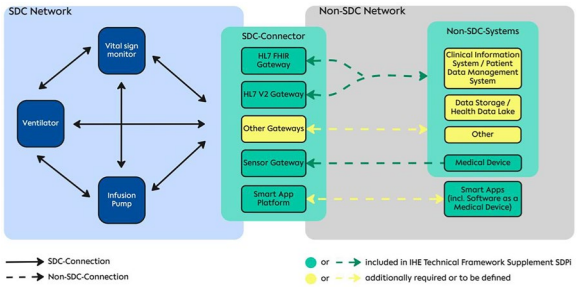

Fig 2 (abstract 000585) Data flow model of the connected SDC- [1] and non-SDC-network of medical devices including descriptions by IHE [4].

Intensive Care Medicine Experimental*, *2025*;13(1)**: ***000586.

Introduction. The development of artificial intelligence, big data and other technologies has promoted the construction opportunities of intelligent ICU. Intelligent ICU needs to be upgraded intelligently in the aspects of disease detection, prediction, auxiliary decision-making, resource allocation and telemedicine to improve the efficiency of ICU treatment.
Methods. We developed a set of ICU intelligent patrol robot, which combines with ICU intelligent system, integrates artificial intelligence, Internet of things, 5G, big data, and has the functions of real-time collection of patient multimodal data, automatic analysis, early warning and prediction, department resource management, teleconsultation. We connected the ICU intelligent patrol robot with the ICU information system, and carried out clinical operation and multi-center verification.
Results. From January 2024 to December 2024, the ICU intelligent patrol robot was initially applied in a tertiary teaching hospital with 22 beds. During this period, a total of 781 critical ill patients' real-time multimodal data (including his system information, monitor information, ventilator waveform, blood filter parameters, and patient abnormal action data) were collected, and automatic analysis, early warning prediction, and ICU management support were carried out. Moreover, the ICU Intelligent Patrol Robot was applied and validated for remote consultation in another 21-bed tertiary teaching hospital, allowing real-time transmission of multi-dimensional patient information and audio/video consultation.
Conclusions. The intelligent patrol robot in ICU has the functions of real-time collection of patient multimodal data, automatic analysis, early warning and prediction, department resource management, teleconsultation, which can effectively improve the level of ICU intelligence and treatment efficiency. ICU intelligent patrol robot is a necessary node device in the future development of intelligent ICU.

Improving post-operative blood management in patients undergoing breast reconstructive surgery

E. Duncan.[1]
[1]Critical Care, Northern Beaches Hospital, Frenchs Forest, Australia.
Correspondence: E. Duncan.

Intensive Care Medicine Experimental, ***2025*;13(1)**: ***000587***.

Introduction. Blood transfusions are more frequent in breast reconstruction patients compared to simple mastectomy with rates of 20–30% vs 4%, respectively. Risk factors include preoperative anaemia, intraoperative blood loss and bilateral surgery. Many surgeons aim for haemoglobin of 90 g/L and haematocrit of 0.25 due to concern for flap failure.
Stringent blood management is associated with reduced morbidity and mortality as well as cost saving. Following studies into postoperative blood management, contemporary practice favours a restrictive approach to haemoglobin targets.
Objectives. This project aimed to review current practice of postoperative blood management in patients with breast cancer undergoing mastectomy with breast reconstruction. These patients were admitted to the High Dependency Unit in a large metropolitan hospital in New South Wales, Australia.
Following a review of current practice, the unit worked with the surgical team to optimise blood transfusion rates.
Methods. This was a retrospective audit patients admitted from January 2023 to January 2025. Data were extracted from operative anaesthetic forms; clinical ward round entries; observation charts and pathology reports. A total of 40 patients were included. Measures were subsequently implemented by the critical care and surgical team to reduce blood transfusion rates.
Results. 40 patients were included in the audit with an average age of 53 years and 100% female. 60% (24/40) patients received at least 1 unit of packed red blood cells. The average number of units per transfusion was 1.72 at initial audit. The majority of patients received their first unit within 24 h of surgery. The most common transfusion threshold was 85 g/L of haemoglobin. It was noted that patients who received

transfusion received more post-operative intravenous fluid but minimal difference in perioperative fluids.
A reduction in transfusion thresholds and careful fluid prescribing resulted in a 42% reduction in blood transfusion and the average unit rate was reduced 1.0 unit per a transfused patient with no reported adverse events.
Conclusions. Breast reconstruction patients are frequently transfused following their operation with relatively high haemoglobin threshold due to concern for flap failure. Although it cannot be completely extrapolated to plastic surgery, evidence from cardiothoracic surgery have shown no inferiority in lower targets therefore this approach should be considered in this population. This audit shows that the majority of patients were transfused at thresholds between 75 and 90: restrictive transfusion practices would eliminate a large proportion of these transfusions.
Recent studies show goal-directed fluid therapy reduces length of stay and result in no increase in complications and that the use of vasopressors does not increase the risk of flap failure. This audit shows patients who are transfused, on average, receive significantly more intravenous fluids. Careful fluid prescribing, particularly in the first 24 h after surgery, is imperative to prevent unnecessary transfusion due to haemodilution.
Simple postoperative interventions can significantly reduce transfusion rates with no documented incidents of flap failure or other complications as shown in this quality improvement project.

USP52 regulates STAT2 stability and potentiates IFN-I signaling: a novel target for antiviral therapy

X. XIAO[1]; S. Li[1]; F. Huang[1]; J. Wang.[1]

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000588***.

Introduction. Viral infections account for over 75% of all infectious diseases worldwide, posing a critical threat in intensive care settings. In severe viral illness, dysregulation of host immune responses often leads to poor outcomes. Type I interferons (IFN-I) are central to the innate antiviral defense, initiating transcription of interferon-stimulated genes (ISGs) that restrict viral replication. However, therapeutic use of IFNs has shown limited success, partly due to incomplete understanding of the regulatory mechanisms controlling IFN-I signaling. Deubiquitinases (DUBs), enzymes that remove ubiquitin from target proteins, have emerged as important post-translational regulators of immune pathways, but many remain poorly characterized.
Objectives. To investigate the role of USP52, a deubiquitinase, in modulating IFN-I signaling and antiviral immunity through regulation of STAT2 protein stability.
Methods. PBMCs were isolated from clinically confirmed viremic patients and healthy donors. mRNA levels of USP52 were measured using RT-qPCR. USP52 was knocked down in vitro using CRISPR-Cas9. Changes in cellular viral susceptibility following the absence of USP52 were assessed using VSV-infected cells, followed by quantification of viral replication by RT-qPCR, Western blotting, and fluorescence microscopy. ifnar1 knockdown MEF cells were used to confirm IFN-I-dependence. Effects of USP52 on STAT2 protein levels, stability and interactions were assessed by co-immunoprecipitation, CHX chase assay and treatment with proteasome (MG132) or lysosomal (MA) inhibitors. The ubiquitination pattern of STAT2 was assessed to identify specific linkage types affected by USP52.
Results. USP52 expression was significantly reduced in PBMCs from infected individuals compared to healthy controls. Knockdown of USP52 resulted in increased viral replication and decreased antiviral gene expression. Notably, the antiviral effect of USP52 was lost in IFNAR1-deficient cells, confirming its dependence on the IFN-I pathway. USP52 did not enhance IFN-β production, but significantly upregulated the expression of downstream ISGs, such as ISG15 and MX1. Immunoprecipitation assays revealed a direct interaction between USP52 and STAT2. Knockdown of USP52 led to rapid STAT2 degradation, which was reversed by proteasome inhibition but not by lysosome inhibition. Ubiquitination assays showed that USP52 specifically inhibited K48-linked polyubiquitination of STAT2, thereby preventing its proteasomal degradation and prolonging its half-life.
Together, these findings demonstrate that the deubiquitinase USP52 stabilizes STAT2 protein levels by inhibiting its K48-linked polyubiquitination and proteasomal degradation, thereby maintaining the integrity of the type I interferon signaling pathway and promoting the expression of downstream ISGs, ultimately enhancing the antiviral activity of IFN-I.
Conclusions. USP52 is a critical positive regulator of IFN-I-mediated antiviral immunity. By stabilizing STAT2 through inhibition of K48-linked ubiquitination, USP52 enhances ISG expression and restricts viral replication. These findings identify USP52 as a promising therapeutic target to augment interferon responses in patients with severe viral infections. This mechanism may offer a novel strategy to overcome current limitations in IFN-based antiviral therapies, with potential relevance in the treatment of viral sepsis, emerging viral pandemics, and immunocompromised states. Future research may focus on small-molecule modulators of USP52 activity as adjuncts to existing antiviral regimens.

Introduction. Monitoring of the inflammatory state in critically ill patients is pivotal for early detection and progression of sepsis and systemic inflammatory response syndrome (SIRS) [1,2]. Sepsis, a leading cause of mortality in ICUs, necessitates timely intervention guided by accurate inflammatory assessment [3]. Perioperative inflammation, a known trigger of postoperative complications [4], highlights the demand for real-time, non-invasive monitoring tools. Current biomarkers often lack real-time capability or require invasive sampling. Heart rate variability (HRV), reflecting autonomic regulation, has emerged as a potential inflammatory indicator [5], though its specificity is confounded by anesthetic modulation [6]. At ESICM 2024, we introduced the Trending of Sepsis and Inflammation (TSI) index, a non-invasive tool integrating HRV and EEG-derived consciousness monitoring [7]. The TSI is now enhanced with sample entropy of the RR signal, a non-linear parameter capturing autonomic complexity. Non-linear HRV metrics, such as sample entropy, are increasingly recognized for characterizing dysregulated inflammatory states [8], offering improved sensitivity. This updated TSI-E aims to refine real-time perioperative inflammatory monitoring.
Objectives. To evaluate the ability of the Trending of Sepsis, Inflammation, and Entropy (TSI-E) index—a novel update integrating sample entropy of the RR signal—to assess inflammatory responses following surgical stimuli. Surgical stimuli elicit inflammation, resulting in significantly higher TSI-E values postoperatively compared to preoperative baselines. Anesthetic confounders are controlled via stable Brain Activity (BA) index measurements.
Methods. A prospective observational study, approved by the local ethics committee, enrolled 41 ASA I-II patients undergoing major abdominal or thoracic surgery at Hospital Quirón Salud Barcelona. Written informed consent was obtained from all participants. The Trending of Sepsis, Inflammation, and Entropy (TSI-E) index—an updated metric incorporating sample entropy of the RR signal, HRV parameters (RMSSD, LF/HF ratio), and the Brain Activity (BA) index (a validated consciousness index analogous to the Bispectral Index, BIS)—was recorded using the CoreSys One monitor (CoreSys Health S.L., Barcelona, Spain). Continuous 5-min data segments were analyzed pre- and post-surgical stimulus under standardized anesthesia. The statistical significant values was considered to be $p < 0.05$.
The TSI-E, developed by CoreSys Health, quantifies inflammatory status on a 0–100 scale: 0–25 (normal), 25–50 (mild inflammation), 50–75 (strong inflammation/risk of sepsis/SIRS), and 75–100 (severe inflammation/septic shock risk). Statistical analysis included Wilcoxon signed-rank tests for pre/post-comparisons and PK statistics to evaluate the behavior of the TSI-E between the pre- and post-surgical stimulus groups. Anesthetic confounders were controlled via stable BA index measurements (p = NS).
Results. Wilcoxon signed-rank tests demonstrated a significant postoperative increase in TSI-E values ($p \leq 0.0005$), supporting the hypothesis that surgical stimuli elicit inflammation. Median TSI-E rose from 12.01 (IQR: 1.04–23.35; normal range) preoperatively to 29.58 (IQR: 25.73–32.58; normal-to-mild transition) postoperatively (Fig. 1). The TSI-E's predictive accuracy, quantified by the PKjstatistic (0.8593), surpassed prior TSI iterations, reflecting enhanced sensitivity to inflammatory dynamics through the integration of sample entropy. Brain Activity (BA) index stability (ΔBA < 5%, p = NS) confirmed consistent anesthesia depth, ruling out autonomic confounders.
Conclusions. The TSI-E index demonstrated significant postoperative increases, supporting its ability to detect surgically induced inflammatory responses through the integration of sample entropy—a non-linear metric capturing autonomic complexity. With strong predictive accuracy (PKj = 0.8593) and stable Brain Activity (BA) index values (p = NS), TSI-E shows promise as a real-time, non-invasive tool for inflammatory monitoring. Future studies should validate TSI-E against gold-standard inflammatory biomarkers (e.g., IL-6, procalcitonin).

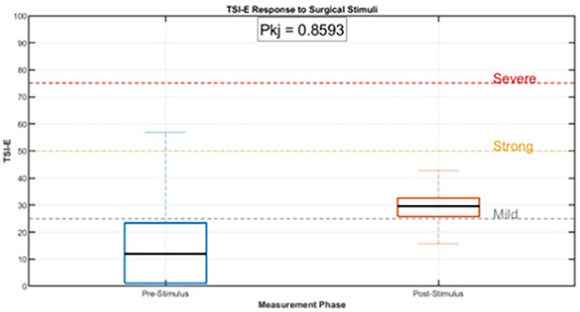

Fig 1 (abstract 000589) Boxplot comparing TSI-E scores before (pre-surgical stimulus) and after (post-surgical stimulus) surgical intervention in 41 ASA 1–2 patients. Post-stimulus TSI-E values increased significantly (median pre: 12.01 vs. post: 29.58), transitioning from normal (0–25) to mild (25–50) inflammatory ranges

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000591***.

Introduction. Cefotaxime, a widely used beta-lactam in the intensive care units (ICU), exhibits high inter-individual pharmacokinetic (PK) variability in critically ill patients due to altered physiology. Although population PK models exist for different groups, most are based on intermittent administration and have no external validation in the critical care context. Current ICU guidelines favor continuous infusion for beta-lactams, but there are no models that have been validated for the cefotaxime.
Objectives. Given this gap and the clinical importance of achieving therapeutic goals, this study evaluates the predictive performance of existing PK models for cefotaxime using external data from continuous infusion ICU patients.
Methods. In this study, adult ICU patients receiving continuous cefotaxime infusion with therapeutic drug monitoring were retrospectively analyzed. Exclusion criteria included age < 18 years, pregnancy, renal replacement therapy, or ECLS. Population PK models were selected from the literature based on their reproducibility and evaluated using external clinical data in R software, accuracy was assessed using prediction error metrics. Based on the best model, personalized dosing was calculated to achieve target concentrations of 20 or 40 mg/L based on bacterial MICs or theoretical threshold to support optimized and individualized antibiotic therapy in critically ill patients.
Results. Two population PK models for cefotaxime were externally validated in 72 ICU patients receiving continuous infusion. The models of *Urien* et al.(1) and *Swartling* et al. (2) were selected based on their applicability and availability of covariates. Both showed under-prediction of observed concentrations, with Swartling's model showing better precision (MDAPE 20%) and lower bias (MDPE -20%) than Urien's (30%, -27%). The Swartling model, derived from ICU data, enabled individualized dosing simulations to achieve target concentrations (20–40 mg/L), highlighting its utility for model-based precision dosing in critically ill patients. (Fig. 1).
Conclusions. This study demonstrates that both PK models, originally developed for intermittent administration of cefotaxime, are also applicable to continuous infusion ICU patients. The Swartling model showed a higher predictive power and greater relevance for critically ill patients. It allows for individualized dosing based on renal function and body weight. Despite a tendency to underestimate concentrations, the model provides acceptable accuracy and clinical utility. These results support the use of the model as a dosing reference and highlight the importance of therapeutic drug monitoring to optimize cefotaxime therapy, especially in severe infections and variable renal function.

Prognostic and predictive value of stress hyperglycemia ratio in ARDS patients under the 2023 new global definition: a multicenter cohort study

S. Li[1]; Y. Wang[1]; X. Liu[1]; C. Chen.[1]
[1]Thoracic surgery, Shanghai Pulmonary Hospital, Shanghai, China.
Correspondence: S. Li.
Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000593***.

Introduction. The 2023 global new acute respiratory distress syndrome (ARDS) definition modifies the 2012 Berlin criteria to addresses its applicability in non-intubated patients or resource-limited settings, resulting in the greater population heterogeneity (1). There remains a critical unmet need for reliable biomarkers capable of facilitating accurate risk stratification and guiding personalized therapeutic interventions in ARDS patients under this revised definition (2).
Objectives. We aim to explore the value of stress hyperglycemia ratio (SHR) in predicting clinical outcomes and guiding personalized hypoglycemic therapy (HGT) in patients under the 2023 revised ARDS definition.
Methods. In this multicenter, retrospective cohort study, 852 ARDS patients who meet the 2023 global definition were stratified into low SHR (n = 525) and high SHR groups (n = 327). Overall survival (OS) were analyzed by Kaplan–Meier method, and prognostic factors were identified by multivariable Cox proportional hazards models. Predictive performance was evaluated via Harrell's concordance index (C-index) and area under the time-dependent receiver operating characteristic curve (AUC), comparing baseline and integrated survival models.
Results. Survival analysis demonstrated that elevated SHR levels were significantly associated with worse OS, along with higher in-hospital, 28-day, and 90-day mortality. Cytokine profiling revealed markedly increased plasma concentrations of IL-12p70, IL-6, IL-8, IL-17A, and TNF-α in high-SHR patients compared to the low-SHR group. Multivariable analysis identified SHR status as an independent predictor of OS (HR: 2.427, 95% CI: 1.578–3.733), with consistent results across both intubated (HR: 2.634, 95% CI: 1.568–4.424) and non-intubated (HR: 3.935, 95% CI: 1.836–8.437) subgroups. Incorporation of SHR status into the baseline model significantly improved its predictive accuracy for OS, increasing the C-index from 0.657 to 0.712 and AUC from 0.690 to 0.747. Among hyperglycemic ARDS patients, hypoglycemic therapy (HGT) conferred survival benefits exclusively in high-SHR cases, regardless of intubation status.
Conclusions. Elevated SHR status was independently associated with increased mortality risk in ARDS patients meeting the 2023 global definition. Notably, among hyperglycemic patients, HGT brought significant survival benefits exclusively to the high-SHR cases.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000595***.

Introduction. RMg utilises rapid nanopore sequencing to identify a comprehensive respiratory pathogen profile earlier than conventional testing(1). RMg sequencing was introduced at University Hospital Southampton NHS Foundation Trust (UHS) in December 2024 as part of a UK pilot implementation project(2). To understand and deliver recommendations into clinical practice, multidisciplinary team (MDT) interpretation and advice was implemented.
Objectives. To assess the outcome of RMg sequencing combined with MDT interpretation on AMS outcomes in adult and paediatric critical care.
Methods. An MDT (healthcare scientist, microbiologist, pharmacist, virologist) reviewed RMg results twice a week to interpret, discuss and communicate findings in February and March 2025. Patients from all ICU areas (general, paediatric, cardiac, neurology) at UHS were eligible for inclusion. Patients were referred for RMg if: they were a new ICU admission for lower respiratory tract infection; or they exhibited a new deterioration in markers of respiratory function; or there were no organisms identified by conventional methods or concern that an organism had not been detected. The MDT determined implications for patient care and findings were disseminated to clinical teams by multiple routes with an immediate focus on those that were time critical. AMS decisions were stratified into pre-agreed outcomes (Table 1).
Results. Sixty-four respiratory samples from 62 patients were sequenced and discussed. The majority of samples 36/64 (56%) were from general adult ICU followed by paediatric ICU 10/64 (16%). Most samples were endotracheal aspirates 41/64 (64%), with the remainder being sputum 14/64 (22%), bronchoalveolar lavage 7/64 (11%) and pleural fluid 2/64 (3%). In 50/64 (78%) cases the MDT outcome impacted clinical care including: assurance of current treatment 35/64 (55%); change to antimicrobial prescription 8/64 (12%) and other predetermined outcomes (Table 1). Antimicrobial (AM) therapy was optimised in 15/64 (23%) of cases. Of these, in 7/64 (11%) cases the RMg sequencing identified unexpected pathogens resulting in a significant change to treatment or investigation focus.

Table 1: (abstract 000595) AMS outcomes.

AMS outcome	Number	%
Continuation of current regime (results support current plan/reassurance)	35	55
AM prescription changed based on RMg (length/backup)	8	12
AM stopped: reduction in number or all AM	4	6
AM regime changed resulting in broader spectrum AM therapy (escalation)	2	3
AM regime changed resulting in narrower spectrum AM therapy (de-escalation)	1	2
Positive outcome on clinical care—total	*50*	*78*
RMg result did not impact current treatment (inc. run failure)	14	22

Conclusions. RMg sequencing, interpretation and discussion in MDT allowed for full utilisation of RMg results in supporting AMS decisions for patient care. The scientist's role in interpreting the raw metagenomic results was vital to allow for treatment decisions to be made. In over two-thirds of cases there was reassurance of current therapy or changes to therapy made, giving confidence to the MDT review model.

Introduction. Lung transplantation is the treatment of choice for patients in the final stage of their lung disease. Infections in this population significantly reduce their survival.
Objectives. The objective of this study is to analyze the early infection of the graft and its relationship with the infection of the preservation fluid.
Methods. This is a retrospective study that analyzes the data of 21 donors with their respective recipients from July 2023 to December 2024. Clinical data, all available cultures of preservation fluids, pretransplant donor respiratory cultures and post-operative recipient cultures in the intensive care unit were analyzed.
The lungs were kept in a bag immersed in Perfadex® preservation fluid and surrounded by ice to maintain a temperature of 4oC during cold ischemia for transport. Two samples of preservation fluid, one for each lung, were sent for culture.
All patients were treated with antibiotic treatment based on prior cultures from a known donor or recipient prior to transplantation.
Results. The prevalence of positive cultures of the preservation fluid was 98% (41/42). The frequencies of microorganisms isolated in the preservation fluid are shown in table and Fig. 1. 47.6% (20/42) of the preservation fluid samples were polymicrobial, and 15 (23%) were positive for at least one high-risk microorganism. The most common single-agent isolated microorganism were Staphylococcus epidermidis (32%) and methicillin-sensitive Staphylococcus aureus (10%), with 33% being a low-risk staphylococcus case.
Conclusions. Despite the near 100% incidence of preservation fluid infection, the rate of related pneumonia is 0. Since almost all the fluids

were contaminated, we cannot clarify the debate about whether the infection of the preservation fluid is related to increased mortality or morbidity in the lung transplant patient.

Introduction. In acute respiratory failure (ARF), both oxygenation and ventilation are typically impaired. Oxygenation is non-invasively monitored using pulse oximetry, while respiratory rate (RR) measurement outside the ICU is typically performed intermittently and manually by nursing staff. In non-intubated patients, tidal volume and inspiratory/expiratory times cannot be continuously monitored without interfering with natural breathing.
Temperature fluctuations within a Venturi mask may be used to detect respiratory phases, enabling continuous RR monitoring in patients receiving oxygen therapy. These signals could also serve as surrogates for tidal volume and the inspiratory-to-expiratory (I:E) ratio. We hypothesize that introducing external airflow to the mask will attenuate the tidal volume signal while preserving RR and timing information.
Objectives. To assess the correlation between temperature signals inside a Venturi mask and respiratory pattern parameters (RP) in healthy volunteers (HV) and to evaluate how these signals behave under various oxygen flow conditions.
Methods. This observational study was conducted with HV positioned supine, with an up tilt 30°. Simultaneous recordings included:
Temperature signals from four SC50 thermistors embedded in a Venturi mask.
Thoracic and abdominal plethysmography signals.
A previous study using a pneumotachograph and an airtight mask in HV demonstrated strong correlations ($r > 0.9$) for RR, timing, and volume parameters (Fig. 1).Each HV underwent a 3-min baseline recording followed by recordings during six different breathing patterns (mouth/nose breathing, shallow/deep respiration) under oxygen flow rates from 0 to 15 L/min, as well as under high-flow nasal cannula (HFNC) at 50 and 60 L/min.
Advanced signal processing techniques were applied to extract respiratory parameters (Fig. 2). Signals from upper and lower thermistors were combined and compared with the summed thoracic and abdominal plethysmography data. Linear cross-correlations (r) were computed for RR, I:E ratio, and volume surrogates, expressed as mean ± standard deviation (SD).
Results. Across all recordings, temperature signals showed strong correlations with plethysmography: RR ($r = 0.98 \pm 0.01$), inspiratory time/total time ($r = 0.88 \pm 0.07$), expiratory area ($r = 0.80 \pm 0.09$), and amplitude–volume surrogate ($r = 0.69 \pm 0.13$). When rapid shallow breathing was simulated, the patterns led to a reduced correlation, particularly with added external flows of 8 and 12 L/min. HFNC at 50 L/min maintained significant correlations ($p < 0.05$) for RR (0.65 ± 0.19), inspiratory to total time (0.65 ± 0.16), and volume/amplitude measures (0.69 ± 0.21).
Conclusions. Temperature signals from within a Venturi mask reliably reflect breathing pattern in healthy volunteers, showing high concordance with plethysmographic data supporting the feasibility of non-invasive respiratory monitoring during oxygen therapy. The system's behavior needs to be improved to ensure better performance with the addition of external flows.

Introduction. In acute respiratory failure (ARF), patient self-inflicted lung injury has emphasized the importance of non-invasive early breathing pattern (BP) assessment.
Objectives. To describe clinical characteristics and BP in patients with ARF secondary to pneumonia and to study its early predictive capacity for unfavorable outcomes (UO).
Methods. This prospective, multicentre observational study included adult patients with ARF due to bacterial or COVID pneumonia requiring oxygen therapy. Exclusion criteria: prior or in-episode non-invasive ventilation, or PaO_2/FiO_2 < 100 on high-flow nasal cannula (HFNC). UO was defined as PaO_2/FiO_2 < 100 on HFNC, mechanical ventilation, or death.
Severity scores, clinical and analytical data were collected at inclusion. BP was recorded for 5 min using SC50 temperature sensors placed in a Venturi mask and analyzed with advanced algorithms to extract breath-by-breath parameters (Fig. 1). Statistical analysis included multivariate modeling.
Data are presented as median (IQR)*p < 0.05 for differences between-groups.
Results. 82 were included: 67 (82%) had favourable (FO) and 15 (18%) (UO).
The relevant clinical and signal characteristics of patients with both outcomes are shown in Table 1,2 and Fig. 2.
Multivariate analysis identified lymphocyte % (↓, p = 0.005), CRP (↑, p = 0.003), and amplitude variability (CV, ↑, p = 0.008) as independent predictors of unfavorable outcome.

Table 1: (abstract 000600) Clinical characteristics

	FO	UO
Female (%)	44.8	40
Age (y)	72 (62–81)	75 (59–80)
BMI (kg/m^2)	28 (25–31)	27 (24–31)
FiO_2*	0.26 (0.24–0.28)	0.31 (0.28–0.35)
O_2 flow (L/min)*	4 (3–6)	6 (4–15)
$PaCO_2$ (mmHg)*	37.5 (34.3–43.1)	33.2 (30.1–36.8)
Borg scale*	2 (0–4.5)	4 (2–6)
Lymphocytes (%)*	11 (7–15)	6 (5–10)
CRP (mg/dL)*	11 (5–19)	25 (6–39)
D-dimer (ng/dL)*	627 (608–1083)	4300 (4300–4321)

Table 2:(abstract 000600) BP Parameters

	FO	UO
TTOT (seg)	2,82 (2,11–3,34)	1,86 (1,73–3,16)
CV TTOT*	0,21 (0,16–0,27)	0,32 (0,27–0,51)
RR (bpm)	23.5 (21.2–25.9)	27.9 (24.1–32.1)
CV RR*	0.23 (0.16–0.31)	0.32 (0.23–0.43)
Amplitude (V)	0.24 (0.17–0.33)	0.19 (0.15–0.26)
CV amplitude*	0.53 (0.31–0.68)	0.93 (0.58–0.98)

Conclusions. Patients with UO exhibited greater variability in initial BP, particularly in signal amplitude, suggesting its potential role as an early non-invasive prognostic biomarker in pneumonia-induced ARF.

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000604***.

Introduction. Recent large-scale multi-center clinical trials and meta-analyses in post-cardiac arrest patients failed to demonstrate efficacy of targeted temperature management (TTM). However, it is unclear if there are distinguishable subgroups in which TTM remains a viable treatment. Causal machine learning is a promising approach to investigate this question.
Objectives. The principal objective is to explore heterogeneous treatment effect (HTE) among adult cardiac arrest patients receiving TTM.
Methods. The analysis was carried out in two datasets: (a) the eICU Collaborative Research Database, which includes 2168 adult cardiac arrest patients eligible for TTM, with 464 receiving TTM; and (b) a randomized trial of 581 cardiac arrest patients with non-shockable rhythm, with 284 receiving TTM (Hyperion, NEJM 2019). We used data from the first 6 h following ICU admission as predictive variables. Clinical endpoints were survival at discharge and the last measured motor subscore of the Glasgow Coma Scale (mGCS) in eICU, while in Hyperion we examined survival and CPC scores at 90 days. We evaluated model performance by classification prediction on the data with a holdout estimator. To identify HTE, we employed several machine learning methods that have been successfully implemented in prior research: S-Learners with XGBoost, Bayesian Additive Regression Trees (BART), Neural Networks, and R-learners with CausalForestDML. We assessed HTE by fitting a logistic regression model with individualized treatment effect (ITE) predictions and treatment, as well as a model with an interaction term between ITE and treatment. A likelihood ratio test ($p > 0.05$) was used to evaluate whether the model with the interaction term was superior.
Results. In the outcome prediction task, all models performed well on test data for binary classification of outcome (Table 1). TTM was not identified as a significant predictive variable determining outcome after cardiac arrest. The CausalForestDML output did not predict that TTM has any effect in the studied samples (Figs. 1 and 2). Moreover, across all models, there was no evidence of HTE for either mortality and neurological outcome in cardiac arrest patients receiving TTM.

Table 1: (abstract 000604) Model performance and p-values for likelihood ratio test

Dataset	Outcome	Model	LLR p-value	AUC ROC	AUC ROC 95% CI
eICU	Mortality	Neural-Network	0.57	0.76	[0.73,0.80]
eICU	mGCS 6	Neural-Network	0.39	0.79	[0.76,0.83]
eICU	Mortality	XGBoost	0.68	0.77	[0.73,0.80]
eICU	mGCS 6	XGBoost	0.93	0.78	[0.74,0.81]
eICU	Mortality	BART	0.29	0.78	[0.74,0.81]
eICU	mGCS 6	BART	0.61	0.80	[0.76,0.83]
eICU	Mortality	Causal-Forest-DML	0.07	NA	NA
eICU	mGCS 6	Causal-Forest-DML	0.17	NA	NA
Hyperion	Mortality	Neural-Network	0.57	0.80	[0.71,0.88]
Hyperion	CPC 1–2	Neural-Network	0.39	0.83	[0.74,0.91]
Hyperion	Mortality	XGBoost	No Effect	0.76	[0.67,0.85]
Hyperion	CPC 1–2	XGBoost	No Effect	0.81	[0.68,0.91]
Hyperion	Mortality	BART	0.86	0.78	[0.70,0.86]
Hyperion	CPC 1–2	BART	0.75	0.85	[0.75,0.93]
Hyperion	Mortality	Causal-Forest-DML	0.07	NA	NA
Hyperion	CPC 1–2	Causal-Forest-DML	0.20	NA	NA

Conclusions. Our analysis confirms prior work that TTM does not improve survival or neurological outcome either in the short-term or at 90 days. Contrary to our primary hypothesis, we found no evidence of either HTE or ITE across subgroups. Our ongoing research is exploring HTE in other large cardiac arrest datasets, however the results to date indicate that alternative mechanisms are needed to explain the lack of efficacy of TTM as a treatment modality in the post-cardiac arrest setting.

Early mastoid effusion on brain imaging is an independent prognostic marker after aneurysmal SAH

S. Kim[1]; J. Oh.[2]

Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000605***.

Introduction. Early mastoid effusion on brain imaging is an independent prognostic marker after aneurysmal SAH
Objectives. The clinical significance of mastoid effusion (ME) in intensive care unit (ICU) patients has not been well elucidated. Recently, an association between ME and intracranial pressure (ICP) has been reported. We aimed to investigate the clinical implications of ME occurrence in the management of aneurysmal subarachnoid hemorrhage (aSAH) patients and its association with the prognosis.
Methods. Data for patients aged > 18 treated for aSAH in a single institution between January 2020 and December 2022 were retrospectively reviewed. Brain CT or MRI images obtained within the first 14 days after the onset of SAH were evaluated for the presence of ME defined as opacification or air-fluid level in the mastoid air cells. We reviewed the patients' demographic information, neurological and medical status at admission, aneurysm and treatment characteristics and clinical outcomes, and analyzed their association with the occurrence of ME.
Results. A total of 114 patients was included for the study. ME was observed in 40 patients (34.5%) within the first 14 days, at a mean of 5.0 ± 3.5 days after the onset of SAH. In multivariate analysis, patients with ME were associated with a higher incidence of tracheostomy (Odds ratio [OR] 10.034, $p = 0.024$), radiologic vasospasm (OR 4.987, $p = 0.018$), higher APACHE II score (OR 1.138, $p = 0.013$), and a poor clinical outcome (OR 4.289, $p = 0.041$) defined as modified Rankin Scale > 2 at 90 days. Poor clinical outcome was independently associated with ME (OR 5.003, $p = 0.006$).
Conclusions. This study demonstrated that ME was observed in 34.5% of aSAH patients, and was associated with poor clinical outcomes. ME may serve as a simple and useful prognostic factor for predicting poor outcomes in aSAH patients.

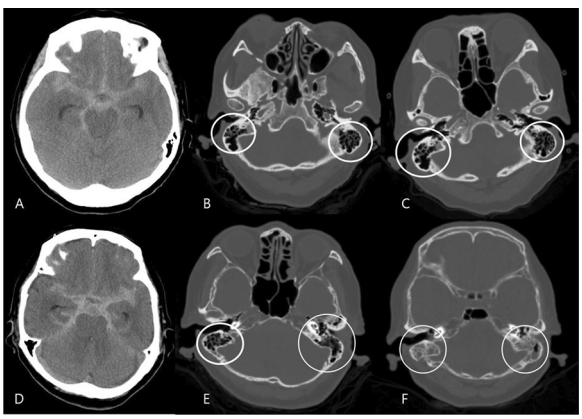

Fig 1 (abstract 000605) Mastoid effusion (ME) in patients with subarachnoid hemorrhage (SAH). (A-C) Case with absence of ME. A 66-year-old female patient with an initial Fisher grade III SAH. The initial brain CT scan showed no evidence of ME. A follow-up CT scan two week later also showed no signs of ME (white circle). The patient's modified Rankin Scale (mRS) score at post-operative 90 days was 0. (D-F) Case with presence of ME. An 80-year-old female patient with Fisher grade III SAH on the initial CT scan, with no signs of ME. Two weeks later, a follow-up CT scan revealed bilateral ME (white circle). The patient had an mRS score of 4 at post-operative 90 days

Introduction. Sepsis is a life-threatening pathological condition with devastating effects on all organ functions. Patients who survive during the initial phase, either enter a persistent hyperinflammatory state resulting in multiple organ failure or move into a chronic immunosuppressive state, both characterized by high mortality rates.
Objectives. To investigate the pyroptotic and apoptotic alterations and the immunosuppressive signals (HLA-DR + innate immunity cells) observed in septic pediatric and adult patients.
Methods. The sample of this prospective single-centre study consisted of adult and pediatric ICU patients with sepsis (S) compared to non-infectious inflammation (I) and healthy controls (C). Whole blood samples were collected within 24 h of ICU admission, following consent, and caspases 1 (pyroptosis), 3, 7, 8 (apoptosis) and CD14 + / HLA-DR + cells (immunosuppressive signal) were determined by flow cytometry in peripheral blood mononuclear cells. Demographics, clinical data and outcomes were recorded.
Results. Out of 120 patients enrolled in the study, n = 51 were adults (sepsis (S) 13, SIRS (I) 10, healthy controls (C) 28) and n = 69 were pediatric patients (28 (S), 31 (I) and 10 (C)). Pyroptotic lymphocytes expressing caspase 1 (AUROC 0.676, p = 0.033), apoptotic lymphocytes expressing caspase 3/7 (AUROC 0.731, p = 0.001), and pyroptotic monocytes expressing caspase 1 (AUROC 0.716, p = 0.009) highly predicted mortality in septic patients. Moreover, apoptotic neutrophils expressing caspase 3/7 (AUROC 0.813, p < 0.001) and caspase 8 (AUROC 0.860, p < 0.001), as well as apoptotic monocytes expressing caspase 8 (AUROC 0.839, p < 0.001) were also identified as mortality predictors. (Fig. 1) CD14 + /HLA-DR + expressing monocytes were significantly reduced in sepsis as compared to healthy controls (p = 0.05).
Conclusions. Increased stimulation of pyroptotic lymphocytes and monocytes along with apoptotic lymphocytes have a highly prognostic value for non-survivors. Apoptosis of neutrophils and monocytes also indicates a significant risk of mortality in sepsis. Low HLA-DR expression in septic patients demonstrated an immunosuppressive state.

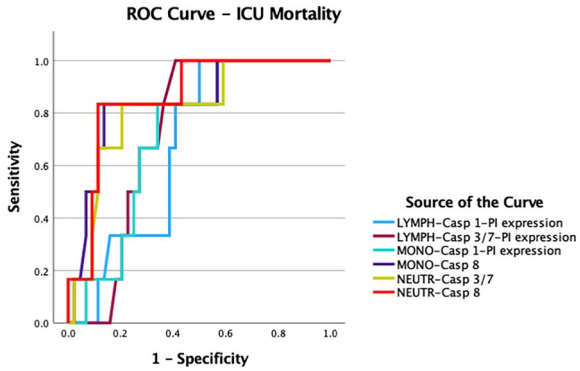

Fig 1 (abstract 000606) ROC curve demonstrating ICU mortality by stimulation of pyroptosis and apoptosis in septic patients

Health professionals' perceptions of implementing a novel family support intervention in intensive care units (FICUS): findings from a multicenter, quantitative study

S. Oesch[1]; M. Riguzzi[1]; L. Verweij[1]; R. Naef.[1]
[1]Institute for Implementation Science in Health Care, University of Zurich, Zürich, Switzerland.
Correspondence: R. Naef.
Intensive Care Medicine Experimental*, *2025*;13(1)**: ***000609.

Introduction. The FICUS cluster-randomized controlled trial (cRCT) (Naef et al., 2022) compares a nurse-led and interprofessionally delivered family support intervention (FSI), implemented using a tailored strategy (Verweij et al., 2023), to usual care. The FSI includes a family care pathway with three core components: engagement and liaison, communication, and support. Designated family nurses were responsible for delivering the FSI to families from admission to the intensive care unit (ICU) through to the post-ICU phase. We examined the implementation of the FSI along the FICUS cRCT (Oesch et al., 2023).
Objectives. To investigate the FSI's acceptability, appropriateness, feasibility, normalization, expected sustainability, and its perceived benefit from health professionals' (HP) perspective.
Methods. This multicenter, cross-sectional, quantitative study included an online survey sent to 518 HPs (September 2023–April 2024) from eight ICUs at the end of an 18-month trial period, during which these ICUs delivered the FSI to family members who participated in the FICUS cRCT. The survey consisted of psychometrically validated instruments to assess the level of FSI normalization (G-NoMAD) (Freund et al., 2023), acceptability (Acceptability of Intervention Measure), appropriateness (Intervention Appropriateness Measure), feasibility (Feasibility of Intervention Measure) (Kien et al., 2021), and self-developed questions to assess the FSI's perceived benefit and expected sustainability after 12 months. Data were analyzed using descriptive statistics as well as mixed linear effects and logistic regression to identify predictors of FSI normalization, sustainability, and benefits.

Results. Overall, 228 participants (44%) completed the survey. The FSI's level of normalization (scale range: 20–100) was high (median = 82; 78% of scale range). Higher FSI normalization in ICU teams was predicted by the perceived need for the FSI and higher levels of acceptability, appropriateness and feasibility. Expected sustainability after one year was predicted by the FSI's feasibility. Perceived benefit of the FSI for family members, patients, or HPs' own work was positively associated with acceptability, appropriateness, and normalization. In addition, the perceived benefit of the FSI for ICU teamwork was predicted by HPs' perceived need for the FSI and its level of normalization.
Conclusions. This implementation study found that by the end of the FICUS cRCT, the FSI was highly normalized within the ICU teams. It was seen as an acceptable, appropriate, and feasible intervention, offering benefits for families, team collaboration, and HPs' individual work. Feasibility was identified as a key predictor of the FSI's expected sustainability. Further research is needed to explore FSI implementation in routine ICU care beyond the trial context and to assess its long-term sustainability in critical care settings.

Inflammation lingers: are steroids enough for deceased donor management?

AM. Goncalves Bullock[1]; A. Tridente[2]; N. Dempsey.[1]
[1]Life Sciences, Manchester Metropolitan University, Manchester, United Kingdom; [2]Critical Care, Whiston Hospital, St Helen's, United Kingdom.
Correspondence: N. Dempsey.
Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000612***.

Introduction. The process of death in deceased organ donors triggers a systemic inflammatory response potentially contributing to organ damage and less favourable recipient transplant (Tx) outcomes [1–4]. Current UK guidelines emphasise early donor steroid administration to modulate inflammation and maximise organ utilisation [5]. However, the dynamics of specific inflammatory mediators during the donor management period (DMP) are poorly understood, and their prognostic value for Tx outcomes remains undetermined.
Objectives. Using kidney donor plasma samples from the Quality in Organ Donation (QUOD) biobank [6] and linked recipient data, we studied the trajectories of three specific cytokines, Interleukin (IL)-8, IL-6 and C-reactive protein (CRP) (representative of early, intermediate and late-stage inflammation) during the DMP and determined their association with short- and long-term Tx outcomes.
Methods. We analysed samples from donation after brain death donors (DBD) (n = 50) and donation after circulatory death donors (DCD) (n = 50). DMP time points considered were; T1 (shortly after donor identification and consent) and T2 (at time of preparation for retrieval). Cytokines were analysed using Luminex immunoassay. Primary outcome was delayed graft function (DGF), defined as need for dialysis within 7 days post-Tx. Secondary outcomes were high serum creatinine at 3- and 12-months post-Tx, defined as > 104 µmol/L in males, or > 84 µmol/L in females. Tertiary outcomes were low estimated glomerular filtration rate (eGFR) at 3 and 12 months post-Tx, defined as < 60 mL/min/1.73 m^2.
Results. DGF was observed in 25% of recipients, while 82% and 75% presented with high 3-month and 12-month serum creatinine. Low 3- and 12-month eGFR was observed in 65% and 61%, respectively. IL-8 dropped to 8% of baseline levels (from T1 to T2) in DBD donors ($P \leq 0.0001$), but only dropped to 38% of baseline levels in DCD donors ($P \leq 0.01$). Conversely, IL-6 was seen to rise to 14 times that of T1 levels in DBD ($P \leq 0.05$) and to 63 times that of T1 in DCD ($P \leq 0.001$). CRP levels were increased to 70 times ($P \leq 0.0001$) and 22 times ($P \leq 0.0001$) that of T1 levels in DBD and DCD donors, respectively. Patients with poor creatinine clearance and poor eGFR function at 3 and 12 months had significantly higher levels of CRP and IL-8 than those patients with the respective better outcomes. Despite the stark increase in IL-6, no association was found with outcome.
Conclusions. Current immunomodulation protocols suppress NF-κB–driven cytokines such as IL-8 [7], while IL-6 and CRP increase, suggesting a differential regulatory effect of steroids that spares components of the acute-phase response. Inflammation persists in deceased donors [8,9] and is associated with less favourable Tx outcomes. The data support the growing evidence for more targeted immunomodulators in the DMP.

Implementation of an early warning score-based track-and-trigger system with proactive round improves outcomes in septic patients: a before-and-after study

R. Tanii[1]; T. Naito[1]; K. Hayashi[1]; S. Fujitani.[1]
[1]Department of Emergency and Critical Care Medicine, St. Marianna University School of Medicine, Kawasaki, Japan.
Correspondence: R. Tanii.
Intensive Care Medicine Experimental, ***2025***;**13(1)**: ***000613***.

Introduction. Early detection and timely intervention, including sepsis bundles, are critical for improving sepsis outcomes [1]. Sepsis, in particular, may benefit from Rapid Response Systems (RRS), which have a similar concept [2]. In 2023, our hospital implemented a new surveillance and proactive response system for high-risk inpatients. This implementation increased RRS activations from 10.3 to 74.1 per 1,000 admissions between 2022 and 2024.
Objectives. To evaluate whether this new surveillance-based proactive intervention system improved outcomes in septic patients.
Methods. This single-center, retrospective, before-and-after study included patients aged ≥ 20 years with unplanned ICU/HCU admissions due to sepsis in 2022 and 2024. Sepsis was defined as qSOFA ≥ 2 with positive cultures or suspected infection. ICU/HCU admission within 24 h of hospitalization, COVID-19, post-emergency operative, or palliative cases were excluded. In February 2023, our hospital implemented a digital dashboard that automatically calculates AI-based Early Warning Scores (EWS) and initiated nurse practitioner (NP)-led proactive round twice daily on daytime weekdays for high-risk inpatients as RRT (Rapid Response Team). The primary outcome was ICU/HCU discharge mortality. Secondary outcomes included 24-h and 30-day mortality after RRS activation, intubation and vasopressor duration, CRRT use, ICU/HCU length of stay, and adherence to key sepsis bundle components prior to RRS intervention related to ICU/HCU admission.
Data from 2023 were excluded due to transitional effects. Comparative analysis was performed between 2022 and 2024 using the Wilcoxon rank-sum test for continuous and the Chi-square test for categorical variables. We also performed multivariate logistic regression to evaluate the association between the new system and outcomes. Additionally, a survival analysis was conducted for the primary outcome stratified by the presence of new system and compared using the log-rank test. All analysis was conducted by R (v4.4.3).
Results. Among 334 unplanned ICU/HCU admissions, 77 met inclusion criteria (26 in 2022; 51 in 2024). No significant differences were observed in basic demographics, including National Early Warning Score (NEWS) on RRS activation, dialysis, blood culture positive rate, or DNAR status. Preemptive RRT round involvement increased significantly in 2024 (4% vs. 28%, p = 0.03), indicating the impact of the new proactive surveillance system. ICU/HCU discharge mortality (27% vs. 6%, p = 0.025) and 30-day mortality (42% vs. 10%, p = 0.002) decreased significantly in 2024. Vasopressor duration also decreased (1.5 days vs. 1 day, p = 0.02), while intubation duration showed a non-significant difference (p = 0.06). Among sepsis bundle components, only blood culture collection prior to ICU/HCU admission improved (46% vs. 78%, p = 0.009).
Multivariate logistic regression showed that the new system was independently associated with reduced ICU/HCU mortality (aOR 0.36, 95%CI:0.16–0.81, p = 0.014, Table). DNAR status was positively associated with mortality (aOR 7.1, 95%CI:1.23–41, p = 0.03). Age, sex, and NEWS score were not significant predictors. Kaplan–Meier analysis showed significantly higher survival with the new system in 2024 (log-rank test, p < 0.001, Figure).

Table. (abstract 000613) Multivariate Logistic Regression for ICU/HCU Discharge Mortality.

Variable	Adjusted OR	95% CI	p-value
Age (year)	1.01	0.97 – 1.06	0.548
Sex (female)	0.57	0.10 – 3.15	0.524
New System (2024)	**0.36**	**0.16 – 0.81**	**0.014**
NEWS on RRS activation	1.01	0.81 – 1.25	0.956
DNAR status	**7.09**	**1.23 – 41.00**	**0.029**

Conclusions. Implementing an EWS-based track-and-trigger system, with a proactive round, was associated with improved outcomes in septic patients requiring ICU/HCU admission. Notably, both ICU/HCU discharge and 30-day mortality were significantly reduced, and vasopressor duration was shortened. These findings suggest that a proactive surveillance and response system could enhance early sepsis management. Adherence to most sepsis bundle elements remains suboptimal, indicating a possibility for further improvement.

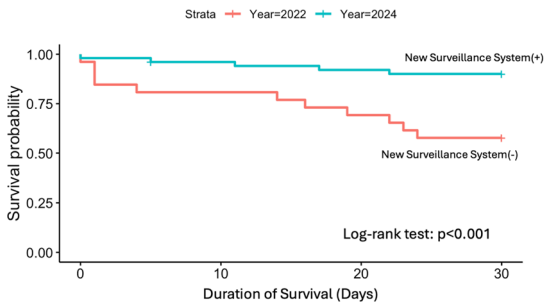

Figure (abstract 000613) Survival analysis with log-ran test
Kaplan–Meier survival curve comparing survival between patients in 2022 and 2024 (before and after system implementation).
Survival was significantly improved in 2024 with the new system (log-rank test, p < 0.001).

Introduction. In recent years, the therapeutic potential of dexmedetomidine in septic shock and sepsis-induced acute kidney injury (SAKI) has garnered increasing attention. Several studies have demonstrated that dexmedetomidine activates both AMPK and SIRT3, and a positive feedback loop may exist between these two proteins.
Methods. This study aims to further explore the efficacy and underlying mechanism of dexmedetomidine in ameliorating SAKI through

retrospective cohort study, molecular docking simulations, cellular and animal experiments.
Results. We analyzed 704 septic shock patients from the MIMIC-IV database and found that dexmedetomidine treatment was associated with improved renal function recovery and reduced in-hospital mortality. Dexmedetomidine alleviated mitochondrial dysfunction in SAKI through the promotion of mitophagy. Molecular docking simulations revealed a strong binding affinity of dexmedetomidine to both AMPK and SIRT3. Knocking out either AMPK or SIRT3 results in a decrease in the expression and activity of the other, indicating the existence of a positive feedback loop between them. Also, this study revealed that dexmedetomidine enhances mitophagy and alleviates mitochondrial dysfunction through the AMPK-SIRT3 positive feedback loop. Dexmedetomidine improves survival rates and attenuates renal injury in mouse model of SAKI, which was reversed by inhibiting AMPK or SIRT3.
Conclusions. These findings indicate that dexmedetomidine, via activating the AMPK–SIRT3 positive feedback loop, enhances mitophagy to ameliorate mitochondrial dysfunction in SAKI, suggesting its potential as a therapeutic agent for SAKI.

raphical Abstract: Dexmedetomidine ameliorates sepsis-induced acute kidney injury by promoting mitophagy through AMPK–SIRT3 positive feedback loop. Dex: dexmedetomidine; Rtecs: renal tubular epithelial cells; Saki: sepsis-induced acute kidney injury.

Introduction. Critically ill patients undergoing venovenous extracorporeal membrane oxygenation (V-V ECMO) often require prolonged deep sedation(1–3). Inhaled sedation has emerged as a feasible alternative to intravenous (IV) sedation for patients with respiratory failure requiring V-V ECMO and controlled mechanical ventilation(4).
Objectives. We aimed to evaluate the hemodynamic changes during the transition from IV to volatile sedation in this patient population.
Methods. This prospective, observational, single-center study included consecutive adult ARDS patients who received volatile sedation during V-V ECMO at IRCCS San Gerardo dei Tintori (Monza, Italy), between May 2022 and February 2025.
Hemodynamic parameters, doses of vasoactive drugs, sedative medications, and sedation levels were recorded every 2 h since ECMO commencement. Ventilatory parameters and blood gas analyses were collected every 8 h, and laboratory tests were performed daily. We analysed data from the last 24 h of intravenous sedation and the first 24 h of volatile sedation, limiting our analysis to the controlled mechanical ventilation (CMV) phase. A general linear mixed model, fitted using the restricted maximum likelihood method, using patient as a random effect, was used to assess differences in hemodynamic parameters before and after the transition to isoflurane.
Results. Seventeen patients were included in the analysis. The most common cause of ARDS was bacterial pneumonia (8 patients, 47%), followed by viral pneumonia (6 patients, 35%), autoimmune disease (2 patients, 12%) and trauma (1 patient, 6%). The median duration of IV sedation before transitioning to volatile sedation was 3 days [interquartile range, IQR 1–5], while the median duration of isoflurane sedation was 5 days [IQR 3–9].
Bispectral index (BIS) levels remained stable before and after switching to isoflurane (respectively, 40 ± 6 vs 44 ± 11, p = 0.09). Mean dosage of noradrenaline significantly decreased during volatile sedation ($p < 0.01$) (see Fig. 1), while systolic arterial pressure and cardiac output remained stable (115 ± 18 during IV sedation vs 114 ± 16 mmHg during volatile sedation, p = 0.31 and 6.8 ± 1.6 during IV sedation vs 7.3 ± 1.7 l/min during volatile sedation, p = 0.83). A mild but significant increase in heart rate after transitioning to volatile sedation was recorded (respectively, 86 ± 17 vs 93 ± 15 bpm, $p < 0.01$). Trend of hemodynamic parameters during the transition to volatile sedation are displayed in **Fig. 2**.
Conclusions. Switching to volatile sedation during V-V ECMO is feasible and is not associated with an impairment of hemodynamics.

Introduction. Sepsis is a life-threatening organ dysfunction caused by a dysregulated host response to infection1. Microcirculatory dysfunction is a hallmark of septic shock and is associated with increased organ failure and mortality2–4. *Optical coherence tomography angiography* (OCTA) is a novel, non-invasive imaging technique that provides high-resolution, reproducible images of the retinal microcirculation within seconds 5,6. The interpretation of OCTA findings is fully automated7. Additionally, the retinal microcirculation may reflect changes occurring in more critical vascular beds, such as the brain, more accurately than sublingual vessels. This study aimed to evaluate the feasibility of using OCTA to assess microcirculatory dysfunction in septic shock.

Objectives. To characterize alterations in retinal microcirculation during septic shock using OCTA.

Methods. We conducted a prospective cross-sectional case–control study in the Intensive Care Department of Hospital da Luz Lisboa. Adult patients (≥18 years-old) with septic shock (defined by Sepsis-3 criteria1 and a cardiovascular SOFA sub-score8 ≥ 3 points after adequate volume resuscitation) were enrolled. Patients with known retinal disease were excluded. Healthy, age- (± 5 years) and sex-matched volunteers were recruited as controls. OCTA of both eyes was performed within 24 h of septic shock diagnosis. Retinal microcirculatory parameters were compared between groups using the paired Wilcoxon signed-rank test.

Results. We included 30 patients and 30 controls. Sixty percent were females. Median age was 71 years (interquartile range [IQR]: 48–81) in patients and 73 years (IQR: 48–80) in controls. Patients had a median APACHE II score of 18 (IQR: 13–22) and SOFA score of 7 (IQR: 5–9) on admission.

Most perfusion and vessel density metrics of retinal microcirculation were significantly lower in patients with septic shock, particularly in peripheral retinal regions (Table 1). These findings were consistent in both eyes. No significant differences were found in foveal avascular zone parameters.

Table 1 (abstract 000620) Differences in OCTA retinal microcirculatory variables between septic shock patients and controls.

	Right eye			Left eye		
	Patients	**Controls**	***p*-value**	**Patients**	**Controls**	***p*-value**
Perfusion density central (%)	21	25	0.254	17	28	0.052
Perfusion density inner (%)	43	45	**0.036**	39	45	**0.017**
Perfusion density outer (%)	45	47	**0.019**	44	47	**0.017**
Perfusion density full (%)	44	46	**0.027**	42	46	**0.012**
Vessel density central (mm/mm2)	9.9	11.1	0.278	7.8	12.6	**0.030**
Vessel density inner (mm/mm2)	18.3	18.6	0.066	16.8	18.7	**0.012**
Vessel density outer (mm/mm2)	18.5	19.1	**0.032**	18.0	19.0	**0.029**
Vessel density full (mm/mm2)	18.0	18.6	**0.047**	17.4	18.7	**0.016**
Foveal avascular zone area (mm2)	0.2	0.2	0.447	0.2	0.2	0.608
Foveal avascular zone perimeter (mm)	2.0	2.0	0.285	1.9	1.8	0.820
Foveal avascular zone circularity	0.7	0.7	0.216	0.7	0.7	0.561

Conclusions. Our findings confirm the presence of retinal microcirculatory alterations during septic shock and demonstrate that OCTA is a feasible non-invasive bedside tool for their assessment. OCTA may overcome the limitations of hand-held vital microscopes currently used for microcirculatory monitoring. Future steps will include longitudinal profiling of these microcirculatory changes throughout the course of septic shock, as well as the potential integration of retinal OCTA-based microcirculatory monitoring into hemodynamic management algorithms.
